A solution of cellulose prepared by heating together 3 grms. of cotton, 10·3 grms. of zinc chloride, 5 grms. of cobaltic oxide, 5 grms. of manganese sulphate, and 0·7 grm. of hydrochloric acid, is squirted into alcohol, the filament is washed with water, dried, cut into lengths, and wound on a carbon bobbin, which is then wrapped in paper and packed with graphite in a crucible. The latter is exhausted and is heated to incandescence for 20 hours. Finally, the filament is coated with carbon by passing through it an alternating current at 400 volts, in an atmosphere containing light hydrocarbons.—A. T. L.

Tungsten or alloys of tungsten ; Manufacture of filaments of ——. E. A. Krüger. Fr. Pat. 460,556, July 21, 1913.

Tungsten powder is mixed with a little carbon and with boric acid, moistened with water, and formed into rods. These are dried, heated for a time at 1000° to 1200° C., and then heated to as high a temperature as possible, in a current of hydrogen, by means of an electric current, until the particles of tungsten bind together. The rods are then rolled and drawn into filaments. By strongly heating the latter in a vacuum, the boron may be expelled, and filaments of pure tungsten formed. These must be mechanically treated to render them again homogeneous. To lessen the wear of the diamonds of the draw-plate, the wires may first be heated in air or oxygen, when an outer layer of tungstic oxide, and inner porous layers are formed, which act as lubricants ; or the tungstic oxide may be removed, and the underlying porous layers rubbed with talc or with powdered metals of high melting point, such as thorium, zirconium, cerium, etc.—T. St.

Electric incandescence lamps ; Process for liberating gases or vapours from chemical compounds in ——. Siemens und Halske Akt.-Ges. Fr. Pat. 460,913, July 31, 1913. Under Int. Conv., Aug. 2, 1912.

In lamps of the kind in which a small quantity of a suitable substance, such as silver chloride, alone or mixed with iron or nickel powder, is present in the bulb, and is heated when the lamp is in use so as to liberate traces of chlorine gas, the chloride, etc., is heated by a special filament or wire instead of by the lamp filament. The heating filament is usually in series with the lamp filament, and may consist of an iron or nickel wire passing through a tube which contains the chloride. This wire is itself attacked by the chlorine and becomes gradually thinner, so that as the chloride is used up, the temperature of the heating filament is increased and the rate of production of chlorine is kept constant.—A. T. L.

Electric incandescence lamps ; Refractory bodies for —— and process for manufacturing same. E. Podszus. Fr. Pat. 461,038, Aug. 1, 1913. Under Int. Conv., Aug. 12, 1912.

Refractory bodies composed of thorium oxide, zirconium oxide, boron nitride, etc., which are used as supports for metallic filaments, or as incandescence bodies, are conductors only when heated, and suffer decomposition during the passage of the current, so that the filament which is wound upon the refractory body is rapidly destroyed. According to the present patent, the refractory body is rendered quite stable by removing the last traces of impurities. For this purpose, the materials are very thoroughly purified, and the refractory bodies, which should be thin, are heated in a muffle to 2000° C. and afterwards in an electric arc, or in a mercury vapour lamp, in an atmosphere of hydrogen or the rare gases. —A. T. L.

III.—TAR AND TAR PRODUCTS.

Vacuum tar. A. Pictet and M. Bouvier. Comptes rend., 1913, **157**, 1436—1439. (See also this J., 1913, 1098.)

It was not found possible to isolate definite compounds from vacuum tar (obtained by the distillation of coal in a vacuum at a low temperature) by fractional distillation. Some of the fractions examined consisted of mixtures of saturated and unsaturated hydrocarbons and oxygenated compounds. The latter were very sparingly soluble in water, insoluble in alkalis, readily acetylated or benzoylated, and formed white sodium compounds. They had an odour resembling that of menthol and in all probability were hydroaromatic alcohols, representing intermediate products in the formation of the phenols of ordinary coal tar. After removing these alcohols by treatment with sodium and unsaturated hydrocarbons by treatment with fuming sulphuric acid, the residual saturated hydrocarbons were fractionated. Two of the fractions which appeared homogeneous had the characters : $C_{10}H_{20}$, b.pt. 172°—174° C., sp. gr. 0·7765 at 23° C., $n_{D}^{23}=1{\cdot}4196$; $C_{11}H_{22}$, b.pt. 189°—191° C., sp. gr. 0·7838 at 22° C., $n_{D}^{22}=1{\cdot}4234$. These hydrocarbons had a faint odour of petroleum and were practically identical with hydrocarbons of the same composition isolated by Mabery from Canadian petroleum, but differed from the decanaphthene and endecanaphthene isolated by Markownikoff from Baku petroleum. The hydrocarbon, $C_{10}H_{20}$, was identified as hexahydrodurene (1.2.4.5-tetramethylcyclohexane), and as the other hydrocarbon, $C_{11}H_{22}$, has very similar properties it is probably hexahydropentamethylbenzene.—A. S.

Tetraphenylethane ; Contributions to the study of diphenylcarbinol : the preparation of symmetrical ——. P. Sabatier and M. Murat. Comptes rend., 1913, **157**, 1496—1500.

Diphenylcarbinol should be formed by acting with water on the Grignard reaction product $(C_6H_5)_2.CH.OMgBr$ (from benzaldehyde and phenylmagnesium bromide, or from formic ester and 2 mols. of phenylmagnesium bromide). Instead, however, there results only a trace of the carbinol, but considerable quantities of benzophenone, diphenylmethane and *sym.*-tetraphenylethane, *i.e.*, on the one hand hydrogenation, on the other dehydrogenation of the diphenylcarbinol seems to have taken place. Experiments with benzophenone and various aliphatic-magnesium compounds gave analogous results, no tertiary alcohol being formed. According to the view expressed above, metallic catalysts, whether of hydrogenation or dehydrogenation should have the same action on diphenylcarbinol, and in fact, copper at 350° C. gave benzophenone and tetraphenylethane ; thoria at 420° C. gave benzophenone, diphenylmethane and tetraphenylethane. By the action of the dehydrogenating catalyst, thorium, at 420° C. on a mixture of the vapours of diphenylcarbinol and methyl alcohol a total reduction to diphenylmethane was effected. With ethyl alcohol in addition to diphenylmethane a little benzophenone and tetraphenylethane were formed.—J. B.

New synthesis of higher phenols. [Isomerides of hydro-urushiol dimethyl ether.] Majim and Nakamura. *See* XIII.

Patents.

p-Nitrosophenylglycine and process for the manufacture of the same. J. D. Riedel Akt.-Ges., Berlin-Britz, Germany. Eng. Pat. 22,694, Oct. 8, 1913. Under Int. Conv., Oct. 8, 1912.

p-Nitrosophenylglycine is obtained directly, and in good yield, from commercial phenylglycine by treatment with a nitrite, nitrous acid, or nitrosyl chloride in presence of fuming hydrochloric acid. The nitrosamine of phenylglycine or its esters is not converted into the *p*-nitroso compound by treatment with alcoholic hydrochloric acid according to Fischer and Hepp's process. *p*-Nitrosophenylglycine is a brown powder, practically insoluble in ether, alcohol, and water ; it is soluble in ammonia, forming a stable deep green solution from which intense green crystals of the ammonium salt can be separated by addition of alcohol.—T. F. B.

Arylides of 2.3-[hydr]oxynaphthoic acid ; manufacture of ——. A. G. Bloxam, London. From Chem. Fabr. Greisheim-Elektron, Frankfort on Maine, Germany. Eng. Pat. 23,732, Oct. 20, 1913. Addition to Eng. Pat. 13,237, June 7, 1913 (see this J., 1913, 1060).

The arylides of 2.3-hydroxynaphthoic acid are obtained by heating the acid with a non-nitrated arylamine in presence of a dehydrating agent and an indifferent solvent or suspending agent. The preparation of the anilide, 2.5-dichloro-anilide, and β-naphthalide, and of the compound with 2.4-toluylenediamine, is described in detail. —T. F. B.

β-Nitro compounds of acyl-p-diaminoanthraquinones ; Process for preparing ——. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 267,445, Oct. 10, 1912.

An acyl compound of *p*-diaminoanthraquinone is treated with aqueous nitric acid in presence of an indifferent diluent, at a temperature above 25° C.—T. F. B.

1-Chloro-anthraquinone ; Process for preparing ——. Farbwerke vorm. Meister, Lucius, und Brüning. Ger. Pat. 267,544, July 15, 1911.

1-Anthraquinonesulphonic acid or one of its salts is heated to a high temperature with thionyl chloride ; the sulphochloride is formed as an intermediate compound, which loses sulphur dioxide and is converted into 1-chloroanthraquinone.—T. F. B.

IV.—COLOURING MATTERS AND DYES.

Halogenated phthaleins ; Action of aniline on ——. W Scharwin. J. Russ. Phys.-Chem. Ges., 1913, **45**, 875—890. Chem. Zentr., 1913, **2**, 2126—2127.

By heating Eosin with aniline in a sealed tube at 180°—200° C. for 5 hours, treating the product successively wit steam, dilute acid, and alkali, dissolving in alcohol, an re-precipitating with water, hexaphenylhexa-aminofluoran (I) was obtained as a dark violet blue powder, easil

$$O<^{(C_6H_5.NH)_3C_6H}_{(C_6H_5.NH)_3C_6H}>C<^{CO}_{C_6H_4}>O$$

I.

$$^{(C_6H_5.NH)_3C_6H_2}_{(C_6H_5.NH)_3C_6H_2}>C<^{CO}_{C_6H_4}>O$$

II.

soluble in alcohol and acetic acid and soluble in co centrated hydrochloric and sulphuric acids. Hexapheny hexa-aminophthalophenone (II) was obtained as a bl violet powder from 10 grms. of tetrabromophenolphthalein and 50 grms. of aniline in a similar manner, and a halogenated hexaphenylhexa-aminofluoran was likewise obtained from commercial Phloxin and aniline. All three compounds can be sulphonated with fuming sulphuric acid (12 per cent. SO_3) and dye wool and silk dark violet blue shades.—A. S.

Patents.

Vat [anthracene] colouring matters; Manufacture of ——. J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. Eng. Pat. 12,818, June 2, 1913.

The green vat dyestuffs obtained by oxidation of dibenzanthrone, with or without subsequent reduction, and followed by heating, preferably in presence of a solvent and a condensing agent (see Eng. Pat. 14,498 of 1912; this J., 1913, 593), are converted into new vat dyestuffs by treatment with bromine. The bromine may be introduced either during or after the formation of the dyestuff from dibenzanthrone. The products dye cotton somewhat more yellowish shades of green than those produced by the unbrominated dyestuff.—T. F. B.

Azo dyes; Process for producing yellow ——. Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. Eng. Pat. 25,029, Nov. 3, 1913. Under Int. Conv., May 15, 1913.

An easily soluble dyestuff, which dyes cotton pure greenish-yellow shades, is obtained by combining the diazo compound of *p*-aminophenylphenthiazole-sulphocarboxylic acid with aceto-acetanilide. The thiazole compound is prepared by oxidising acetyldehydrothiotoluidinesulphonic acid with permanganate and eliminating the acetyl group from the product. In place of the carboxylic acid mentioned, other carboxylic acids may be used, obtainable from dehydrothiotoluidine, its homologues and substitution products, or from the corresponding polythiazoles, and the aceto-acetanilide may be replaced by any other aceto-acetarylide.—T. F. B.

Colouring matters of the anthraquinone series; Manufacture of ——. J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. Eng. Pat. 5534, March 5, 1913.

See Fr. Pat. 459,105 of 1913; this J., 1913, 1101.—T. F. B.

Wool-dyestuffs; Manufacture of brownish-yellow ——. Farbwerke vorm. Meister, Lucius, und Brüning, and R. Schmidlin, Höchst on Maine, Germany. Eng. Pat. 14,952, June 28, 1913. Addition to Eng. Pat. 13,672 of 1912, dated July 25, 1911.

See Ger. Pat. 265,197 of 1912 and Addition to Fr. Pat. 443,809; this J., 1913, 1101; 1914, 19.—T. F. B.

Sulphur [sulphide] dye; Green ——. *Green colouring-matter containing sulphur. Olive-green sulphur dye.* J. Flachslaender and K. P. Grälert, Elberfeld, and M. Buff, Vohwinkel, Assignors to Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. U.S. Pats. 1,081,598, 1,081,599, and 1,081,600, Dec. 16, 1913.

See Ger. Pats. 254,328 and 254,304 of 1911; this J., 1913, 189.—T. F. B.

Sulphur [sulphide] dye; Catechu-brown ——. *Brown sulphur colouring matter.* J. Flachslaender and K. P. Gralert, Elberfeld, and M. Buff, Vohwinkel, Assignors to Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. U.S. Pats. 1,081,601 and 1,081,602, Dec. 16, 1913.

See Ger. Pats. 253,934 of 1911 and 253,239 of 1912; this J., 1913, 80, 16.—T. F. B.

Sulphur [sulphide] dye; Blue ——. A. Thauss, Assignor to Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. U.S. Pat. 1,081,638, Dec. 16, 1913.

See Fr. Pat. 450,420 of 1912; this J., 1913, 593.—T. F. B.

Monoazo dyestuffs for wool, fast to washing, and process for producing them. Act.-Ges. f. Anilinfabr. First Addition, dated July 3, 1913, to Fr. Pat. 430,146, May 26, 1911. Under Int. Conv., Nov. 8, 1912.

See Eng. Pat. 16,537 of 1913; this J., 1914, 19.—T. F. B.

V.—FIBRES; TEXTILES; CELLULOSE; PAPER.

Spruce wood; Action of chlorine on ——. E. Heuser and R. Sieber. Z. angew. Chem., 1913, **26**, 801—806.

Moist spruce wood containing: moisture, 12·05; ash, 0·2; fat and resin, 1·24; cellulose, 58·16 per cent., was rasped, steamed in a Gooch crucible, cooled to 0° C. and chlorinated by the method described by Renker (this J., 1909, 1269). Four successive treatments with chlorine of half an hour each, with intermediate extractions with boiling sodium sulphite, were necessary to obtain a cellulose completely free from lignin reactions. The amount of hydrochloric acid formed and the loss of weight of the material after extraction with sodium sulphite were determined after each chlorination, at first with half-hourly treatments with the gas and subsequently with hourly treatments; observations extended over a period of 22 hours' chlorination, when the cellulose was completely reduced to a powdery oxycellulose. At the limiting stage of 2 hours, hydrochloric acid equivalent to 31·1 per cent. of chlorine on the dry ash- and resin-free wood had been formed, mostly in the first hour. After this stage, the formation of hydrochloric acid and the loss in weight of the cellulose were very small. So long as lignin was present in the material, the cellulose appeared to be protected from the oxidising action of the gas and the production of oxycellulose was almost negligible. Later, there was a large production of oxycellulose but the effect on the yield of cellulose was very small. As tests for lignin, the phloroglucinol and aniline reactions were not characteristic and disappeared after a short treatment with chlorine. More reliable tests were Maule's reaction (permanganate and ammonia), dark colouration with concentrated sulphuric acid, orange colouration with chlorine gas, yellow microchemical stain with zinc chloride-iodine and, to a certain extent, the ferric ferricyanide reaction. With 2 hours' chlorination and 31·1 per cent. of chlorine converted into hydrochloric acid, the fixation of chlorine by the fibre substance was only 9·47 per cent.; no other acid products were detected and, since very little oxycellulose was produced, it is to be inferred that, while a portion of the lignin was chlorinated, another portion suffered complete oxidation. Lignin chloride was isolated by extraction with alcohol, but with a yield of only 7·1 per cent. on the dry wood. Analysis of this chloride showed C 47·03, H 4·59, Cl 22·66 per cent. It was probably not a simple substance but a mixture of chloro derivatives; it did not yield pyrogallol derivatives nor any furfural on distillation with acid; on fusion with alkali large quantities of oxalic acid were produced.
—J. F. B.

Spirit from wood; Production of ——. R. von Demuth. Z. angew. Chem., 1913, **26**, 786—792.

The author gives a brief history of the subject and a bibliography and a description of the working of the process of Tomlinson and Ewen (U.S. Pats. 1,032,392 and 1,032,440—1,032,450; this J., 1912, 832) at the factory of the Du Pont de Nemours Powder Co., Georgetown, S. Carolina, U.S.A., erected in 1910. Sulphurous acid as a hydrolysing agent gave unsatisfactory results and sulphuric acid was substituted for it. Simonsen (this J., 1898, 365, 481, 1164) obtained good results with sulphuric acid on the laboratory scale and the failure of his process on the large scale was due to the use of too much water. In the American process hydrolysis is effected under pressure in rotary spherical digesters, whereby good results are obtained with considerably smaller quantities of water and acid than those used by Simonsen. The steel digesters are lined with acid-proof material and the contents are heated by direct steam. After rather more than 1 hour, when about one-half of the cellulose is saccharified, the steam is blown off; if the digestion be prolonged, decomposition of the sugar occurs. The hydrolysed wood is conveyed to a diffusion battery similar to that employed in sugar manufacture, and after extraction of the sugar, the residue is pressed, and used as fuel. The solution is partly neutralised with lime, clarified by settling, fermented with yeast cultivated in a mash of rye and malt, and then distilled. Owing to lack of cooling water the yields were unfavourable in the summer months, but in the winter months the yield corresponded to 7·3 litres of 100 per cent. alcohol per 100 kilos. of wood dry substance. Moreover, owing to American excise restrictions, it was not possible to supply sufficient nutrient materials to the yeast, and experiments of the authors indicated that the yield could be increased to 9·5 litres of alcohol per 100 kilos. if these restrictions were removed. Besides the alcohol there were obtained: oil of turpentine (0·2—0·3 kilo. per 1000 kilos. of wood dry substance), calcium sulphate, fusel oil, spent wash, and a residue of rye, malt, yeast, etc.. from the fermented wort, containing 3·5 per cent. of nitrogen. At the present time about 2 million litres of alcohol (100 per cent.) are produced annually at the Georgetown factory.—A. S.

Fabrics; Inflammability of ——. Daily Express, Jan. 24, 1914. [T.R.]

Regulations published recently under the Fabrics (Misdescription) Act, 1913, prescribe the following test for inflammability: "A textile fabric shall be deemed to conform to the standard of non-inflammability if, when tested in accordance with the prescribed method of testing, it is not set alight, or, if set alight, burns without a flame or with a flame which does not spread but converges and dies out. The prescribed method of testing shall be as follows:—A sample of the fabric measuring not less than one square yard shall be taken, and, after it has been four times in succession thoroughly washed with soap and water, dried and ironed, shall be suspended vertically without folds or creases, and so that the lower edge shall not be a selvedge or a folded edge. The flame of a wax taper not less than one-eighth of an inch or more than three-sixteenths of an inch in thickness shall then be brought in contact with the fabric at its lower edge, and shall be kept in contact for not less than twelve or more than fifteen seconds."

Examination of rosin size. Marcusson *See* XIII.

Patents.

Drying pulp and the like; Apparatus for ——. H. P. Coe, New York. Eng. Pat. 16,712, July 21, 1913.

Improvements in apparatus for drying sheets of pulp, relating to the method of driving the rollers which feed the sheets into the drying chamber, the arrangement of the air ducts and flues, and the provision at the entrance of the machine of a lifting table provided with a bed of rollers, which table facilitates the introduction of wet material into the machine at the different feeder levels. J. B.

Sizing [for paper] and method of preparing same. A. A. Dunham, Bainbridge, N.Y., Assignor to Casein Co. of America. U.S. Pat. 1,080,143, Dec. 2, 1913.

One part of an alkaline (sodium) silicate is mixed with about 25 parts of modified starch, and the mixture dissolved by heating with a liquid.—E. W. L.

Artificial threads, filaments, or other shaped objects from copper cellulose solution; Process for the manufacture of ——. Verein. Glanzstoff-Fabriken A.-G., Elberfeld, and E. Bronnert, Mülhausen-Dornach, Germany. Eng. Pat. 4922, Feb. 26, 1913. Under Int. Conv., Sept. 2, 1912.

See Fr. Pat. 454,811 of 1913; this J., 1913, 865.—T. F. B.

Cellulose acetate; Manufacture of ——. F. Paschke, Assignor to Safety Celluloid Co., Ltd., London. U.S. Pat. 1,082,167, Dec. 23, 1913.

See Eng. Pat. 15,868 of 1912; this J., 1913, 192.—T. F. B.

Non-inflammable solutions of cellulose nitrates, utilisable as lacquers. Fr. Pat. 461,034. *See* XIII.

VI.—BLEACHING; DYEING; PRINTING; FINISHING.

Oxidation; The recognition of the beginning of ——. *A contribution to the analysis of bleaching liquors.* F. H. Thies. Färber-Zeit., 1913, **24**, 525—527.

The fact that the white produced by the bleaching process is mainly dependent on the kier boiling renders the valuation of bleach-liquors by practical tests impossible. The decolourisation, more or less, of a scale of indigo dyeings has been suggested, but the author considers that the best method of direct estimation is by measuring the oxidising effect of the bleach-liquor on the fibre itself. The author uses a colourimetric comparison of the dyeings obtained on the treated material by steeping it in a 0·1 per cent. solution of Methylene Blue at 90°—100° C. Low degrees of oxidation can be thus compared with the assistance of a scale prepared by partially precipitating solutions of ammoniacal copper sulphate, details for the preparation of which are given. A graphical representation is given of some experiments on the effect of the time and temperature factors in such oxidations, as indicated by the weakening of the fibre.—J. B.

Silk-weighting; The theory of ——. P. Heermann. Mitt. kgl. Materialprüf.. 1913, **31**, 289—301. (See also this J., 1904, 820 and 1911, 1007.)

In opposition to Ley (Chem.-Zeit., 1912, 1405 and 1466), the author re-affirms that with pure materials (stannic chloride and disodium phosphate) and quite neutral silk, the basicity of the baths is unaffected by the weighting process as such. After the pinking process the fibre contains almost pure stannic hydroxide, which reacts with hot phosphate solution thus:

$$Sn(OH)_4 + Na_2HPO_4 = Sn(ONa)_2HPO_4 + 2H_2O.$$

The double phosphate is only stable in the presence of alkali phosphate and is hydrolysed on washing:

$$Sn(ONa)_2HPO_4 \rightarrow Sn(OH)_2HPO_4 + 2NaOH.$$

The free alkali is neutralised by the excess of phosphate in the wash water: $Na_2HPO_4 + NaOH = Na_3PO_4 + H_2O$. No acidification of the phosphate bath can result except from acid carried over by the silk. The third of the above reactions, which shows the disposal of the free alkali, explains Ley's inability to find free caustic soda. The author has observed an increased alkali content in the phosphate present in the wash water as against the phosphate present in the bath.—J. B.

Naphthenic acid and sodium naphthenate. Davidsohn. *See* IIa.

Natural water and the catalytic action of some colloidal substances at great dilution [in tanning and dyeing]. Sommerhoff. *See* XV.

Patents.

Fibrous materials; Process for degreasing raw or manufactured —— *by means of fat solvents.* C. Netz und Co. Ger. Pat. 267,487, Feb. 14, 1913.

Dichloro-ethylene or trichloro-ethylene is used as a degreasing agent, either alone or mixed with other fat solvents. These solvents remove the surface fat, but appear only to penetrate very slightly the interior of the fibre.—T. F. B.

Bleaching; Process of ——. A. J. Rossi, Niagara Falls, N.J., Assignor to The Titanium Alloy Manufacturing Co., New York. U.S. Pat. 1,080,718, Dec. 9, 1913.

MATERIAL is bleached by means of a mixture of titanous and ferrous chlorides, which can be made by dissolving iron and titanium, or an alloy of the two, in dilute hydrochloric acid and filtering the solution.—J. B.

Titanous salts; Treating [bleaching] materials with solutions of ——. C. M. E. Schroeder, Rutherford, N.J., Assignor to The Titanium Alloy Manufacturing Co., New York. U.S. Pat. 1,080,721, Dec. 9, 1913.

MATERIAL is bleached by immersing it in a bath containing metallic titanium, titanium and iron, or a titanium-iron alloy, and an acid solvent of titanium and iron, *e.g.*, hydrochloric acid.—J. B.

Dyeing and bleaching machines. C. Callebaut and J. de Blicquy, Brussels, Belgium. Eng. Pat. 24,722, Oct. 30, 1913.

IN machines for dyeing tops or similar material in ball form, the circulation cylinders are provided with removable linings to allow for the accommodation of balls of varying diameter.—J. B.

[Dyeing and bleaching.] Apparatus for treating yarn with a liquid. H. Hablützel. Fr. Pat. 460,829, July 28, 1913. Under Int. Conv., Aug. 12, 1912.

THE yarn is suspended on sticks in a vat over which runs a carriage having a pair of endless chains provided with hooks to pick up the yarn sticks as the carriage travels along. The path of the endless chains is so arranged that a stick full of yarn is picked up as the carriage approaches it, raised partially out of the vat and then dropped back into the vat on the other side of the carriage. When the dyeing operation is over, another carriage provided with a pair of inclined endless chains runs along the vat, picking up the yarn, raising it out of the vat and draining it, finally dropping it on to a table, whence it is removed by hand.—J. B.

Silk; Process of weighting ——. M. Günther. Fr. Pat. 460,137, July 8, 1913. Under Int. Conv., July 8, 1912.

TITANIUM salts are employed in conjunction with the salts of tin, zirconium, or the rare earths.—J. B.

Fast shades on vegetable fibres; Production of —— *and dyestuffs therefor.* H. Levinstein, J. Baddiley and Levinstein, Ltd., Blackley. Eng. Pat. 28,296, Dec. 7, 1912.

AN extension of Eng. Pat. 27,525 of 1912 (this J., 1913, 1005) for the production of dyestuffs giving fast shades on after treatment with formaldehyde, using certain other diamines, and other extra-nuclear amino derivatives of 2-amino-5-naphthol-7-sulphonic acid, in addition to those specified in the first patent.—J. B.

Dyeing apparatus; Indigo ——. C. Becker, Ilkley, and H. Mueller, Ben Rhydding. Eng. Pat. 6075, March 11, 1913.

THE material (loose fibre, slubbing, roving or yarn) is contained in a basket within and hinged to one side of the dye-vat, which is provided with a circulating apparatus, the upper or entrance pipe of which is below the surface of the liquor. When the material is impregnated, the basket or cage is tilted up out of the bath so as to discharge the material directly to squeezing rollers at the side of the vat.—J. B.

Ice-colours on cotton yarn, cops, cross-reels and loose cotton; Process for producing ——. A. G. Bloxam, London. From Chem. Fabr. Griesheim-Elektron, Frankfurt, Germany. Eng. Pat. 17,279, July 28, 1913. Addition to Eng. Pat. 6379 of 1912 (this J., 1912, 635).

DEVELOPED dyestuffs are produced by padding the material with an arylamide of 2.3-hydroxynaphthoic acid and combining with a diazo compound of an unsulphonated amine without intermediate drying. The anilide of 2.3-hydroxynaphthoic acid, for example, applied in caustic soda solution, gives with the diazo compound from *p*-nitro-*o*-toluidine a scarlet red, with that from *o*-anisidine a red, and with that from α-naphthylamine a dark red.—J. B.

Dyeing machine. F. H. Rogers, London. From Psarski Dyeing Machine Co., North-West Cleveland, Ohio, U.S.A. Eng. Pat. 18,303, Aug. 12, 1913.

THE material is contained in a hemispherical vessel, uniformly perforated, which is provided with a flat lid, perforated only in the neighbourhood of its centre. The dye-liquor is circulated through the perforations in the hemispherical bottom and out through the perforations about the centre of the lid, the arrangement of the perforations being such that in penetrating through the mass of the material every portion of the dye-liquor travels approximately the same distance.—J. B.

Dyeing, washing, cleansing and otherwise treating yarn in hanks; Process and apparatus for ——. J. Schlumpf. Second Addition, dated June 16, 1913, to Fr. Pat. 421,183, Oct. 7, 1910 (this J. 1911, 486; 1912, 227.)

IMPROVEMENTS in the mechanical arrangements for dyeing hanks as described in the chief patent.—J. B.

Dyeing hair and fur; Process of ——. Act.-Ges. für Anilinfabr. Fr. Pat. 460,566, July 21, 1913. Under Int. Conv., Oct. 10, 1912.

A PERSULPHATE is used for developing oxidation colours on hair. Brighter colours are obtained than with the usual oxidising agent, *p*-toluylenediamine giving, for example, beautiful blonde to brown shades.—J. B.

Printing textile fabrics. H. Levinstein and Levinstein, Ltd., Blackley. Eng. Pats. 29,021, Dec. 17, 1912 and 1123, Jan. 15, 1913.

A SUBSTANTIVE dyestuff capable of forming an insoluble compound when heated with formaldehyde is printed together with a thickening agent and formaldehyde or a substance capable of liberating formaldehyde on steaming, such as hexamethylenetetramine. On steaming shades are produced which are fast to washing. Dyestuffs containing 1 or 2 mols. of resorcinol are preferred.—J. B.

Sizing threads or yarns; Apparatus for —— *or like operations.* Wilcock, Wood and Co., and F. W. Bottomley, Shipley. Eng. Pat. 3080, Feb. 6, 1913.

THE trough of the sizing machine is connected with a reservoir in which is a weighted block, the upward or downward motion of which causes the liquor to run to or fro between the trough and the reservoir. In this way the trough can be emptied or filled without a stoppage of the running threads.—J. B.

Cellulose finishing preparation. Soc. Industrielle des Téléphones. Fr. Pat. 260,915, Oct. 16, 1912.

To a cellulose solution, such as is used for coating aeroplane fabric or for electrical insulation, an inert substance is added, for instance barium sulphate, zinc sulphate or oxide, magnesium oxide, etc. Colouring matter may be added and the coating may be varnished after application. —J. B.

Scalding, bleaching, dyeing, oxidising, washing, and drying textile materials as they are discharged from spinning machines; Method of and apparatus for ——. P. J. Grandsire fils, Darnétal, France. Eng. Pat. 16,005, July 11, 1913. Under Int. Conv., July 31, 1912.

SEE Fr. Pat. 448,248 of 1912; this J., 1913, 423.—T. F. B.

Vat-dyestuff compounds suited for dyeing. R. Wedekind und Co. m. b. H., and M. Iljinsky, Uerdingen on Rhine, Germany. Eng. Pat. 28,656, Dec. 12, 1912.

SEE Fr. Pat. 453,427 of 1913; this J., 1913, 746.—T. F. B.

Fixing dyestuffs, pigments, or metallic powders on textile fibres; Processes for ——. R. B. Ransford, London. From Soc. de la Manufacture d'Indiennes Emile Zundel, Moscow. Eng. Pat. 714, Jan. 9, 1913.

See Fr. Pat. 452,677 of 1912; this J., 1913, 653.—T. F. B.

Dyeing and printing; Process of ——. C. Möllenhoff, Leverkusen, Assignor to Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. U.S. Pat. 1,081,621, Dec. 16, 1913.

See Fr. Pat. 409,748 of 1909; this J., 1910, 753.—T. F. B.

Stabilising caustic alkaline solutions of hydrogen peroxide, and utilising the stabilised solutions for bleaching. Fr. Pat. 460,959. *See* VII.

Fireproofing composition. U.S. Pat. 1,080,966. *See* IX.

VII.—ACIDS; ALKALIS; SALTS; NON-METALLIC ELEMENTS.

Arsenic in sulphuric and hydrochloric acids; Rapid method of determining ——. H. Koelsch. Chem.-Zeit., 1914, **38**, 5.

Twenty-five c.c. of sulphuric acid (or 100 c.c. of hydrochloric acid) are boiled with 200 c.c. of water and 5 c.c. of potassium iodide solution (50 grms. per litre) until the liquid is only yellow or faint brown, then after addition of 5 c.c. of sodium sulphite solution (25 grms. of crystalline salt per litre), boiling is continued for 5 mins., the liquid diluted to about 700 c.c., made nearly neutral to methyl orange with caustic alkali, treated with sodium bicarbonate, and titrated with $N/10$ iodine solution. Small amounts of nitric acid are negligible, but larger quantities and the presence of substances that react with iodine in alkaline solution render the method useless. For a gravimetric determination the diluted acid is treated with iodide and sulphite as described, and the reduced arsenic precipitated from the hot liquid by means of sodium sulphide solution (40 grms. per litre). The precipitate is separated, dissolved in ammoniacal hydrogen peroxide, and the arsenic precipitated as magnesium ammonium arsenate. The results were in close agreement with those obtained by standard methods.—C. A. M.

Nitrous anhydride; Intermediate formation of —— by the action of oxygen on nitric oxide. Behaviour of nitrous anhydride towards potassium hydroxide. G. Klinger. Z. angew. Chem., 1914, **27**, 7—8.

Dry nitrous anhydride is absorbed quantitatively by concentrated sulphuric acid and by dry potassium hydroxide, without evolution of nitric oxide: when a solution of alkali hydroxide or the moist solid is used, absorption is not complete. Again, when nitric oxide mixed with a large excess of oxygen is passed over dry potassium hydroxide, the volume contraction is always 1¼ times the volume of nitric oxide present: hence, the reaction, $4NO+O_2=2N_2O_3$, must take place, and not $2NO+O_2=2NO_2$. It follows that nitrous anhydride is the first product of the action of oxygen on nitric oxide, the peroxide being formed from the anhydride as the second stage of the reaction (see also Lunge, this J., 1905, 131; 1906, 533; Raschig, this J., 1905, 923; 1907, 965; 1911, 168).—T. F. B.

Natural soda deposits of Africa, with some notes on the alkali trade. J. Watson. J. Chem., Met., and Min. Soc., S. Africa, 1913, **14**, 235—242.

The paper contains a survey of soda deposits in Africa with special reference to the soda-lake at Zoutpan, 25 miles N. of Pretoria. The deposit is now being worked by South African Alkali, Limited. The crude soda, dried in the sun, contains about 61 per cent. of carbonate and 6 per cent. of chloride; after calcination a sample showed 67 per cent. of carbonate and 17 of chloride. The author suggests the use of the crude soda as a substitute for lime in gold mining. He believes that the greater solubility of soda and sodium sulphate as compared with lime and calcium sulphate would save time, and avoid the deposition of sulphate in the mill service water pipes. Furthermore, calcium sulphate is a cyanicide while sodium sulphate is not. The paper concludes with a review of the possibilities of the alkali industry in S. Africa.—W. H. P.

Chloride solutions; Electrolysis of —— with a mercury cathode. E. A. Le Sueur. Amer. Inst. Chem. Eng. Metall. and Chem. Eng., 1914, **12**, 61.

Preliminary experiments have led to the conclusion that the best type of electrolytic alkali cell with mercury cathode, is that in which the under side of the mercury is used as the electrode, leaving the upper side out of contact with the electrolyte. Owing to its low specific gravity, the alkali metal amalgam would then tend to rise to the surface of the mercury, and could be removed periodically. —T. F. B.

Sulphur and potassium hydroxide in aqueous solutions, The reaction between ——. H. V. Tartar. J. Amer. Chem. Soc., 1913, **35**, 1741—1747.

When sulphur is heated with aqueous solutions of potassium hydroxide, the primary reaction, *i.e.*, when sulphur is not present in excess, is represented by the equation, $6KOH+8S=2K_2S_3+K_2S_2O_3+3H_2O$. When sulphur is present in excess, a secondary reaction occurs, in which it combines with the potassium trisulphide to form pentasulphide; it is possible that the tetrasulphide is formed as an intermediate product. The nature of the reaction is not affected by variations of temperature (below 100° C.) and concentration of the solution. All the experiments were carried out in presence of hydrogen, and in the subsequent operations contact with air was avoided as far as possible. The potassium present as thiosulphate and the sulphur as polysulphide, thiosulphate, sulphite, and sulphate were determined by methods outlined by Haywood (see page 99,) whilst potassium combined as polysulphide was determined by a slightly modified form of the volumetric zinc method, it being found that when an ammoniacal solution of zinc chloride is added to a solution of a potassium polysulphide, the corresponding zinc polysulphide is formed.—T. F. B.

Cadmium; Researches on ——. [Cadmium-ammonium sulphates.] M. Veres. Comptes rend., 1914, **158**, 39—40.

The double sulphates, $2CdSO_4,(NH_4)_2SO_4$ and $CdSO_4,(NH_4)_2SO_4,6H_2O$, were prepared, the former by heating ammonium bisulphate with one-fifth of its weight of crystallised cadmium sulphate to 300° C. and removing the excess of bisulphate by means of 85 per cent. alcohol; and the latter by slow evaporation of an aqueous solution of $2CdSO_4,(NH_4)_2SO_4$. When $2CdSO_4,(NH_4)_2SO_4$ was heated with concentrated sulphuric acid at 100° C., then treated successively with glacial acetic acid and with ether for the removal of the sulphuric acid, the ammonium sulphate was removed as well, leaving rhombic crystals of anhydrous cadmium sulphate.—A. S.

Phosphates and oxides; Action of phosgene on ——. J. Riban. Comptes rend., 1913, **157**, 1432—1433.

With reference to the recent work of Barlot and Chauvenet (this J., 1914, 21), the author points out that he showed in 1882 (this J., 1883, 177) that by the action of a mixture of carbon monoxide and chlorine on tricalcium phosphate, in presence of carbon as a catalyst, a mixture of phosphorus oxychloride and calcium chloride was produced: $Ca_3(PO_4)_2+6CO+12Cl=2POCl_3+6CO_2+3CaCl_2$, and that a similar reaction could be applied to the manufacture of aluminium chloride.—A. S.

Perchlorates of aluminium, chromium, and magnesium. R. F. Weinland and F. Ensgraber. Z. anorg. Chem., 1913, **84**, 368—372.

Aluminium perchlorate (hexahydrate) was prepared by dissolving aluminium chloride-hexahydrate in aqueous

perchloric acid, heating until hydrogen chloride ceased to be evolved, and concentrating *in vacuo* over sulphuric acid; and corresponding chromium and magnesium salts, like ferric perchlorate, by concentrating respective solutions of the oxide in perchloric acid; nonahydrated chromic perchlorate was obtained by operating at the temperature of the water-bath. The products are crystalline and very hygroscopic. Sodium tetraperchloratoaluminate, $[Al(ClO_4)_4]Na,12H_2O$, was prepared by concentrating a solution of aluminium oxide and sodium perchlorate in aqueous perchloric acid; it is analogous to the similarly produced iron compound, but no corresponding perchloratochromate could be obtained.
—F. Sodn.

Chromic oxide jellies. E. H. Bunce and L. S. Finch. J. Phys. Chem., 1913, **17**, 769—779.

An empirical investigation of the conditions of formation of chromic oxide jellies. Chromic chloride or sulphate gave a jelly with caustic soda or potash or ammonia in the presence of sufficient sodium acetate. With a considerable excess of caustic alkali a green jelly was produced; with a small excess, or with ammonia in any excess, a violet jelly. Sodium oxalate, potassium bitartrate and citric acid could not be substituted for sodium acetate. Freezing and agitation were detrimental to the formation of jellies. The jellies when dried were not reversible. No jelly was formed on adding potassium hydroxide alone to solutions of chromic nitrate, chloride or sulphate, although in the case of the sulphate a viscous solution was obtained on long standing. Chrome alum, however, gave a jelly with sodium or potassium hydroxide alone, but not with ammonia, even in the presence of sodium acetate.—J. B.

Rare earths: Dimethylphosphates of ——. J. C. Morgan and C. James. Chem. News, 1914, **109**, 13—15.

The dimethylphosphates of a number of rare-earth metals were prepared and their use for fractional precipitation or crystallisation studied. Dimethylphosphoric acid was prepared by Schiff's method (Chem. Centr., 1857, 761, 864), methyl alcohol (250 c.c.) being added, drop by drop, to 200 c.c. of phosphorus oxychloride, kept at 25°—30° C. After 1—1½ hours the syrupy liquid was heated to expel hydrochloric acid and methyl chloride, then diluted, neutralised with barium carbonate, filtered from barium phosphate, digested with the calculated quantity of sulphuric acid at 95° C., and filtered from barium sulphate, leaving a solution of dimethylphosphoric acid. The rare earth salts were prepared by dissolving the oxide, hydroxide or carbonate in the acid solution: their crystalline form and solubilities are shown in the following table:—

Dimethylphosphate of:	Crystalline form.	Parts dissolved by 100 parts of water:	
		at 25° C.	at 95° C.
Lanthanum ...	Hexagonal crystals	103·7	—
Cerium	.. plates	79·6	65
Praseodymium .	.. ..	64·1	—
Neodymium ...	.. ..	56·1	22·3
Samarium	.. prisms	35·2	10·8
Gadolinium ...	Long needles	23·0	6·7
Yttrium	.. ..	2·8	0·55
Erbium	.. ..	1·78	—
Ytterbium	.. ..	1·2	0·25

In using the dimethylphosphates for the separation of the rare earths, fractional precipitation was effected by heating the aqueous solution to progressively higher temperatures up to 95° C., and the final filtrate was subjected to fractional crystallisation. The method proved to be much quicker than those known hitherto. Lanthanum, cerium, praseodymium, and neodymium were at once left in the final mother liquor: samarium, europium, and gadolinium were much less soluble, but more soluble than terbium, dysprosium, and holmium; erbium, thulium, yttrium, ytterbium, etc., collected in the least soluble fractions. The solubilities of the dimethylphosphates being the reverse of the usual type, the method proved useful for the rapid purification of many of the rare earths, *e.g.*, for the removal of traces of neodymium from samarium.—A. S.

Thallium, lithium, caesium, and rubidium nitrites. W. C. Ball and H. H. Abram. Chem. Soc. Trans., 1913, **103**, 2130—2134.

All the above-mentioned nitrites are most readily obtained by allowing the sulphate of the metal to react with barium nitrite. Cæsium nitrite and rubidium nitrite resemble potassium nitrite. Rubidium nitrite is remarkably deliquescent, only slightly soluble in hot alcohol and practically insoluble in acetone. It is therefore best prepared by precipitation from its aqueous solution with alcohol. Thallous nitrite is a soft crystalline substance of deep orange red colour. It melts without decomposition, and at a higher temperature evolves red fumes and leaves a yellow residue. Lithium nitrite crystallises with 1 mol. H_2O. It is very soluble in hot alcohol even when anhydrous. It melts in its water of crystallisation below 100° C., and only loses water slowly at this temperature. At 160° C. it loses water rapidly and also evolves traces of oxides of nitrogen.—W. H. P.

Bismuthinitrites. W. C. Ball and H. H. Abram. Chem. Soc. Trans., 1913, 103, 2110—2130. (See also this J., 1905, 686; 1910, 46, 902.)

The bismuthinitrites of the univalent metals fall into two classes of the general formulæ $X_3Bi(NO_2)_6$ and $X_2YBi(NO_2)_6$, where X represents ammonium, potassium, rubidium, cæsium or thallium and Y either lithium, sodium or silver. Of the twenty possible compounds the authors have obtained all but $(NH_4)_3Bi(NO_2)_6$. A further series, containing nickel in addition to a metal of the X series, can be obtained by adding a nickel salt to a solution of the nitrite of the metal in the presence of bismuth. The bismuthinitrites resemble the cobaltinitrites in formulæ, colour, solubility, etc., in many cases. The bismuthinitrites are all easily hydrolysed and it is therefore impossible to purify them by washing with water. The nitrites used in their preparation must be entirely free from chlorides and as free from alkali as possible. The existence of the above series explains to some extent the separation of sodium from potassium in the presence of cæsium and bismuth nitrite. Sodium cæsium bismuthinitrite is relatively insoluble, while potassium cæsium bismuthinitrite is not formed at all.—W. H. P.

Radium D: Alleged separation of —— from lead in radio-active lead by means of the Grignard reaction. C. Staehling. Comptes rend., 1913, 157, 1430—1432.

The author repeated the experiments of Hofmann and Wölfl (Ber., 1907, 2425), but were unable to obtain any evidence of the separation of radium D from lead.—A. S.

Cyanamide: Polymerisation of —— to dicyandiamide in aqueous solution. G. Grube and J. Krüger. Z. physik. Chem., 1913, 86, 65—105.

The polymerisation of cyanamide to dicyandiamide in aqueous solution was accelerated by addition of alkali, but whilst within the limits studied the velocity of polymerisation increased continuously with increasing additions of ammonia, in the case of sodium hydroxide and calcium hydroxide, it increased up to a maximum and then decreased again as the concentration of the alkali was increased. Polymerisation appeared to be due to the union of undissociated cyanamide with cyanamide ions to form monobasic dicyandiamide ions:

$$CNNH_2 + CNNH' \rightarrow C_2N_2N_2H_3',$$

since for a given concentration of total cyanamide, polymerisation proceeded most rapidly in a solution in which the concentrations of undissociated cyanamide and of cyanamide ions were equal. The dissociation constant of cyanamide was found to be of the order 10^{-11} and that of dicyandiamide 10^{-13}, from which it follows that in a molar solution (1 grm.-mol. per litre), acid sodium cyanamide would be hydrolytically dissociated to the extent of 3 per cent. and the acid ammonium salt to the extent of 79—89 per cent. For the preparation of dicyandiamide from commercial calcium cyanamide, these results show that the addition of a foreign base is unnecessary. From the solution of the commercial product so much lime should be precipitated that the concentrations of undissociated cyanamide and of cyanamide ions in the solution are equal, and this condition should be maintained, as far as possible, during the process by periodical precipitation of further quantities of lime. (See also Morrell and Burgen, this J., 1913. 1155.)—A. S.

Nitrogen ; Active ——. E. Tiede and E. Domcke. Ber., 1913, **46**, 4095—4103.

Further experiments have confirmed the view expressed previously (this J., 1913, 232) that the yellow after-glow considered by Strutt (this J., 1911, 683; 1912, 70) to mark the re-formation of ordinary nitrogen from an active modification produced by the action of electric discharges, is due to the presence of a small quantity of oxygen and indeed forms an extraordinarily sensitive test for the presence of traces of oxygen in nitrogen. An apparatus is described in which pure nitrogen can be generated by heating barium azide in a vacuum and then subjected to the electric discharge. If the apparatus be rinsed with the nitrogen several times to remove all traces of foreign gases, then the yellow after-glow does not appear when the electric discharge is subsequently produced, but makes its appearance immediately a little oxygen is generated by heating a small quantity of silver oxide enclosed in the apparatus.—A. S.

Sodium nitrate. Shipments and consumption from 1911 *to* 1913. W. Montgomery and Co. Dec. 31, 1913. [T.R.]

12 months ending Dec. 31st.	1911.	1912.	1913.
	Tons.	Tons.	Tons.
Shipments from South American Ports to all parts	2,412,000	2,452,000	2,660,000
Consumption in U.K.	132,000	130,000	124,000
Do. in Continent	1,564,000	1,778,000	1,700,000*

Nitrate industry of Chile. Oil, Paint, and Drug Rep., Dec. 8. 1913. [T.R.]

According to the annual report of the Nitrate Propaganda Association, the total production of nitrate of soda in Chile in 1912 was 2,885,959 short tons, as compared with 2,784,361 tons in 1911. Exports from the whole district in 1912 were 2,753,500 tons, as compared with 2,705,382 tons in 1911, 2,579,945 tons in 1910 and 2,357,968 tons in 1909. The United States during last year received about 500,000 tons of the product. Germany received about 600,000 tons, and the United Kingdom 1,000,000 tons out of the total listed exports. Of iodine the United States took 183 tons, as against 264 tons to European countries and 65 tons to the United Kingdom.

Considerable progress is being made in the use of oil as fuel for boilers in the oficinas; its use is stated to effect a saving of about 40 per cent. It is proposed to carry out extensive experiments on a large scale, with a view to discover a method of treating low-grade caliche.

Patents.

Sulphuric acid ; Process and apparatus for concentrating and distilling ——. C. Stoffmehl. Fr. Pat. 460,627, July 10, 1913.

A masonry tower, provided with an acid-proof and dust-proof lining, contains internally a helical system of flue chambers, arranged stepwise one below the other. Each flue chamber is sealed at the top by means of a silica plate, which is surmounted by a silica evaporating basin, the lip of each basin protruding well over the edge of the next lower vessel. Outside the tower, above and close to the highest, internal flue chamber, an external flue chamber is covered by a silica plate and series of basins, in which preliminary heating takes place; the lowermost external basin communicates by way of a silica funnel and tube with the highest internal evaporating basin, the furnace gases passing upwards through all the internal heating chambers in turn, then to the external chambers, and finally through flues in the masonry of the tower into the chimney. The flues are so constructed that the masonry reaches a uniformly high temperature, and the sulphuric acid vapours, which are formed in the process of concentration, are aspirated through an opening in the top of the tower and condensed.—O. R.

Ammonia from its elements ; Process for preparing ——. Farbenfabr. vorm. F. Bayer und Co. Fr. Pat. 460,859, July 29, 1913. Under Int. Conv., Aug. 5, 1912.

An increased yield of ammonia is obtained from nitrogen and hydrogen, heated under pressure in the presence of a catalyst, if the compressed gases are allowed to expand as they leave the reaction chamber.—O. R.

Hydrosulphites from aqueous hydrosulphite solutions ; Direct preparation of anhydrous ——. Chem. Fabr. Griesheim-Elektron. Fr. Pat. 460,610, June 23, 1913.

Aqueous hydrosulphite solutions are evaporated *in vacuo* with thorough and continuous agitation, so as to prevent the formation of lumps ; an organic base, such as aniline, may be added to the solution in such quantity that free aniline remains after the evaporation of the water, further heating being then required for the removal of the base.—O. R.

Tin oxides ; Process for the preparation of ——. E. P. Wetzig. Fr. Pat. 460,857, July 29, 1913.

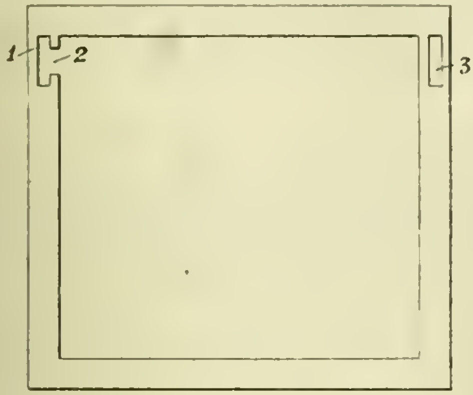
Tin is melted in a furnace, and air and the flames from the furnace are simultaneously directed on to the surface of the molten metal.—O. R.

Hydrogen peroxide ; Process of stabilising caustic alkaline solutions of —— *and utilisation of the stabilised solutions for bleaching.* Deutsche Gold- und Silber-Scheide-Anstalt vorm. Rössler. Fr. Pat. 460,959, July 11, 1913.

Aqueous solutions of sodium peroxide are stabilised by the addition of a small quantity of an "anticatalyst," such as a magnesium compound, preferably freshly precipitated, colloidal magnesium silicate, the resulting mixture being ready for immediate use for bleaching; the "anticatalyst" is claimed to protect cellulose fibres, especially cotton, from the action of caustic alkali. Thus, separate solutions containing 0·15 kilo. of sodium silicate, 0·12 kilo. of magnesium chloride, and 0·4 kilo. of soap respectively, are added to a solution of 1·6 kilos. of sodium peroxide in 400 litres of water; 100 kilos. of cotton, impregnated with 200 kilos. of water, are then added to the bath, which is heated to 65°—67° C. during one hour, maintained at that temperature for a second hour, and finally heated to 87° C. until the bath is exhausted.—O. R.

Hydrogen and oxygen by electrolysis of water ; Production of ——. Soc. Anon. L'Oxhydrique Française. First Addition, dated June 25, 1913. to Fr. Pat. 459,967, Sept. 21, 1912 (this J., 1913, 1156).

Each frame, constructed of wood, ebonite, etc., is provided with an opening 3, and a similar opening, 1, the latter communicating with the interior of the frame by a side opening, 2. The frames are placed together so that the openings 1, and 3, in adjacent frames are in contact, and are separated by diaphragms, thus forming the anode and cathode compartments. The anode compartments will thus discharge oxygen into the channel formed on one side of the cell, and the alternate compartments will discharge hydrogen into the channel on the opposite side. The frame may be of wood, with ebonite or rubber pieces forming the openings.—B. N.



Acetic acid ; Manufacture of ——. N. Grünstein, Assignor to Chem. Fabr. Griesheim-Elektron, Frankfort on Maine, Germany. U.S. Pat. 1,081,959, Dec. 23, 1913.

See Eng. Pat. 8076 of 1912 ; this J., 1913, 141.—T. F. B.

Phosphate of lime ; Process for the treatment of ——. J. Ciselet, Forest-lez-Bruxelles, and P. Noblet, Ixelles, Belgium. Eng. Pat. 8608 of 1912, date of appl., Jan. 27, 1913.

See Fr. Pat. 436,551 of 1911 ; this J., 1912, 448. Reference is directed in pursuance of Sect. 7, Sub-sect. 4, of the Patents and Designs Act, 1907, to Eng. Pats. 1790 of 1865, 686 of 1875, and 2981 of 1882.—T. F. B.

Sulphur from iron pyrites : Process for the extraction of ——. W. A. Hall, New York. Eng. Pat. 20,758, Sept. 11, 1912. Under Int. Conv., July 26, 1912.

See Fr. Pat. 458,028 of 1912 ; this J., 1913, 1156.—T. F. B.

Sulphur and sulphates from sulphites ; Manufacture of ——. P. A. Newton, London. From Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. Eng. Pat. 28,820, Dec. 14, 1912.

See Ger. Pats. 264,920 and 265,167 of 1912 ; this J., 1913, 1068.—T. F. B.

Carbide ; Process for coating —— *with calcium cyanamide.* V. Imperatori, Assignor to Soc. Italiana per il Carburo di Calcio, Rome. U.S. Pat. 1,081,938, Dec. 16, 1913.

See Fr. Pat. 448,078 of 1912 ; this J., 1913, 425.—T. F. B.

Evaporating pans or surfaces for brine and the like. Eng. Pat. 9570. *See* I.

VIII.—GLASS ; CERAMICS.

Fluorspar in glass, with calculations for its use. L. Springer. Sprechsaal, 1914, 47, 4—5, 20—21.

The use of fluorspar in glass is deprecated except for special cases and under favourable circumstances. It attacks the hearth and walls of the furnace and makes the exit-gases more injurious. By formation and decomposition of silicon fluoride it causes a scum of silica on the surface of the glass, and also alters the constitution of the glass in respect of the proportion of acid to base. On the other hand it is said to impart brilliancy to bottle-glass, and to increase its resistance under pressure. The method of calculating raw materials and costs from molecular formulæ is explained.—H. H. S.

Glass ; Requirements of —— *for bottling purposes.* R. L. Frink. Trans. Amer. Ceram. Soc., 1913, **15**, 706—727.

Bottle glass requires to withstand the corrosive action of carbonated liquids contained in it under a fairly high pressure, and also the severe changes of temperature due to the washing and steaming process which the bottles undergo in cleaning. Bottles filled with beverage were purchased and the liquid was compared with unbottled liquid of the same manufacture. Green glass was more soluble in beer than amber glass. Of a dozen bottles the lime content of the glass was found to range from 3·3 to 12·5 per cent. Owing to the presence of magnesia and an uncertain amount of hydration and carbonation, lime is the most unreliable constituent of glass and is responsible for three-fourths of loss in manufacture. The soda content of the bottles tested ranged from 13·5 to 26 per cent. ; the alumina from 1 to 8 per cent. ; magnesia from 0·5 to 4 ; silica from 66 to 74 per cent. With a constant proportion of alumina, solubility increased with increase of soda and decrease of lime, whilst with a constant proportion of lime, solubility decreased with increase of alumina. A composition of least solubility contained 12 per cent. of soda and of lime and 5—6 per cent. of alumina. A series of microphotographs illustrates the lack of homogeneity found in bottle glasses. To meet all requirements of bottling, the author recommends the composition : Na_2O 13—14, CaO 12, Al_2O_3 3—5, SiO_2 70—71 per cent.—H. H. S.

Plate glass chemist ; Some chemical reactions of interest to the ——. F. Gelstharp. Trans. Amer. Ceram. Soc., 1913, **15**, 585—590.

The chief point investigated was the behaviour of arsenic trioxide in glass manufacture. Its oxidising power by formation, and subsequent volatilisation, of metallic arsenic is disputed, and instead it is shown to be a reducing agent. Soda ash and arsenic trioxide react according to the equation : $As_2O_3+3Na_2CO_3+O_2=2Na_3AsO_4+3CO_2$. With saltcake (sodium sulphate) white arsenic forms first sulphides and sulpharsenate of sodium, and ultimately sodium arsenate ; the formation of sodium sulphite is not regarded as possible. With limestone and with lime, calcium arsenate is formed. In all cases an appreciable proportion of the arsenic introduced remains in the melt.

Another problem was the interaction of sand, soda ash and limestone. Only in certain proportions, when the ratio Na_2O : CaO was not less than 2 : 1, was the product a uniform glass.—H. H. S.

Glasses ; Investigation of surface devitrification of —— *under thermal after-treatment.* C. J. Brockbank. Trans. Amer. Ceram. Soc., 1913, 15, 600—605.

The physical and chemical changes which may take place in the surface layers of glass on reheating from the solid to the plastic state are due to volatilisation of alkalis with consequent production of silicates of higher silica content. If maintained at the critical temperature for several days, the change will proceed throughout the solid glass. Soda-lime silicates, as most liable to the defect, were investigated with regard to influence of chemical composition on devitrification. The softening point was determined by the distorted reflection of a pointed steel rod poised vertically on the heated glass, and the dimming point was indicated by the disappearance of these reflections, the muffle being provided with a thermo-couple. The results show that magnesia, and still more alumina, are beneficial constituents of glass. The use of dolomite is of decided advantage. In addition to its influence against devitrification, alumina in amounts above 3 per cent. greatly increases the viscosity of glass.—H. H. S.

Clays, bauxites, and some related substances; Thermal analysis of ——. R. Wohlin. Silikat-Zeits., 1913, **1**, 225—229.

The heating curves obtained by gradually raising the temperature of finely divided clays to 1300° C. (reached in 75 minutes) exhibit a more or less pronounced heat absorption at 560°—580° C., corresponding to the loss of water of constitution, and an emission of heat at 960° C., due, in the author's opinion, to physical change (probably a rise in specific gravity). Both of these disturbances are characteristic of the clay substance, the evolution of heat being most marked in those cases in which pronounced absorption has been observed. Bauxites of the formula, Al_2O_3,H_2O, are characterised by an absorption of heat at about 540° C. and those of the formula, $Al_2O_3,3H_2O$, by an absorption at about 310° C.; dehydration is complete at these temperatures, so the monohydrated oxide is evidently not formed as an intermediate product in dehydrating the trihydrate, and, similarly, artificial aluminium hydroxide is completely dehydrated at a low temperature. With both types, there is also often observed an evolution of heat at 1060° C., owing probably to increase of specific gravity. Bauxites of the supposed type, $Al_2O_3.2H_2O$, are mixtures of the above, for they exhibit absorption of heat both at 310° and 540° C., and at those temperatures only. The above characteristic behaviour of clay, $Al_2O_3,2SiO_2.2H_2O$, and of the two types of bauxite has been applied to the detection of these in minerals, and this method of thermal analysis is claimed to give more reliable results than are deduced from ultimate chemical analysis, besides being more rapid. —F. Sodn.

Clays and clay suspensions; Electrical conductivity of ——. [*Determination of soluble salts.*] A. V. Bleininger and C. S. Kinnison. Trans. Amer. Ceram. Soc., 1913, **15**, 523—531.

Soluble salts in clays may be rapidly estimated by determining the electrical conductivity, which is approximately proportional to the concentration of the salts within certain limits. For unknown clays qualitative analysis should first be conducted, but the method is recommended chiefly for the control of slips to which sodium carbonate or silicate has been added for the casting process.—H. H. S.

Clays: Effect of overburning upon the structure of ——. A. V. Bleininger and E. T. Montgomery. Trans. Amer. Ceram. Soc., 1913, **15**, 71—88.

The formation of vesicular structure in clays during burning leads to the presence of pore space into which water cannot penetrate, and which therefore finds no expression in absorption tests as commonly practised. The magnitude of these "blebs" is of considerable and unfavourable influence on the properties of the burned material. Conditions of burning, such as incomplete oxidation and too rapid firing, affect the phenomenon, but when all precautions are taken, a certain amount of gaseous matter is given off by every clay, resulting in more or less permanently enclosed pore space. The inherent structure of the clay and that imparted to it in moulding are important factors. Some clays, on burning, develop vesicular structure long before their porosity as measured in absorption tests approaches zero; others reach the stage of non-absorption and then form blebs rapidly. The authors investigated the effect of overburning rather than of normal conditions in order to ascertain the readiness with which different clays became spongy and to determine how important a factor the enclosed pore space is in bringing about swelling. A definite rate of firing, a rise of 20° C. per hour, was maintained during all the tests. Pore space was calculated from the dry and wet weights of specimen briquettes, and their true and apparent specific gravity. The results show that molecular changes still proceed after vitrification and that equilibrium is only reached when complete fusion has been brought about.—H. H. S.

Clays; Function of time in vitrification of ——. G. H. Brown and G. A. Murray. Trans. Amer. Ceram. Soc., 1913, **15**, 193—216.

Following the work of Bleininger and Boys (this J. 1911, 1384) clays were heated to their maturing temperatures at definite rates and the effect compared by means of porosity and shrinkage determinations. Before testing, the sample discs were fired in a gas kiln to 850° C. until the clays were fully oxidised. The effect of time in the firing of clay products is of great importance. A rapid rate of firing requires a higher finishing temperature than a slower one. The higher the content of fluxes the more marked will be the influence of the time factor. General rules governing time-temperature relations are not possible, owing to the fact that certain properties of clays, such as their viscosity at kiln temperatures, vary widely according to composition and physical structure. Vesicular structure (see preceding abstract) is produced by excessive temperature and also by longer burning at lower temperatures. The rate of burning must depend on the character of the clay and the size of the product to be fired. For most purposes rates of firing of from 10° to 35° C. per hour are suitable. Firing at constant rate cannot be applied to practical work. Within 40° of the minimum maturing temperature, the rate should be lowered to 10° C. per hour until the burn is finished. When uniformity of temperature cannot be obtained in a kiln, the minimum maturing point should be maintained until the clay has reached the desired degree of density. The greater the tendency of a clay to produce vesicular structure, the lower should be the burning temperature with a corresponding increase in time. For this purpose it is necessary to know the temperature limits within which the time factor becomes effective. Every clay should be studied by means of pyrometers, cones, and shrinkage and porosity determinations.—H. H. S.

Felspar; A commercial method of testing ——. J. Minneman. Trans. Amer. Ceram. Soc., 1913, **15**, 101—111.

The common practice of making cones of samples of new consignments of material and firing them in comparison with a cone of standard felspar is not justified by its results. The variation in deformation temperatures is not so great as is indicated by chemical analysis with regard to the content of the quartz impurity. If quartz be added to pure felspar, very little change in deformation is noticed until 15 per cent. is reached, after which deformation is decreased with increase of quartz. The author suggests that flint to the extent of 15 or 20 per cent. be added to the samples of felspar when making the trial cones. The fired cones should be examined for colour and the presence of black specks.—H. H. S.

Felspar and a deformation study of some felspar and felspar-quartz mixtures. A. S. Watts. Trans. Amer. Ceram. Soc., 1913, **15**, 144—166.

The potash spar of commerce, usually regarded as orthoclase, is really microcline. Deposits of pure albite (soda-felspar) do not exist on a commercial scale, and the material on the market always contains small quantities of potash and lime. The relative influence of potash and soda bases in causing cones of felspar to deform was tested by various mixtures of microcline and albite. Pure potash spar deforms at cone 10; the most fusible member of the series consists of a mixture of 7 of albite to 3 of microcline, which goes down before cone 6; mixtures containing 44—77 per cent. of albite to 53—21 of microcline are all completely deformed before cone 6, but the rate of deformation decreases as the microcline content increases. High soda content hence does not indicate low deformation temperature, and the proportion of soda spar cannot be determined in this manner except by careful observation of the rate of deformation. Potash spars are very slightly affected by additions of quartz or flint; substitution of quartz for felspar up to 20 per cent. may be made without materially affecting the temperature at which deformation begins or is completed; substitution up to 35 per cent. does not affect it more than half a cone. Mixtures of soda spar and quartz have in all cases more rapid rates of deformation than any mixture of potash spar and quartz. This property might be convenient in glazes where fluidity is desired, but would tend to cause warping in porcelain bodies. Soda spar-quartz mixtures do not deform at a lower temperature than pure soda spar. Ware made from soda spar gives a dead woody ring. In manufacture there is no advantage in introducing more than half the fluxes as soda spar.—H. H. S.

Kaolin-felspar mixtures: Deformation study of ——. H. Wilson. Trans. Amer. Ceram. Soc., 1913, **15**, 217—232.

The deformation of mixtures of pure microcline felspar and pure kaolin was studied. With pure felspar deformation occurred at cone 9. With 2 and 3 per cent. of kaolin, deformation began later, but proceeded more rapidly, the end being reached earlier than with pure felspar. With 5 and 6 per cent. the rate declined to that of pure felspar, but deformation began and finished later than with the latter. At 9—11 per cent. of kaolin, deformation proceeded at a more rapid rate than with any other mixing, though it began late. Beyond 10 per cent., deformation began and finished at higher temperatures as the quantity of kaolin was increased. The results indicated two eutectics, one in the region of 2—3 of kaolin and 98—97 per cent. of felspar, the other with 9—11 of kaolin to 91—89 per cent. of felspar. When kaolin was added to a 1 : 9 mixture of quartz and felspar, there was most rapid deformation with 8 per cent., and next with 10 and with 0 per cent. of kaolin. Hence felspar with both quartz and kaolin as impurities may deform either with or before pure felspar.—H. H. S.

Talc as a [pottery] body material. C. W. Parmelee and G. H. Baldwin. Trans. Amer. Ceram. Soc., 1913. **15**. 532—546.

Commercial talc may be either talc or steatite. It can be substituted for clay in bodies in considerable quantities without affecting the working properties. It has a decided influence, even in small quantities, in promoting translucency and whiteness of ware. Talc promotes vitrification, which proceeds slowly and without the sudden fusion caused by lime, and it also increases the toughness of the body as measured by abrasion loss.—H. H. S.

Porcelain bodies; Viscosity of ——. A. V. Bleininger and P. Teetor. Trans. Amer. Ceram. Soc., 1913, **15**, 328—337.

The vitrification of ceramic bodies requires for its explanation two assumptions, the existence of surface tension tending to contract the mass, and a lowered viscosity or softening, which will permit the displacement and rearrangement of the molecules. As a measure of viscosity the deformation under tensile strain was used. Specimens of porcelain bodies were made up of such shape that they could be hung from a fireclay grid and a weight attached to the bottom. The specimens possessed a cross-section of approximately 1 sq. in. after burning them to vitrification; their length was 4½ ins., their width 1½ ins., mould measurement. The load was applied to each bar after firing to cone 10, by means of a fireclay piece provided with a groove into which fitted the bottom of the porcelain, and was maintained at 5 lb. per sq. in. Porcelains tested embraced compositions of 35—50 per cent. of clay and 10—25 per cent. of felspar. Complete vitrification, as indicated by the ink test, was not possible with less than 19 per cent. of felspar. Excess of felspar proved undesirable, the viscosity being reduced. The higher the clay content, the less marked was the effect of felspar. A sharp line of demarcation appeared between bodies containing less and more than 45 per cent. of clay. The former possessed a very much higher temperature coefficient of decrease of viscosity and hence were more subject to deformation, and accordingly undesirable. Under tensile stress at kiln temperatures, the strength of porcelain bodies was found to be low, about 5 lb. per sq. in. with maximum elongation, and to be but a small fraction of the tensile strength at ordinary temperatures. The permissible elongation under a load of 5 lb. per sq. in. appeared to be about 5 or 6 per cent.—H. H. S.

Sanitary ware; A process of making [engobes for] ——. J. B. Shaw. Trans. Amer. Ceram. Soc., 1913. **15**, 467—481.

A description of the manufacture of sanitary ware with some experiments on the composition of the intermediate engobe or slip. All slips were fired at cone 9. A clay content of more than 40 per cent. required a felspar content of more than 15 per cent. to get sufficient vitrification at cone 9 unless more than 1 per cent. of lime was present. Lime could be introduced up to 10 per cent. in slips containing 40 per cent. of clay without attacking the overglaze or destroying opacity. The presence of lime assisted the start of vitrification but was not essential to good slips. More than 45 per cent. of felspar made a slip too vitreous and likely to craze, and similar results were obtained with less than 40 per cent. of clay and more than 15 per cent. of felspar. The following limits are assigned for satisfactory slips: felspar 20—45, flint 10—40, china clay 30—60, calcium carbonate 0—10 per cent.—H. H. S.

Refractory bodies; Development of special ——. E. T. Montgomery. Trans. Amer. Ceram. Soc., 1913, **15**, 606—619.

Refractory bodies are of two classes; those which have high thermal conductivity and low coefficient of expansion inherent in their constituents, and those which have an open porous structure of just the proper density to conduct heat with the least detriment to the body. The former class, which includes fused magnesite, fused alumina and fused quartz, is the safer. The latter class may be made from combinations of alumina, kaolins and ball clays. The Marquart pyrometer tubes, inner and outer, have the approximate composition: 30 per cent. of calcined alumina, 30 of raw ball clay, and 40 of calcined clay for the inner, and 40 per cent. of calcined alumina, 30 of raw ball clay, and 30 of burnt clay for the outer tube. The body is glazed with a refractory glaze to make it impervious, and has an absorption of 13·7 per cent. Various bodies were made up with fused magnesia, burnt alumina and kaolin respectively as refractory elements, and with a percentage of ball clay to render them plastic enough to be formed into tubes by means of a die. The magnesia trials gave the best results, followed by those of alumina and then of kaolin. A mixing particularly recommended is: ball clay 30, kaolin 55, fused magnesia 15 parts by weight. Fired at cone 12 it is impervious to gases without a glaze, does not absorb liquids and withstands sudden cooling.—H. H. S.

Tile; Production of a pink vitrified floor ——. R. Heidingsfeld. Trans. Amer. Ceram. Soc., 1913. **15**, 140—143.

The tile body was vitrified at cone 11, and the best pink was obtained from a mixture of Fe_2O_3 1, Al_2O_3 90, and Cr_2O_3 9 per cent., mixed as a stain with 10 times its weight of the body-mixing: 64 per cent. of spar, 5 of flint and 31 of kaolin. The pink thus obtained could be darkened to ruby by substituting 5 per cent. of calcium phosphate for 5 per cent. of alumina in the stain composition. The calcium phosphate probably acted as a flux, bringing out at cone 11 a dark pink which would have been produced without its use at a higher temperature. —H. H. S.

Hydrous silicates formed under steam pressure. L. E. Barringer. Trans. Amer. Ceram. Soc., 1913, **15**, 125—139.

For insulating ware similar to that described in Eng. Pat. 19,035 of 1905 (this J., 1906, 700), it was found that a high percentage of silica was desirable and also that an inert fibrous material like asbestos was necessary to impart mechanical strength. A suitable mixture consists of 30 parts of slaked lime, 45 of flint and 25 of asbestos. It is shaped by presses, dried, subjected to steam pressure of not less than 135 lb. per sq. in., and again dried, when the pieces are ready for use. A pressure of 150 lb. per sq. in. for about four hours gives the best results. Other oxides and hydroxides than those of calcium gave varying results. Zinc, magnesium and lead oxides gave good results, as also did manganite. Of these hydrous silicates of calcium, magnesium, zinc and lead, that of calcium had the highest disruptive and mechanical strength and the highest absorption. The formulæ for the substances were: $CaO,SiO_2,0{\cdot}54\ H_2O$; $MgO,SiO_2,\ 0{\cdot}45\ H_2O$; $ZnO,SiO_2.\ 0{\cdot}05\ H_2O$; the lead compound giving a doubtful result, —H. H. S.

Crazing of white ware; Method of testing [delayed] ——. H. Harkort. Trans. Amer. Ceram. Soc., 1913, **15**, 368—372.

Ware crazed on coming from the kiln is not so serious an item of loss in manufacture as ware which crazes after an interval during which it may have been despatched and put into use. For this delayed crazing the author suggests the quenching test. A drying oven was heated by electric current with the greatest possible uniformity by means of wire winding. Heating was accomplished gradually in order that the piece should acquire the temperature indicated by the thermometer. The piece was then quenched in cold water. If crazing did not result, the test was repeated at a temperature 10° C. higher. Ware which had a quenching temperature limit of 120° C. crazed in a few days; of 150°, in three or four months; of 160°, in 15 months; over 170° C., crazing seldom resulted in the period of observation, 2½ years. Variations up to 20° C. were observed from different thicknesses of glaze, the thicker glaze rupturing the more easily. Another method of conducting the quenching test consisted in repeating it at a fixed temperature, say 120° C., until crazing occurred. The results agreed with those of the previous method. Ware which failed at 190° was not crazed after 15 repetitions at 120° C.—H. H. S.

Underglaze colours containing chromium; Effect of zinc in ——. F. K. Pence. Trans. Amer. Ceram. Soc., 1913, **15**, 118—124.

An inference by Heubach (this J., 1912, 1129) that the green developed by chromium is not destroyed by the presence of zinc in the stain, as it is by zinc in the glaze, is not confirmed by the author. Whether a mixture of zinc oxide and chromium trioxide be fired alone or with the normal constituents of glaze-stains, such as silica, alumina, and boric oxide, the green is destroyed in the stain as actively as in a glaze. The tint obtained is determined by the composition of the stain, and varies from brown to grayish pink.—H. H. S.

Matt glazes. F. K. Pence. Trans. Amer. Ceram. Soc., 1913, **15**, 413—419.

The theory advanced previously (this J., 1912, 1128) that mattness is due to crystallisation from a glass matrix, was confirmed by microscopic examinations at different stages of development of the glaze. The evidence indicated that in true matts the glaze behaved in every way analogous to a bright glaze, except that all of the components did not always enter into solution and that on cooling segregation of crystals took place. The best way of obtaining a matt glaze was found to consist in facilitating most effectively the process of solution and subsequent crystallisation. Special types of matt glaze might be produced by different phenomena, such as vesicular structure, but a causal relation was found to exist between crystallisation and the production of true matt glazes. In the case of calcium-alumina and barium matt glazes the crystals were very tiny and in some cases did not amount to more than 20 per cent. of the mass, whilst presenting a smooth matt texture. Zinc matt glazes exhibited relatively large crystals and correspondingly coarse texture. Barium matt glazes have hitherto been regarded as due to immaturity, but the author succeeded in obtaining a true matt from the formula: $0{\cdot}15\ K_2O$, $0{\cdot}05\ ZnO$, $0{\cdot}15\ PbO$, $0{\cdot}30\ CaO$, $0{\cdot}35\ BaO$, $0{\cdot}25\ Al_2O_3$, $1{\cdot}88\ SiO_2$, the glaze being fired at cone 02.—H. H. S.

Leadless enamels [on cast iron]. H. F. Staley and G. P. Fisher. Trans. Amer. Ceram. Soc., 1913, **15**, 620—627.

Experiments were made by eliminating lead from a commercial cast iron enamel, and by converting a leadless sheet steel enamel into one for cast iron. The latter method was unsatisfactory, enamels for sheet steel being too refractory and too high in fluorides; crazing resulted if the fusibility was brought to the desired pitch. It was not possible in all cases to stop crazing by decreasing fusibility. The following four recipes are recommended for leadless enamels, the figures applying to the raw mixings:—

	1	2	3	4
Felspar	422·0	430·0	410	410
Fluorspar	122·5	154·5	—	—
Borax	151·0	151·0	241	241
Na_2CO_3	80·8	107·0	—	—
$NaNO_3$	27·4	27·4	27	27
$BaCO_3$	90·3	90·3	—	—
$CaCO_3$	26·9	—	—	—
ZnO	150·0	110·0	—	125
SnO_2	83·0	83·0	80	80
Cryolite	—	—	120	120
Boric acid	—	—	443	222

The felspar used contained 10·8 per cent. K_2O and 4·44 Na_2O. All fluxing oxides in common use except lead oxide and boric oxide gave a matt finish in enamels when used in excesive amounts. Crazing was liable to occur if the fluorides exceeded 15 per cent. of the weight of the melted glass.—H. H. S.

Lead in the ceramic industry; Problem of ——. L. Petrik. Sprechsaal, 1914, **47**, 1—3.

The solubility of lead glazes is tested by official methods which vary somewhat in different countries. The German method is to heat for half an hour with a 4 per cent. solution of acetic acid. In the English method, solubility is tested at ordinary temperatures in 0·25 per cent. hydrochloric acid. The method proposed by the author consists in digesting 5 grms. of the finely ground substance for one hour in an Erlenmeyer flask with 150—200 c.c. of 0·33 per cent. hydrochloric acid at 37°—40° C. Sodium acetate is then added to promote settling, and to dissolve lead chloride. The residue after filtration is also washed with sodium acetate solution. Lead is then estimated as sulphate. In a comparison of these methods, a glaze which had a solubility of 0·17 per cent. PbO by the English method, yielded 0·25 by the German and 0·56 by the author's method. As low solubility can only be obtained in glazes containing a high percentage of lead by fritting some of the constituents, a series of frits was tested. The frits contained a constant molecular proportion of $0{\cdot}75\ PbO$, $0{\cdot}12\ Al_2O_3$, and $2{\cdot}4\ SiO_2$ and varying amounts of lime, potash, and boric anhydride. With $0{\cdot}20\ CaO$, $0{\cdot}05\ K_2O$, the solubility was 0·57 per cent. (Petrik); addition of $0{\cdot}125\ B_2O_3$ to the frit gave 0·79; of $0{\cdot}25\ B_2O_3$, 2·54; of $0{\cdot}375\ B_2O_3$, 7·02 per cent. When the lime and potash proportions were reversed, *i.e.*, with $0{\cdot}05\ CaO$ and $0{\cdot}20\ K_2O$, solubility was 3·42 per cent.; addition of $0{\cdot}25\ B_2O_3$ gave 5·95; of $0{\cdot}375\ B_2O_3$, 12·88 per cent. PbO. The first frit of the series was accordingly the best, viz., that of the formula $0{\cdot}75\ PbO$, $0{\cdot}20\ CaO$, $0{\cdot}05\ K_2O$, $0{\cdot}12\ Al_2O_3$, $2{\cdot}4\ SiO_2$.—H. H. S.

Patents.

Mica sheets; Process and apparatus for making ——. Meirowski und Co. Akt.-Ges., Porz on Rhine, Germany. Eng. Pat. 15,568, July 5, 1913. Under Int. Conv., July 22, 1912.

To overcome the adhesion of lumps of split mica and to separate them into single flakes which can be applied to an adhesive backing, the split mica lumps are introduced into a rotating sieve drum. When sufficiently separated the flakes pass individually through the meshes of the sieve drum on to the adhesive backing, or on to a wire-gauze or finely perforated carrier band.—W. C. H.

Kilns or apparatus for drying china clay and other materials. The Oil-Flame Furnace Co., Ltd., London, and E. Buchholtz, Harrow. Eng. Pat. 29,065, Dec. 17, 1912.

To obtain more uniform heating of the floors of drying kilns, a central flue extends from each of the furnaces located at the front of the kiln to the rear of the kiln under the floor. The flue is closed at its rear end and is provided with openings in its side walls adapted to conduct heating gases from the furnace to flues extending laterally and communicating at their outer ends with collecting flues arranged parallel to the central flue and connected with a main outlet flue. The openings in the flues may increase in size as their distance from the furnace increases. H. H. S.

Crucible. G. N. Jeppson, Assignor to Norton Co., Worcester, Mass. U.S. Pat. 1,081,535, Dec. 16, 1913.

A porous crucible or container has glazed and unglazed portions which are isolated from each other by a septum of glazing composition.—H. H. S.

Refractory composition. G. N. Jeppson, Assignor to Norton Co., Worcester, Mass. U.S. Pat. 1,081,536, Dec. 16, 1913.

Previously fused alumina is mixed in a loose, dry state with a small quantity of a refractory binding material. The mixture forms with water a plastic mass which is capable at high temperatures of binding previously burned portions of like composition without fluxing them. —H. H. S.

Glazed refractory article [crucible]. A. T. Malm, Assignor to Norton Co., Worcester, Mass. U.S. Pat. 1,081,542, Dec. 16, 1913.

A crucible or other article comprised of alumina and a ceramic binding material is covered with a porcelain glaze having a coefficient of expansion closely approximating to that of the body. H. H. S.

Enamel; Process for dulling ——. A. J. Schüler, Hamburg, Germany. Eng. Pat. 28,679, Dec. 12, 1912.

An enamel coating of ordinary composition is first fired upon the article, and then a second coating of enamel is fired on, which is prepared by intimately mixing together ordinary enamel ingredients comprising about equal proportions of alkali and silica, fusing them to form a vitreous mass, which is ground and mixed with an almost equal quantity of raw silicious materials. To give surfaces suitable for writing with pencil, graphite or chalk, magnesium carbonate, borax or soda is mixed with the materials of the second coating.—W. C. H.

Porous article. U.S. Pat. 1,081,573. *See* XXIII.

IX.—BUILDING MATERIALS.

Portland cement; Properties of —— as affected by different burning temperatures. P. H. Bates. Trans. Amer. Ceram. Soc., 1913, 15, 420—443.

Increase of lime in the raw mixing caused increase of tricalcium silicate and aluminate, accompanied by decrease of calcium orthosilicate and disappearance of the compound, $5CaO,3Al_2O_3$, but to burn the material containing higher lime required a higher temperature. Investigation of various mixtures fired to the temperatures 1100°, 1200°, 1300°, 1350°, 1400°, 1450°, and 1500° C., was carried out with regard to changes in constitution of the resulting clinker and also concerning physical properties of the cement. With increase of temperature there was an increase in the amount of $3CaO,SiO_2$; alumina tended to pass into $3CaO,Al_2O_3$, and iron oxide entered into the orthosilicate, colouring it brown and apparently preventing inversion of the β- to the γ-form on cooling. There was but slight change in strength beyond the temperature at which satisfactory material was first obtained. —H. H. S.

Ultramarine; Behaviour of —— in cement ware. K. Haerting. Z. angew. Chem., 1913, 26, 800.

Ultramarine used for colouring cement ware is gradually decolourised in the interior of the mass, although the exterior remains apparently unaltered. This takes place more rapidly in tropical regions. In a six-year old building the surface of some coloured cement plates became covered with a deposit which proved to be almost pure sodium sulphate. Under the deposit the plate appeared unaltered, but the coloured layer was found to extend to a depth of only 0·2 mm., the remaining 2·5 cm. having been completely decolourised.—A. S.

Cast-iron; Concrete-covered ——, a new structural material. F. von Emperger. Stahl u. Eisen, 1913, 33, 1803—1808, 1972—1979.

An account is given of the use of beams of cast-iron with a covering of reinforced concrete in bridge- and building-construction. The total diameter of the beams is twice that of the iron cores. It is claimed that with such beams the great strength under pressure of cast-iron can be utilised, without the disadvantage of its brittleness. —T. St.

Gypsum; Calcining of ——. L. C. Snider. Eng. and Min. J., 1913, 96, 1220.

In the continuous Cummer process, a rotary kiln is used through which gypsum crushed to nut size passes in about ten minutes. When discharged it has a temperature of 260° C., and it is stored in brick bins in which it acquires a uniform temperature to produce plaster of the right quality. This is pulverised and sifted. The continuous process requires less fuel and power than the older process. —W. R. S.

Slags; Study of some calcareous and magnesian ——. A. V. Bleininger, G. H. Brown, C. S. Kinnison and A. A. Klein. Trans. Amer. Ceram. Soc., 1913, 15, 547—569.

The production of slags for building purposes where better materials are not available is suggested as an independent industry. Suitable compositions should not contain less lime than is represented by 56 per cent. of limestone to 44 of shale or 52 of dolomite to 48 of shale per cent. The dolomitic slags show greater fluidity, crystallise more readily and are superior in hardness and toughness. Impure stones, rejected for lime making, are suitable for this industrial application. The basic slags of the limestone series are coarser in grain than the corresponding dolomitic slags, and have higher indices of refraction.—H. H. S.

The Dunn pulverised coal burner. Roush. *See* IIa.

Patents.

Portland cement; Manufacture of ——. G. T. Hill, Norwood, Transvaal, and C. G. Stone, Johannesburg. Eng. Pat. 5908, March 10, 1913.

From 1 to 10 per cent. of magnesium silicate (as soapstone, steatite, etc.), is incorporated with Portland cement preferably by grinding with the clinker. Mortar made with the product is said to be stronger and more waterproof than that made with ordinary cement.—F. Sodn.

Waterproof cement and method of making. R. Schuler, New York, Assignor to The Gibraltar Stone Co. U.S. Pat. 1,081,155, Dec. 9, 1913.

A mixture of Portland cement, alum, a soluble soap, puzzuolana cement, and slaked lime. The Portland cement (200 parts) is preferably mixed in separate portions with the alum (3 parts), potash soap (3 parts), puzzuolana cement (28 parts), and lime (24 parts), and the portions are then mixed together.—F. Sodn.

Artificial stones ; Method of and means for manufacturing ——. G. Hidoux and J. Bernheim, Paris. Eng. Pat. 7002, March 22, 1913.

The incombustible waste from house refuse, or the slag from destructors, or a mixture of both, is ground "as finely as normal commercial conditions permit," mixed with green calcareous or other clay, previously dried and sifted, the mixture moistened with a jet of water or of air charged with atomised water, or of steam, moulded under pressure and finally baked at 950° to 1000° C. Suitable proportions are 65 to 75 per cent. by volume of incombustible waste, 35 to 25 of clay, and 8 to 10 per cent. of water. The plant used comprises a millstone grinder, a sieve, and a hopper provided with a distributor for dealing with the incombustible matter, a disintegrator, a dryer, a millstone grinder, a sieve, and a hopper provided with a distributor for the clay, a mixer provided with spiral wings for mixing the incombustible waste with the clay, a grinder, a sieve, a hopper and a moulding press. —W. C. H.

Lithographic stone ; Manufacture of artificial ——. V. Hereng, Brussels. Eng. Pat. 12,640, May 30, 1913. Under Int. Conv., May 30, 1912.

Equal weights of two or three kinds of Portland cements (obtained from different manufacturers), trass, and oolitic limestone (such as French stone or Euville stone), are mixed and sifted before being introduced into a perforated mould where the mixture is first compressed in the dry state and then immersed in water in which it is maintained under a high pressure, about 135,000 kilos. per sq. m., until completely impregnated. As the volume of the mass cannot increase, air is expelled, and the stone so formed is hardened from the centre to the periphery by remaining in water for at least three months, after which it is dried very slowly in a damp room protected from currents of air.—H. H. S.

Fireproofing composition. W. A. Hall, New York, Assignor to William A. Hall Lumber and Fibre Co. U.S. Pat. 1,080,966, Dec. 9, 1913.

An alkaline mixture made from approximately equal proportions of a salt having fireproofing properties and an acid reaction and a salt having an alkaline reaction, especially from ammonium sulphate and trisodium phosphate.—F. Sodn.

Wood ; Apparatus for preserving ——. G. B. Shipley, Milwaukee, Wis. U.S. Pat. 1,081,158, Dec. 9, 1913.

A measuring tank, which may be supported on a weighing machine, is connected, on the one hand, with a retort for the wood and, on the other, with a source of preservative fluid. Means are provided for conveying fluid to the tank for weighing; for producing uniform pressures (above atmospheric) in the tank and retort; for conveying the weighed fluid to the retort, and additional fluid at a pressure above that obtaining in the retort; and for allowing the excess fluid from the retort to return to the tank for re-weighing, and thence to the source.—F. Sodn.

Refractory materials ; Treatment of —— and apparatus therefor. G. Weintraub and H. Rush, Lynn, Mass., U.S.A. Eng. Pat. 20,348, Sept. 6, 1912. Under Int. Conv., May 28, 1912.

See U.S. Pat. 1,071,488 of 1913; this J., 1913, 944.—T.F.B.

Refractory materials. British Thomson-Houston Co., Ltd., London. From General Electric Co., Schenectady, U.S.A. Eng. Pat. 29,389, Dec. 20, 1912.

See U.S. Pat. 1,072,413 of 1913; this J., 1913, 1070.—T.F.B.

Hydraulic cement ; Process for the manufacture of a ——. C. L. Carlson, Stockholm. Eng. Pat. 2239, Jan. 28, 1913. Under Int. Conv., Aug. 19, 1912.

See Fr. Pat. 452,399 of 1912 ; this J., 1913, 659.—T. F. B.

Mortar ; Process of manufacturing a waterproof ——. A. Markus, Assignor to A. Prée, Dresden, Germany. U.S. Pat. 1,082,035, Dec. 23, 1913.

See Fr. Pat. 446,375 of 1912 ; this J., 1913, 144.—T. F. B.

X.—METALS ; METALLURGY, INCLUDING ELECTRO-METALLURGY.

Dry blast ; Economy of ——. J. von Ehrenwerth. Iron and Steel Inst., May, 1913.

Calculations showed that the percentage economy of fuel due to reduction of the moisture of the blast from 15 to 5 grms. per kilo., without considering the consequent reduction of temperature of the waste-gases, ran between 6 and 11 ; and that due to the lowering of temperature of the waste-gases between 3 and 15. The total economy was from 9 to 25 per cent. The economy of drying the blast is greater the lower the temperature of the blast and the higher the original temperature of the waste gases. There being less fuel charged, the total volume of material, and hence the volume of blast, per unit of production, is less ; thus the blowing engine and stoves can cope with a larger production, and the furnace yield is increased. The temperature in the melting-zone is raised, and not only is the melting accelerated but the silicon is increased and the sulphur lowered. The advantages are, however, dependent on local conditions, being greatest in the case of furnaces working with high temperatures both of blast and waste-gas, as in making ferromanganese, ferrosilicon, or ferrochrome, and in places where the atmosphere is moist.—J. T. D.

Cast iron ; The magnetic properties of ——. E. Gumlich. Stahl u. Eisen, 1913, **33**, 2133—2136. (See also this J., 1912, 539.)

Manganese and combined or dissolved carbon all reduce the permeability of iron. For dynamo-iron, therefore, these elements should be kept as low as possible, and silicon should be present only in sufficient amount to bring about separation of carbon as graphite. It is desirable, after casting, to anneal and cool slowly. For permanent magnets, in which high coercive strength is desired, carbon in solution is most advantageous, the best results being obtained with C 1·2—1·5, Mn 1—2 per cent. with little or no silicon, and a hardening temperature of 850° to 900° C.—T. St.

Steel ; Studies in the cold flow of ——. P. Longmuir. Iron and Steel Inst., May, 1913.

Three annealed steel rods, 0·201 in., 0·214 in. and 0·212 in. in diameter, and containing respectively C 0·10, 0·48 and 0·89 per cent. ; Mn 0·89, 0·87 and 0·78 ; Si 0·06, 0·058 and 0·07 ; S 0·103, 0·039 and 0·035 ; P 0·307, 0·050 and 0·046, were drawn down by successive reductions of 0·001 in. until they would not admit of further cold flow. The maximum stress values of the steels, originally 35·98, 43·48 and 50·87 tons per sq. in. in the rod, were increased to 75·63, 90·0 and 104·0 tons, respectively, by reduction to a thickness of 0·072 in.; after further reduction to 0·024 in. in the first and 0·056 in. in the second sample, the values were 112·0 and 100·0 tons per sq.in respectively. In the case of a steel containing C 0·25, Mn 0·35, Si 2·50, S 0·025, P 0·020 and Al 0·75 per cent., which was drawn down from 4- to 20-gauge under commercial conditions

(the reduction per pass varying from 0·04 in. to 0·006 in.), the original maximum stress of 50·26 was increased to 74·5 tons per sq. in. A series of six crucible steels—containing C 0·10 to 1·47 per cent., and normal amounts of Mn, Si, S and P—were reduced to 25-gauge wire by means of light draughts and frequent annealings. Up to 0·26 per cent. C the maximum stress values of the wires (about 46 tons per sq. in.) were about double those of the annealed rods; from 0·75 per cent. C onwards the maximum stress values of the wires (52—60 tons per sq. in.) although not differing materially from those of the rods as rolled, were about 50 per cent. greater than those of the annealed rods. In the higher carbon ranges the resistance to torsion of the finished wire as compared with that of the rolled or annealed rod was very marked. From a study of the evidences of polishing action exhibited by the outer surfaces of drawn wires, the author is of opinion that Beilby's theory (analogy with the mobility of a liquid) cannot be sustained, since the vitreous or non-crystalline form is not attained by cold drawing or rolling. As regards the readjustment of structure by annealing after cold working, it is pointed out that the crystals do not regain their original size but become permanently smaller as the diameter of the wire diminishes. The causes of cracking and cupping during drawing are discussed in some detail; and, in connection with the latter phenomenon as caused by segregation, an account is given of experiments made with a number of composite bars each of which contained a core of steel having a different composition from that of the surrounding metal.
—W. E. F. P.

[*Iron and steel.*] *So-called "crystallisation through fatigue."* F. Rogers. Iron and Steel Inst., Sept., 1913.

The crystalline structure frequently exhibited by wrought iron or steel which has failed in service by reason of repeated stress does not appear to be the result of fatigue, since in every case of such failure coming under the author's notice a fracture of similar appearance could be obtained in an unfatigued part of the metal. Examples of the failure of wrought iron are given in which such crystalline structures, in both the new and the fatigued metal, were due to the presence of low-grade iron or steel scrap.—W. E. F. P.

Iron and steels; Transformations of —— at high temperatures. K. Honda and H. Takagi. Rev. Mét., 1913, **10**, 1326—1336.

Pure iron, tungsten steel (W 5 and C 0·6, per cent.) and leven carbon steels (C 0·14—1·50, Si 0·05—0·34, Mn 0·27—67, P 0·010—0·051, S 0·014—0·044, Cu 0·05—0·13, per ent.) were heated and allowed to cool under conditions ermitting observation by magnetometric methods of the hanges occurring more particularly between the temperaures of 700° and 800° C. With pure iron, the transormation β→α was found to correspond to a small temerature interval, which, like that of γ→α, increased with he carbon content of the material. No sensible evolution f heat occurred during either of these transformations in he case of the steels; but during the eutectic separation f α-iron and the iron-cementite solid solution (which curred at a temperature 30°—40° C. higher when heating han when cooling) the magnetism of the samples increased nd heat was evolved. Recalescence in steels thus ppears to be due to the separation of the solid solution nd not to the polymorphous transformation β→α or γ→α.
—W. E. F. P.

on; Rusting of —— in water. W. A. Bradbury. Chem. News, 1913, **108**, 307—308.

xperiments are described in support of the view that e rusting of iron in water is due to dissolved oxygen d carbonic acid. Boiled water to which 5 per cent. of turated solution of magnesium chloride had been added owed no action on iron, either at the ordinary temrature or boiling.—J. T. D.

Cyanidation; Slimes agitation for ——. H. A. Megraw. Eng. and Min. J., 1913, **96**, 1161—1164.

The more important agitation processes are reviewed. Agitation was originally performed by means of compressed air injected through portable or fixed pipes. Mechanical stirrers were next introduced, the best device being a central vertical shaft provided with arms halfway down the tank and swinging rods weighted with iron suspended from the lowest arms. Centrifugal pumps taking away pulp from the bottom and throwing it back at the top of the tank insure thorough mixing. In another form of stirrer the central shaft and horizontal arms are hollow and serve to force air through the liquid. In the Hendryx agitator the central tube is rather large and contains a turbine which forces material upwards and discharges it at the top. Mechanical stirring is dispensed with in air agitators such as the Pachuca tank, the principle of which is similar to the Hendryx, but the flow of pulp is accomplished by compressed air. The working cost is rather high, and there is a tendency for sandy material to settle. In the Parral tank the air discharges are set tangentially, causing a rotary motion. The Trent agitator has hollow arms through which the pulp is forced out into the tank, thus causing the arms to rotate. The Dorr machine has a central hollow shaft carrying two inclined arms which move the pulp toward the lower end of the shaft, through which it is taken up and discharged at the top. The addition of oxidising agents has been abandoned almost everywhere: the essential thing being to keep slime pulps agitated.—W. R. S.

Magnetite in mattes and slags. J. W. Bennie. Eng. and Min. J., 1913, **96**, 1213.

The reaction $FeS+10Fe_2O_3=7Fe_3O_4+SO_2$ is stated to occur in the roasting of sulphide ores and probably also in blast and reverberatory furnaces (this J., 1913, 1111), while the reaction $3FeS+5O_2=Fe_3O_4+3SO_2$ takes place in pyritic and partial pyritic smelting. Ferrous sulphide reduces both ferric and magnetic oxides to the lowest oxide if the temperature is sufficiently high; a fall in the temperature of the furnace therefore causes an increase in the quantity of magnetite, and this has been observed repeatedly in practice. Only a small amount of magnetite is formed through oxidation of ferrous silicate in the blast furnace; most of it is derived from the oxidation of ferrous sulphide below the temperature of formation of ferrous silicate. (See also this J., 1913, 738.)—W. R. S.

Zinc smelting; By-products in electric ——. W. M. Johnson. Eng. and Min. J., 1913, **96**, 1157—1159.

Experimental smelting has been in progress for some years past at Hartford, Conn., U.S.A. The results so far obtained indicate that electric smelting is advantageous where the retort process fails, *i.e.*, with complex sulphide ores. The cost of roasting is reduced, as the object is to leave enough sulphur in the ore to combine with the copper and iron. Besides spelter the process yields copper matte and lead bullion containing the gold and silver. The slag produced is extremely poor in values.
—W. R. S.

Pulverised coal; Use of ——, in metallurgical furnaces. J. Lord. Proc. Engineers' Soc. of W. Pennsylvania, 1913, **29**, 363—417.

The coal (slack) employed for puddling-, heating-, and other furnaces at the works of the American Iron and Steel Manufacturing Co., Lebanon, Pa., contains 1·1 per cent. of moisture, 33·2 of volatile matter and 9·6 of ash. After being dried, it is ground in horizontal (tube) or upright mills until 95 per cent. will pass through a sieve of 100 meshes per sq. in. (over 80 per cent. of the product will pass through a sieve of 200 meshes per sq. in.) and conveyed through pipes to the storage tanks of the respective furnaces, to which it is subsequently delivered at a uniform rate, and under an air-pressure of about 1/16 lb. per sq. in. at the furnace mouth, by means of an adjustable "burner" of the screw-conveyer type; a low air-pressure is employed to minimise the destructive effects of the projected fuel upon the interior of the furnace. The coal should contain at least 30 per cent. of volatile matter and not more than 0·5 of moisture or 1 of sulphur; the bulk of the ash is either deposited at the bases of the stacks or collected in the latter by means of suction-fans; the furnace charges are not adversely affected by the small amounts of ash which settle upon them. The average cost of preparing and delivering the fuel to the furnaces did not exceed 50 cents (2s. 1d.) per ton of pulverised coal produced in 1912. In four furnaces employed for the production of high-grade puddled bar from grey forge pig iron, the maximum and minimum consumptions of pulverised coal per ton of puddled bar were respectively 1472 and 1169 lb. over a period of two months; during the same period, the maximum and minimum amounts of fuel required for heating iron piles for rolling were 570 and 516 lb., respectively, per gross ton of rolled bars. In discussion W. A. Evans stated that danger arising from explosion or spontaneous combustion of dry, powdered coal, could be avoided by keeping the material in motion and not allowing it to remain in the storage-bins for longer than a week. Owing to the volume of flame produced, furnaces for pulverised coal require about 4 times as much combustion-space as ordinary grate furnaces, and this should be entirely free from metallic cooling surfaces. Ash trouble may be minimised by the use of high-grade coal, by employing a bed of cinders in the combustion chamber, and by regulating the temperature of the flues to prevent deposition of slag; chequer-work is considered unsuitable for this method of firing. The use of powdered coal is stated to be more economical than that of producer-gas or oil to the extent of about 25 per cent. in the former, and probably much more in the latter, case.—W. E. F. P.

Sodium amalgam and water; Interaction of ——. H. B. Baker and L. H. Parker. *Action of variously treated waters on sodium amalgam.* L. H. Parker. Chem. Soc. Trans., 1913, **103**, 2060—2073.

Water condensed from steam which had been passed through a red-hot tube was found to act with a strikingly slower velocity on sodium amalgam than did ordinary distilled water. The activity of ordinary water was probably due to the presence of traces of hydrogen peroxide, which passed over during distillation but were destroyed by superheating the steam. Water which had been exposed in sealed Jena-glass flasks to the action of metals (copper, silver, platinum, mercury, and aluminium) exhibited increased activity towards sodium amalgam, especially in the case of aluminium. It is suggested that during the prolonged contact of the metals with water and dissolved oxygen a small amount of hydrogen peroxide was formed, although not detectable by the ordinary colour tests. The activity of water which had been exposed to radium bromide (a treatment known to transform the water partially into hydrogen peroxide) was in every case greater than that of the same water untreated.

—F. Sodn.

Mineral production of the United Kingdom in 1912. Board of Trade J., Jan. 8, 1914. [T.R.]

The following table, showing the quantity and value (definitive figures) of the minerals produced in the United Kingdom in 1912, as compared with 1911, is taken from the General Report with Statistics on Mines and Quarries, 1912, Part III.

Description of Mineral.	1911.		1912.	
	Quantity.	Value at the Mines and Quarries.	Quantity.	Value at the Mines and Quarries.
	Tons.	£	Tons.	£
Alum shale	10,516	1,051	11,258	1,155
Arsenical pyrites	1,170	1,290	2,450	2,049
Arsenic	2,144	14,413	2,194	17,901
Barium (compounds)	44,118	40,386	45,377	39,430
Bauxite	6,007	1,294	5,790	1,414
Bog ore	2,700	540	3,340	835
Chalk	4,884,020	199,573	4,285,412	190,799
Chert, flint, etc.	71,577	14,074	74,718	13,426
Clay and shale	13,835,038	1,758,466	12,808,950	1,633,736
Coal	271,891,899	110,783,682	260,416,338	117,921,123
Copper ore	3,135	14,620	1,787	12,985
Copper precipitate	127	3,548	146	6,404
Diatomite	—	—	62	62
Fluorspar	55,231	18,941	47,246	17,263
Gold ore	2,752	992	170	4,784
Gravel and sand	2,275,177	172,214	2,191,451	167,640
Gypsum	276,684	104,221	285,291	110,591
Igneous rocks	6,524,696	1,241,967	6,638,215	1,210,418
Iron ore	15,519,424*	4,035,893	13,790,391*	3,763,837
Iron pyrites	10,114	4,237	10,522	4,324
Lead ore	23,910	219,314	25,409	295,614
Lignite	120	60	62	31
Limestone (other than chalk)	12,183,355	1,268,853	11,500,660	1,206,022
Manganese ore	4,987	3,997	4,170	3,371
Mica	25,335	8,748	29,962	11,317
Natural gas cubic feet	221,400	Not stated	161,200	Not stated
Ochre, umber, etc.	14,585	13,732	13,947	13,661
Oil shale	3,116,803	857,120	3,184,826	765,730
Salt	2,082,688	601,324	2,122,250	577,473
Sandstone	4,044,907	1,194,420	3,839,567	1,132,391
Slate	425,125	1,050,667	383,422	972,022
Soapstone	—	—	8	2
Sulphate of strontia	5,869	4,400	19,370	15,020
Tin ore (dressed)	7,746	837,957	8,166	1,012,29
Uranium ore	67	Not stated	42	Not stated
Wolfram ore	266	24,629†	193	16,87
Zinc ore	17,652	82,690	17,704	87,86
Total value	—	124,579,313	—	131,220,85

*Exclusive of 372 tons in 1911 and 431 tons in 1912 of micaceous iron ore used for paint, and placed under the heading "Ochre, umber, et

† Value of 251 tons only for 1911 and of about 192½ tons only for 1912.

The increase in the total value of the minerals raised during the year is mainly accounted for by the increased value of coal, the average price of coal being 9s. 0·68d. per ton in 1912, as compared with 8s. 1·79d. in 1911.

The quantity of coal exported, exclusive of coke and manufactured fuel and of coal shipped for the use of steamers engaged in foreign trade, was 64,444,395 tons. France received over 10 million tons, Italy over 9 million tons, Germany over 8 million tons, Russia and Sweden each over 4 million tons, Spain nearly 3½ million, Argentina over 3¼ million, Egypt nearly 3 million, Denmark over 2¾ million, and Norway and the Netherlands each over 2 million. Adding the 3,107,140 tons exported in the form of coke and manufactured fuel, and the 18,291,370 tons shipped for the use of British and foreign steamers engaged in foreign trade, the total quantity of coal which left the country was 85,842,905 tons, as against 87,081,382 tons in 1911. The amount of coal remaining for home consumption was 174,573,433 tons, or 3·823 tons per head of the population; 35,322,147 tons were used in the manufacture of coke and briquettes, and 17,997,854 tons in the blast furnaces for the manufacture of pig iron, as against 36,096,857 tons and 19,218,491 tons, respectively, in the previous year.

The iron ore raised in the United Kingdom yielded 4,451,636 tons of iron, or more than one-half of the total quantity of pig iron made in this country.

Mercury imports and exports; British ——. A. S. Pickering. Jan., 1914. [T.R.]

	Imports.	Exports.
	Bottles.	Bottles.

The estimated consumption in the United Kingdom is 14,000 bottles per annum.

Metals; New apparatus for the pulverisation (atomisation) of ——. *(Schoop process.)* V. Bernard. Rev. Mét., 1913, **10**, 1377—1382.

A PORTABLE apparatus ("pistol-syringe") for simultaneously producing a fine spray of fused metal, alloy, lass or enamel and projecting the same continuously pon any suitable surface. The metal, etc., in the form f wire, is automatically fed—at a rate depending upon its sibility—into an oxy-coal-gas or similar flame, and, s melted, is atomised and projected by means of compressed air. It is stated that 1 kilo. of copper (or brass), inc, aluminium or lead may be atomised and redeposited y this means at a total cost, including metal, of 7·75, 80, 9·50 or 1·40 fr. (6s. 2d., 3s., 7s. 6½d., or 1s. 1½d.), spectively, the time occupied being about 30 mins. r copper or brass and about 20 for zinc.—W. E. F. P.

erium: Alloys of —— with silicon and bismuth. R. Vogel. Z. anorg. Chem., 1913, **84**, 323—339.

UCH heat is evolved in the production of the alloys of rium with both silicon and bismuth, and the reactive ture of the fused products has rendered thermal investition difficult. Cerium and silicon form at least one mpound, probably of the formula CeSi, and an eutectic ntaining 47 per cent. Si (m.pt. 1240° C.). The alloys are rd and brittle, and stable in the air. At very high mperatures cerium, like magnesium, attacks silica and rcelain. Cerium forms with bismuth the compounds, Ce$_3$, Bi$_3$Ce$_4$, BiCe, and Bi$_2$Ce, the melting points of which, e those of cerium-aluminium compounds (this J., 1912, 5), are remarkably high, that of the compound, Bi$_3$Ce$_4$, ing approximately 1630° C. The bismuth alloys slowly ell up and disintegrate in air, the moisture accelerating dation, especially with those containing 25—75 per cent. Bi, which may become heated to visible combustion; dilute acids attack the alloys readily. Hardness reaches a maximum with the compound, Bi$_3$Ce$_4$, for which it is between 5 and 6 on Mohs' scale.—F. SODN.

Concrete-covered cast iron, a new structural material. Von Emperger. *See* IX.

Fractionation of alloys and minerals in the electric microfurnace. Fletcher. *See* XXIII.

PATENTS.

Iron: Purification or extraction of ——. G. H. Benjamin, New York. Eng. Pat. 27,968, Dec. 4, 1912.

SEE U.S. Pat. 1,051,065 of 1913; this J., 1913, 198. The iron may be refined in one electric furnace and then transferred to another electric furnace, heated to a lower temperature, in which the necessary ingredients are added. Magnesia may be added to combine with the nitrogen in the charge, and compounds may also be used to facilitate the combination or uniform mixing of the iron with the added materials.—T. F. B.

Cast-iron: Method for removing sulphur from ——. W. F. Prince, Elizabeth, N.J. U.S. Pat. 1,081,403, Dec. 16, 1913.

MANGANESE is added to the cast iron in the ladle and the metal is then treated with an oxidising agent, *e.g.*, air, to oxidise part of the manganese, and agitated to accelerate the combination of manganese and manganese oxide with the sulphur and the separation of manganese sulphide and oxide from the charge.—A. S.

Iron blast-furnace flue-dust; Method of utilising ——. R. Baggaley, Pittsburgh, Pa. U.S. Pat. 1,081,921, Dec. 16, 1913.

MOLTEN iron or steel is run into a receiving vessel, and at the same time flue-dust and fines from iron blast-furnaces are introduced in such manner as to cause them to be enveloped by, and thoroughly mingled with, the molten metal.—T. ST.

Iron ores and blast-furnace dust; Agglomeration of —— into briquettes. W. Mathesius. Fr. Pat. 460,954, July 10, 1913. Under Int. Conv., July 10, 1912.

A MIXTURE of very basic alumino-silicates (3 mols.) and ferrous hydroxide (1 mol.) is moistened with hot water, mixed with the ores or dust, and formed into briquettes. Setting takes place in a few hours, 1 to 2 per cent. of the alumino-silicates being required. Powdered lime may be used in place of the alumino-silicates, but it must be pulverised in the moist state with the proper amount of ferrous hydroxide at a high temperature. The agglutinant formed as described melts above 1500° C., but by the addition of relatively small quantities of magnesium oxide, strontium oxide, barium oxide, titanic oxide, etc., the melting point may be reduced to 1000° to 1100° C.—T. ST.

Steel; Melt or compound for use in the hardening or tempering of ——. S. N. and E. R. Brayshaw, Manchester. Eng. Pat. 22,167, Oct. 2, 1913.

THE substance, which is stated to be very fluid at 130°—140° C. and practically unaffected by heating to 700° C., is composed of the nitrates and nitrites of sodium and potassium in equimolecular proportions, and may also contain similar compounds of lithium or alkaline-earth metals.—W. E. F. P.

Steel; Art of manufacturing ——. G. H. Benjamin, New York. U.S. Pat. 1,080,807, Dec. 9, 1913.

MOLTEN bessemerised iron from which carbon, phosphorus, and silicon have been partially removed, is fed on to a heated hearth, a basic flux added, and the charge heated by gas and air. The slag is separated, and the hearth, together with the iron, is removed from the first atmosphere, lime is added, and the charge is heated electrically to a temperature sufficiently high to bring about combination of the remaining carbon, phosphorus, and silicon, with the lime. After the slag has been removed, the hearth and iron are again moved into a reducing heating atmosphere, the necessary carbon added, and the resulting steel tapped.—T. St.

Steel ; Purifying ——. E. Humbert, South Chicago, Ill. U.S. Pat. 1,081,532, Dec. 16, 1913.

A mixture of silica sand, 10 to 30 per cent., and lime, 70 to 90 per cent., is melted, and carbon is added to the extent of 10 to 30 per cent. of the total lime and sand. The molten steel is poured into a finishing vessel upon the melted mixture, so as to convert silicates of manganese and iron into a readily fusible calcium silicate.—B. N.

Zinc ores ; Reduction of —— in the electric furnace. W. McA. Johnson, Hartford, Conn. U.S.A. Eng. Pat. 27,881, Dec. 3, 1912. Under Int. Conv., Oct. 17, 1912.

Complex zinc ores are roasted at a temperature not exceeding 1000° C., then intimately mixed with 15 to 20 per cent. of soft coal and the necessary fluxes, and subjected to a preheating, with stirring, at a temperature of 800° to 950° C. All remaining sulphates are thus reduced to sulphides, and iron and copper oxides are reduced to metal. While still hot, the charge is transferred to an electric furnace, where a matte of iron and copper sulphides is formed, and sinks to the bottom of the charge, taking with it all the sulphur. On their way to the condenser the zinc vapours pass through a deoxidising body of carbon. The zinc, being thus freed from sulphur and oxygen, condenses to a liquid and the formation of "blue powder" is avoided. The temperature of the charge in the electric furnace must be kept sufficiently low to prevent the liberation of sulphur from the matte, or the formation of carbon bisulphide, and the charge should be so proportioned that the amount of iron and copper is from 5 to 7 times that of the sulphur.—T. St.

Smelting volatile metals ; Electrically ——. W. McA. Johnson, Hartford, Conn. U.S. Pat. 1,080,912, Dec. 9, 1913.

The charge, which contains a reducing agent, and is proportioned to yield a fusible slag which forms a molten electrode, is progressively heated in the absence of air, by passing an electric current through the charge, the evolved metallic vapours and the electrode. The volatile reaction products are conducted through the charge, thereby progressively cooling it, and also into contact with carbon at a temperature which gives maximum reduction, the carbon being continuously replaced. The volatile metal is condensed apart from the charge.—B. N.

Zinc-furnace with integral condenser ; Electric ——. J. Thomson, New York, U.S. Pats. 1,080,862 to 1,080,866, Dec. 9, 1913.

(1) The furnace comprises a reaction chamber, with walls provided with a number of side openings extending outwards, and leading into a condenser composed of vertical spaces or galleries, and the products of the reaction pass through these in a downward, or a downward and then upward direction to side openings in the outer walls leading to the atmosphere. An underlying receptacle receives the products of the reaction from the condenser. The furnace is provided with a horizontal carbon resister in contact with the inner ends of a number of carbon terminal members, the outer ends of which are located in the furnace walls, in contact with two sets of metallic strips extending through the walls of the furnace. (2) A rod resister, resting on side supports, is used, the lower surface being exposed to an underlying trough or sump; the upper and side surfaces are encased within the charging material. The furnace is provided with outer walls, forming a gallery or galleries extending along the outer side or sides, with ports in the walls in axial alignment with corresponding ports in the resister support or supports. (3) The carbon resister bed is supported on spaced grate bars arranged above a sump, and the resister is retained in place by walls provided with openings leading the gases to the condensers on opposite sides of the resister. The top portion of the openings are below the top of the adjacent resister, and the lower portion of the openings communicate with the space between the grate bars, so that any fumes passing through the resister to the space between the grate bars can flow directly through the openings to the condensers. (4) The carbon resister, in the form of a reaction bed, is supported on a grate formed of rods, with an underlying carbon filter bed, and the grate is of lesser electrical conductivity than the carbon above and below. (5) The lower surface of the carbon resister rests on a grate, and the side surfaces are retained by spaced rods. The resister and rods are embedded in a charge of the reacting material, and the reaction occurs primarily along the vertical sides of the resister by means of conducted or radiated heat or by both.—B. N.

Zinc ; Method and furnace for the extraction in a vacuum of metallic —— from zinc ores. E. Herter. Fr. Pat. 460,404, July 15, 1913. Under Int. Conv., July 15, 1912.

Zinc oxide is reduced at about 1500° C. with carbon in a vacuum furnace heated internally by an electric current. The vapours may be allowed to condense in the furnace or may be drawn into a condensing chamber maintained at 500° C. The zinc vapours thus condense almost completely into molten zinc.—T. St.

Zinc ; Method of extracting ——, from ores, especially those containing lead. Minerals Products Ltd., and H. C. Woltereck. Fr. Pat. 460,233, July 10, 1913. Under Int. Conv., July 11, 1912.

The crushed, roasted ore is treated, at atmospheric pressure, with a boiling solution of ferrous sulphate by which, it is claimed, zinc oxide is converted into sulphate according to the equation: $ZnO+FeSO_4+H_2O=ZnSO_4+Fe(OH)_2$.—W. E. F. P.

Metal colloids ; Production of ——. H. Crookes and L. Stroud, London. Eng. Pat. 28,776, Dec. 13, 1912.

Metal colloids are obtained, it is claimed, without the use of sodium chloride, by the addition of a very dilute solution of the metal salt (about 1 part of metal in 1000 of solution) to a solution of peptone; and are rendered permanent by adding about 0·1 per cent. of phenol to the mixture. For the preparation of silver and iron colloids, the solutions of peptone employed contain about 300 and 150 grains per quart, respectively.—W. E. F. P.

Solder. J. and E. Wilkins, and J. G. Morris, London. Eng. Pat. 29,239, Dec. 19, 1912.

A solder, for aluminium, composed of Zn 5—5½ and Sn 8, parts by weight.—W. E. F. P.

Soldering composition. M. and E. Richardson, London. Eng. Pat. 23,077, Oct. 13, 1913.

The solder (for aluminium, etc.), consists of Sn 58·6, Zn 23·4 and Pb 17·6, parts by weight.—W. E. F. P.

Metals or metallic alloys ; Salicylate electrolytes for use in the electrolytic deposition of ——. P. Marino, London. Eng. Pat. 28,953, Dec. 16, 1912.

The metal or metals to be deposited may be present in the electrolyte either as the salicylate or other salt. The other ingredients are ammonium, potassium or sodium salicylate, equal in amount to the weight of the metallic salt, and from 5 to 10 grms. of sulphosalicylic acid for each litre of water. The bath is rendered alkaline by addition of ammonia. A current density of 0·3 to 0·4 ampère per sq. dcm. of area of the article to be covered is used, and the electrolyte is agitated continuously o heated. Cyanide or thiocyanate of potassium may b added to the electrolyte, the precipitate which is forme being dissolved and added to the bath.—T. St.

[Copper-nickel] Alloy ; New metal ——. C. E. Monkhouse, London, and M. H. Denton, Sheffield. Eng. Pat. 1819, Jan. 22, 1913.

A "WHITE metal" composed of Cu 40, Ni 8½, Zn 5, Pb 1 and Sn 2½, parts by weight. The alloy—which is stated to resemble silver in appearance—is prepared by melting the nickel under a flux of white glass, adding half the copper gradually and the remainder in bulk, then the zinc and finally the tin and lead together.—W. E. F. P.

Nickel-copper alloys. P. J. A. Douglass, Halifax, Nova Scotia. Eng. Pat. 8331, April 9, 1913.

CLAIM is made for alloys composed of Ni 67, Cu 33, ferromanganese 2—8, Al 5 and Sn 6—10, parts by weight; and Ni 67, Cu 33, ferro-silicon (55 per cent. Si) 5—15 and Cr 1—8, parts by weight; to either of which 3—5 per cent. W may be added. The alloys are stated to be hard, tough, incorrodible and suitable for the manufacture of cutting tools.—W. E. F. P.

[Tungsten.] Wire drawing [; Lubricant for ——]. British Thomson-Houston Co., Ltd., London. From General Electric Co., Schenectady, N.Y., U.S.A. Eng. Pat. 2001, Jan. 24, 1913.

FOR use more particularly in the hot drawing of tungsten wire, claim is made for a lubricant composed of an aqueous suspension of finely divided graphite (*e.g.* "aquadag") containing sufficient organic binding material (*e.g.* glucose) to cause the graphite to adhere firmly to the wire on heating.—W. E. F. P.

Tungsten ores ; Process of treating ——. F. M. Becket, Niagara Falls, N.Y., Assignor to Electro Metallurgical Co., New York. U.S. Pats. 1,081,566 and 1,081,571, Dec. 16, 1913.

(1) ORES of the iron tungstate type are heated and then treated with an acid reagent, *e.g.*, sulphuric acid, under such conditions that the ratio of tungsten to phosphorus in the ore is increased. (2) A low-phosphorus manganese-bearing ore of the iron tungstate type, after being partially reduced, is treated so as to increase the ratio of tungsten to manganese in the product, and then the reduction is completed.—A. S.

Tungsten and alloys thereof ; Method of preparing ——. F. M. Becket, Niagara Falls, N.Y., Assignor to Electro Metallurgical Co., New York. U.S. Pats. 1,081,567, 1,081,568, and 1,081,570, Dec. 16, 1913.

(1) CRUDE ferrotungsten is subjected to an oxidising roast and the product is treated so as to remove phosphorus and increase the tungsten-content, and then reduced. (2) Crude ferrotungsten is subjected to an oxidising roast, the resulting oxide reduced without substantial fusion of the reduced product, and the latter treated with acid to remove phosphorus or iron and phosphorus, and increase the tungsten-content. (3) Phosphorus-bearing ores of the iron tungstate type are partially reduced, treated so as to increase the ratio of tungsten to phosphorus in the product, and then the reduction completed.—A. S.

Ferrotungsten ; Method of dephosphorising——. F. M. Becket, Niagara Falls, N.Y., Assignor to Electro Metallurgical Co., New York. U.S. Pat. 1,081,569, Dec. 16, 1913.

SUBDIVIDED solid ferrotungsten is fed to the surface of a molten basic oxidising bath, containing an oxygen compound of tungsten, and kept at a temperature near to or above the fusing point of the ferrotungsten.—A. S.

Ores and other material ; Lixiviating apparatus for ——. C. Robinson, Mount Vernon, N.Y., U.S.A. Eng. Pat. 2805, Feb. 3, 1913.

LONG rectangular tanks are divided by partitions into series of receptacles with pyramidal hopper-like bottoms. In each receptacle is a central vertical tube open at both ends and provided at the top with a deflecting hood. Secured to the bottom of each receptacle is a nozzle connected by a pipe with an air manifold which is common to all the receptacles in one tank. Each nozzle is provided with an inclined valve seat, and a conoidal valve closure. A guided vertical rod secured to the valve closure serves to hold the latter in a vertical position, and tends by its weight to keep the valve closed. Ore pulp with solvent liquid is fed continuously into the first receptacle of a series, and by means of air driven under pressure through the nozzles, is agitated and conveyed up the central pipes, at the top of which it becomes deflected towards, and passes along shelves by gravity to the next receptacle, in each case. Particles of pulp are thus continuously brought into contact with fresh portions of the solvent liquid.
—T. ST.

Magnetic separator. H. J. H. Nathorst, Gellivare Malmfält, Sweden. Eng. Pat. 12,368, May 27, 1913. Under Int. Conv., June 4, 1912.

A CYLINDRICAL drum rotates about stationary magnetic poles, which are consecutively of different polarity, the core of each of the two outermost poles having a lesser cross-section than the core of the nearest inner pole. There may be four poles, the two inner poles being similarly magnetised, and their combined cross-section greater than that of either of the cores of the outer poles. The flux of lines of force thus formed gives the separator a good power of separation.—T. ST.

Furnace ; Electrical reduction ——. R. E. Frickey, Heroult, Cal., Assignor to Noble Electric Steel Co., San Francisco, Cal. U.S. Pat. 1,080,824, Dec. 9, 1913.

THE furnace is of the long and narrow type, and comprises a crucible with a number of feed stacks through which charges of ore are fed. A pair of end electrodes, and a number of middle electrodes, spaced apart and arranged in a row, extend in a downward direction through the conducting charge into the crucible. The electrodes are connected with a number of transformers, the primary circuits of which are connected with a three-phase system in such a manner that the phase angle is 60° between voltages supplied to adjacent pairs of electrodes, and so that a concentrated zone of energy is produced under the central electrodes.—B. N.

Reducing compounds ; Apparatus for ——. H Niewerth, Berlin, Germany. U.S. Pat. 1,081,287, Dec. 9, 1913.

THE material is contained in a closed vertical shaft, connected with two inclined auxiliary shafts containing carbon, one near the top and the other near the bottom. The upper outer ends of the two auxiliary shafts are in communication, and means are provided to admit air to the shafts, and to cause a circulation through the shafts in either direction of the air and products of combustion.—T. ST.

[Cyanide] Solutions ; Method of aerating ——. W. E. Darrow, Amador City, Cal. U.S. Pat. 1,081,436, Dec. 16, 1913.

CYANIDE solution is formed into a film by allowing it to descend a tower filled with solid fragments, and air is admitted under pressure, with the solution, at the top of the tower.—T. ST.

Ores ; Process of treating —— for separating precious metals. D. C. Reinohl, Washington, D.C. U.S. Pat. 1,081,514, Dec. 16, 1913.

PULVERISED ore is saturated with a cyanide solution, and the pulp is heated and agitated in the presence of the atmosphere, and the strength of the solution augmented progressively.—T. ST.

Settling-tank and filter [for ore pulp] ; Combined ——. D. C. Reinohl, Washington, D.C. U.S. Pat. 1,081,515, Dec. 16, 1913.

A CYLINDRICAL tank with a converging bottom contains an inner similarly shaped filtering vessel, for the separation of solution from treated ore pulp. The filtered liquid is run off, and a central discharge pipe, controlled by a valve, allows of the removal of the tailings by gravity. Discharge pipes at different levels allow of clarified liquid being drawn off progressively from above the tailings. —T. St.

Ores; Apparatus for treating ——. D. C. Reinohl, Washington, D.C. U.S. Pat. 1,081,516, Dec. 16, 1913.

Ore is fed into an inclined cylindrical conduit open to the atmosphere, and is supplied with solvent in continuously greater quantity, as it passes along, so that its fluidity constantly increases, and the strength of the solvent is maintained. The pulp is agitated and aerated by arms fitted to an axial revolving shaft, and means are provided for heating the pulp.—T. St.

Ores: Furnace for treating ——. J. W. Frey, Silver Spring, Md. U.S. Pat. 1,081,732, Dec. 16, 1913.

Ore is treated in a cylindrical roasting chamber which rotates within a furnace casing. This consists of a base portion, provided with bearings for the roasting chamber, and an upper portion made up of two separable quarter-cylindrical members. An inverted U-shaped frame, secured to the base, forms a support for the upper members, and for a stack through which the furnace gases escape. The roasting chamber rotates on hollow shafts journaled on the bearings in the casing. Steam is admitted into the chamber through one hollow shaft, and gaseous products escape through the other, over the end of which is disposed a deflector.—T. St.

Ores; Process and opparatus for the perfect roasting of —— in furnaces of all systems. E. Bracq. Second Addition, dated May 13, 1913, to Fr. Pat. 434,494, Sept. 22, 1911 (this J., 1912, 343, and 1913, 609).

The mechanism governing the division, propulsion and rabbling of the charge is disposed outside the heating chamber or chambers of the furnace and is independent of the central shaft; the latter is counterpoised and grooved externally, so that when raised or lowered, the shaft rotates and the attached rabble arms move in a helical path along the hearth.—W. E. F. P.

Roasting furnace; Mechanical ——, with helical hearth. P. Banette. Fr. Pat. 460,728, Oct. 11, 1912.

The hearth is supported at the centre by a hollow, helical, metal tube which surrounds the central shaft of the furnace and through which air is circulated. The central shaft, upon which the rabble arms are supported so that they remain in position by their own weight, is counterpoised and provided at the base with a guide engaging with a helical groove having the same pitch as the hearth. The admission of the charge to the furnace is regulated by the vertical movement of the central shaft.—W. E. F. P.

Antifriction alloy of aluminium suitable for parts of machinery. R. Esnault-Pelterie. First Addition, dated July 5, 1913, to Fr. Pat. 405,157, July 16, 1909 (this J., 1910, 284).

The metal of the iron group, used according to the chief patent, may be replaced by one of the metals Mo, W, V, Ti, Ta, Nb, etc.—T. St.

Nickeling of aluminium; Direct ——. M. Canac née Quentin. First Addition, dated Sept. 16, 1912, to Fr. Pat. 446,949, Oct. 14, 1911 (this J., 1912, 394).

The articles are first cleansed with potash and milk of lime, then immersed in a bath of potassium cyanide, and afterwards passed through a bath containing metallic iron and hydrochloric acid. They are finally introduced into the plating bath containing nickel chloride and boric acid, the successive operations being in each case separated by a prolonged washing with cold water.—B. N.

Gold; Extraction of —— contained in auriferous mispickel and other arsenical ores. A. Grandjean. Fr. Pat. 460,439, June 20, 1913.

The finely ground ore is mixed with permanganate of potassium or sodium, and sufficient water to dissolve the permanganate and form a thin paste. After several hours an excess of hydrochloric acid is added, and when no more gas is evolved, the mass is stirred vigorously with water, and filtered. Gold and other metals are precipitated from the solution by means of zinc, and the gold recovered by cupellation.—T. St.

[*Gold.*] *Precious metals; Process for recovering —— from very dilute solutions, particularly from sea-water.* E. Baur and O. Nagel. Fr. Pat. 460,680, July 23, 1913. Under Int. Conv., July 29, 1912.

The solution (sea-water) is filtered through powdered charcoal, textile material, infusorial earth or colloidal hydroxide of iron, by which and similar substances—it is stated—the salts of precious metals are absorbed until a certain concentration is attained; *e.g.*, when a solution containing 10 mgrms. of gold (as gold-sodium chloride) per cub. m. is brought into contact with pulverised wood charcoal, the gold salt is absorbed by the charcoal until the latter contains 0·05 per cent. Au. —W. E. F. P.

Converter-bottoms; Manufacture of ——. L. Thomas. Fr. Pat. 460,519, July 18, 1913.

To produce smooth, straight blowing-holes, the pegs around which the material forming the converter-bottom is moulded are provided with loose sheaths of thin sheet iron which are allowed to remain in the structure when the pegs are withdrawn.—W. E. F. P.

Nickel; Extraction of metallic —— from nickel ores. Mineral Products, Limited, and H. C. Wolterеck. Fr. Pat. 460,575, July 21, 1913.

The ore, crushed to walnut size, is treated in externally heated retorts, with a mixture of superheated steam and air (nickel sulphide ores), or superheated steam alone (magnesium nickel silicate ores known as *garniérite*), at a temperature of 400° to 750° C., to oxidise the nickel. The mass may be treated, in the retorts, with reducing gases at about 500° C., and the resulting finely divided nickel separated by means of carbon monoxide, or in magnetic separators; or it may be extracted with hot dilute sulphuric acid, and the nickel recovered electrolytically. The whole of the nickel in some magnesium-nickel silicate ores may be dissolved out by treating directly with hot dilute sulphuric acid.—T. St.

[*Copper.*] *Ores; Process of chloridising* ——. A. D. Ledoux. Fr. Pat. 460,579, July 21, 1913. Under Int. Conv., Aug. 13, 1912.

A mixture of the roasted ore (or residue) with sodium chloride is introduced continuously into a heated furnace of the superposed chamber type, the heat developed by the reactions occurring in the first portion of the charge being sufficient, it is claimed, to promote reaction in the succeeding portion, and so on.—W. E. F. P.

Cupola furnace; Gas-fired ——. G. Gautier and L. Esselin. Fr. Pat. 460,967, July 22, 1913. Under Int. Conv., July 22, 1912.

A cupola for use more particularly with gases containing both hydrogen and oxygen, has an annular gas-chamber between the outer casing and the furnace proper; the walls of the latter are constructed of blocks spaced apart to form several series of superposed openings inclined downwards, into each of which a burner extends from the gas-chamber. The return of flame to the latter is prevented by metal grids.—W. E. F. P.

Metallic layer; Process for obtaining a —— by the projection of a fused metal melted by means of an electric current which traverses it. Soc. de Métallisation. Fr. Pat. 461,028, Oct. 19, 1912.

The metal is heated by the resistance which it offers to the passage of an electric current, or is melted by employing it as electrodes for the production of an electric arc, and the molten metal is projected on to the material to be coated by means of a current of gas.—B. N.

Ores and metals ; Method and apparatus for treating ——. L. Petit Devaucelle. Fr. Pat. 461,029, Oct. 19, 1912.

Ore is agitated with a liquid which will dissolve a particular constituent, and is at the same time reduced to a fine state of division, by subjecting it to a rapid stream of a fluid containing small particles of the ore. The ore and liquid are contained in a cylindrical vessel, the bottom having the form of an inverted cone, at the apex of which is a conical nozzle for introducing the fluid under pressure. Inside the vessel and directly above and in line with the nozzle is a hollow truncated cone, which serves to direct the circulation of the liquid and powdered ore. The contents of the vessel may be heated by means of a jacket, or by a coil placed inside.—T. St.

Iron ; Protecting —— from rust. A. Lang, Karlsruhe, Assignor to H. F. von Seldeneck, Frankfort, Germany. U.S. Pat. 1,082,161, Dec. 23, 1913.

See Eng. Pat. 21,638 of 1909 ; this J., 1910, 1255.—T. F. B.

Steel ; Process of making ——. P. P. Reese and S. S. Wales, Munhall, Assignors to Carnegie Steel Co., Pittsburgh, Pa. U.S. Pat. 1,082,359, Dec. 23, 1913.

Patents.

attery ; Primary galvanic ——. S. Yai, Tokyo, Japan. Eng. Pat. 15,909, July 10, 1913.

N air-tight amalgamated zinc casing encloses a hydrogen-bsorbing material, such as a mixture of graphite and anganese peroxide, the air being extracted from the sing and replaced by a solution of ammonium chloride. —B. N.

tteries ; Preparation of absorbents to be used in the cells of electric dry ——. P. Rabbidge, Neutral Bay, New South Wales. Eng. Pat. 19,783, Sept. 1, 1913. Under Int. Conv., Sept. 27, 1912.

E absorbents are prepared from suitable vegetable re, treated with a water solution containing sulphuric d and potassium or sodium permanganate until bleached. —B. N.

Electrodes ; Storage-battery ——. H. C. Hubbell, Newark, N.J. U.S. Pat. 1,081,531, Dec. 16, 1913.

A "thread-like material" formed from a mixture of powdered metallic nickel or cobalt or both, is mixed intimately with nickel or cobalt hydroxide, dried, and a metallic nickel or cobalt coating is deposited on the exposed surface of the thread-like material. The material is then formed into a "matted cake," and enclosed in a suitable conducting envelope or container.—B. N.

Furnaces ; Electric ——. E. Stassano, Turin, Italy. Eng. Pats. 22,723 [Addition to Eng. Pat. 8901, April 10, 1911] and 22,724, Oct. 8, 1913. (See this J., 1911, 1067).

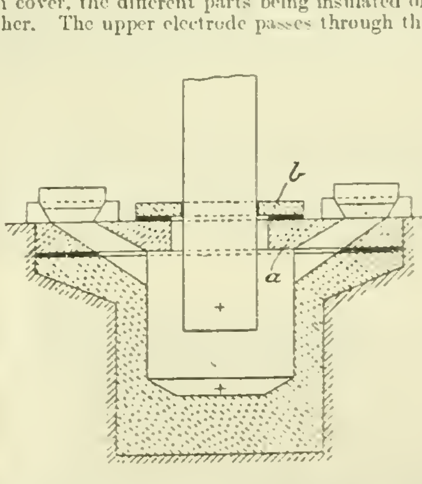
(1) The furnace chamber is oscillated by means of a motor, the wheel connected with the motor being combined with a hand control, and the latter put in gear through a pinion made to slide on a shaft by means of a pedal control. This allows of small displacements being imparted to the chamber, in order to regulate a casting operation. (2) The rod, to which the electrode is fixed, carries in front an insulated stirrup, provided with insulated wheels adapted to travel on two insulated rails mounted on the bottom of the electrode chamber, and the rear end of the carriage, connected with the controlling piston actuating the electrode, rests on guides fixed to the wall of the chamber. Water is circulated through the front and rear walls of the electrode chamber. Two insulated tubes are arranged within the rod, the inner tube discharging water into the outer one at the end where connection is made with the electrode, so that a tight joint may be made where the electrode passes through the wall of the furnace chamber.—B. N.

Furnace ; Electric ——. F. M. Chaplet and La Néo-Métallurgie. First Addition, dated July 2, 1913, to Fr. Pat. 370,005, Sept. 25, 1906 (this J., 1907, 210).

The conductor bringing the current to the base of the furnace has the same cross-section throughout its length, and may debouch from the furnace through the upper part or the side wall, but at such a height that escape of the product from the furnace is impossible. The external portion of the conductor may be cooled in any convenient manner.—B. N.

Furnaces ; Arrangement for closing electric arc ——. I. Hole and O. R. Olsen. Fr. Pat. 460,236, July 10, 1913. Under Int. Conv., July 10, 1912.

The furnace is covered by a single, double or multiple carbon cover, the different parts being insulated one from the other. The upper electrode passes through the upper cover, *b*, which may be adjusted so as to prevent contact of the cover and electrode, and the latter is provided with guides so as to avoid lateral oscillation. Two or



more inclined charging openings, which may be hermetically sealed, are arranged in the lower cover, *a*, along the sides of the furnace, and the walls of the latter are insulated from the base.—B. N.

Furnace ; Reheating with the electric ——. F. Fischer. Fr. Pat. 460,526, July 19, 1913. Under Int. Conv., Nov. 5, 1912.

The furnace is supplied with hydrogen, or gases containing hydrogen, in order to rapidly transmit the heat to the objects to be heated.—B. N.

Ionisation of gases ; Apparatus for measuring ——. Siemens Bros. and Co., Ltd., London. From Siemens und Halske Akt.-Ges., Berlin. Eng. Pat. 18,827, Aug. 19, 1913.

Production of hydrogen and oxygen by electrolysis of water. Addition to Fr. Pat. 459,967. *See* VII.

XII.—FATS ; OILS ; WAXES.

Phytosterol ; Detection of —— in animal fats. M. Fritzsche. Z. Unters. Nahr. Genussm., 1913, 26, 644—648.

The following shortened modification of the method of Marcusson and Schilling (Chem.-Zeit., 1913, 37, 1001) is recommended :—Fifty grms. of the melted fat are treated with 20 c.c. of a 1 per cent. alcoholic solution of digitonin, and the mixture mechanically stirred for 5 minutes at 60° to 70° C. In the case of fluid and semi-solid fats, the mass is at once filtered with the aid of suction in a Buchner's funnel, and the residue washed six times with ether (5 c.c.), whilst in the case of solid fats an addition of 20 c.c. of chloroform is made to the hot liquid, and the residue washed with 2 portions (5 c.c.) of hot chloroform and then with six portions of ether to remove all fat. The residue (digitonide) is dried for about 5 minutes at 30° to 40° C. and dissolved in 2 c.c. of hot acetic acid, and the solution boiled for about 5 minutes in a test tube with a vertical tube to act as condenser, and then filtered through cottonwool. The tube and filter are twice washed with 0·5 c.c. of hot absolute alcohol and the combined filtrate and washings evaporated on the water bath in a current of air. The residual phytosteryl or cholesteryl acetate is dissolved in 1 c.c. (or less) of absolute alcohol, and the crystals drained on porous porcelain and examined in the usual way.—C. A. M.

Catalysts ; Influence of impurities on the activity of ——. III. Experiments with platinum as a hydrogen-carrier. C. Paal and E. Windisch. Ber., 1913, 46, 4010—4016. (See also this J., 1911, 715 ; 1913, 1089.)

Metal powders purified with alcohol and ether were platinised by shaking with a solution of chloroplatinic acid, and metallic oxides and carbonates were platinised by the action of sodium carbonate and hydrazine hydrate on a solution of chloroplatinic acid containing the oxide or carbonate in suspension. Experiments with these products as catalysts in the hydrogenation of cottonseed oil showed that of the metals only magnesium and nickel had no influence on the activity of the platinum ; the platinum was much less active in presence of aluminium, cobalt, and bismuth, and rendered completely inactive by iron, copper, zinc, silver, tin, and lead. Of the oxides and carbonates examined, only the magnesium compounds were without influence. (See also Fr. Pats. 425,729 and 434,927 of 1911; this J., 1911, 1022 ; 1912, 346.)—A. S.

Indian, Japanese and Chinese beeswax. H. Fischer. Z. öffentl. Chem., 1913, 19, 473—476.

Further details are given of the adulteration of E. Indian beeswax, which includes Indian, Japanese and Chinese waxes (this J., 1913, 665, 982). All these waxes show the same characteristic of low acid value. The Chinese and Japanese waxes are harder, cleaner and of better quality than the Indian wax. The latter, although showing the same m.pt. as ordinary beeswax, is softer to the touch, and, unlike the Chinese and Japanese wax, is not readily bleached by the sun. "Rosin wax," consisting of 40 to 80 per cent. of American rosin and paraffin wax, is largely imported into India, and appears to be occasionally, though not commonly, used as an adulterant of beeswax. Persistent emulsions sometimes obtained in treating Indian beeswax are due to the borax used in the purification and to oil present as adulterant. Chinese and Japanese beeswax is not adulterated with oil, but frequently contains paraffin wax. Trigona wax, fragments of which are present in almost every consignment of Indian beeswax, is described as humble beeswax in Germany. It is unbleachable and is only suitable for special technical purposes. During the last ten years the price of humble beeswax (Germany) has risen from M. 40 to M. 100—120 per 100 kilos. (from £11 19s. to £29 17s.—£35 16s. per cwt.). In India humble beeswax is not known as a separate commercial product.—C. A. M.

Detection of a yellow dye in edible fats. W. Arnold. Z. Unters. Nahr. Genussm., Dec. 1, 1913, 654.

A yellow dye which has long been in use for artificially colouring fats may be detected by the following test :—One vol. of the melted fat is dissolved in 2 vols. of petroleum ether and well shaken with 0·5 vol. of hydrochloric acid of sp. gr. 1·19. After separating, the acid layer will be found coloured yellow to orange, and this colour may be discharged by the addition of 1 drop of stannous chloride solution. Fats containing none of the dye may give more or less colour to the acid, but the distinguishing test is the decolourisation with stannous chloride. This property indicates that the dye is probably one of the easily reduced nitro-dyes. Its presence in a fat may interfere with Baudouin's test for sesame oil if carried out in the usual way, but this can be obviated by using a solution of 0·1 part of stannous chloride in hydrochloric acid instead of the pure acid.

Naphthenic acids and sodium naphthenate. Davidsohn *See* IIa.

Patents.

Oils and greases ; Machines for testing the lubricatin properties of ——. R. C. Hislop, London. Eng. Pa 29,086, Dec. 17, 1912.

The oil or grease is subjected to friction between a bod rotating on a horizontal spindle and one or more movab bodies to which pressure may be applied by means of spring mounted upon a second spindle in the same a as the main shaft. The motions of the movable bodi and hence the degree of friction of the oil, may be record upon cylinders which are simultaneously rotated fro the main shaft.—C. A. M.

Grease ; Process of manufacturing a consistent — Chem. Fabrik. Troisdorf Dr. Hülsberg und Seil Fr. Pat. 460,418, July 16, 1913. Under Int. Con May 26, 1913.

A lubricating grease is prepared by heating the vari constituents (mineral oil, oleine, lime or equival materials) under pressure. For example, a mixture of mineral oils, compounds of alkaline-earths with oleic or other fatty acid, or magnesium or aluminium salts of fatty acids, is heated at about 150° C. (by means of superheated steam) under a pressure of about 5 atmos.—C. A. M.

Oil from fish ; Process of extracting —— W. E. Overton, Solomons, Md. U.S. Pat. 1,080,294, Dec. 2, 1913.

As much as possible of the oil and watery fluids is extracted from a quantity of fish by pressure, and the watery portion is separated from the oil, heated, and returned to the pressed mass, with which it is well mixed. Subsequent application of pressure to the wet mass results in the removal of a further quantity of oil, together with the watery fluids, from which the oil is afterwards separated.—E. W. L.

Oils and fats ; Method of obtaining sulphonated ——. R. Russ, Assignor to Stolle and Kopke, Rumburg, Austria-Hungary. U.S. Pat. 1,081,775, Dec. 16, 1913.

The oils, etc., are treated with sulphuric acid, the excess of acid removed by the addition of water or a washing liquid, and the sulphonated product separated by centrifugal action.—C. A. M.

Alkaline oils [for protecting ordnance from the effects of smokeless powder] ; Process for the preparation of ——. J. T. Westermann. Fr. Pat. 460,419, July 16, 1913.

Linseed, or other vegetable oil, is mixed with an alcoholic solution of caustic alkali or ammonia in such proportion that the free alkali in the mixture shall not exceed 2 to 3 per cent. Petroleum oil (preferably 10 to 50 per cent.) may also be added to the mixture. The resulting products will form emulsions with water, and are particularly useful for protecting ordnance from the effects of smokeless powder.—C. A. M.

Solvents for fats ; Process and apparatus for separating the vapours of ——. E. Bodin, H. Dupont, and M. Riom. Fr. Pat. 460,746, July 25, 1913. Under Int. Conv., Mar. 31, 1913.

The solvent is brought into contact tangentially with the heated wall of an extraction vessel so that a rotatory movement is communicated to the vapours and the liquid.
—C. A. M.

Solutions of organic compounds producing emulsions with water ; Liquid or solid ——. R. Vidal, Paris. Eng. Pat. 28,832, Dec. 14, 1912. Addition to Eng. Pat. 15,827, July 6, 1912.

See Addition of Dec. 11, 1911, to Fr. Pat, 445,053 of 1911 ; this J., 1913, 498.—T. F. B.

XIII.—PAINTS ; PIGMENTS ; VARNISHES ; RESINS.

Egyptian blue. A. P. Laurie, W. F. P. McLintock, and F. D. Miles. Roy. Soc. Proc., 1914, A 89, 418—429.

Experiments with a mixture of fine sand 36 grms., fusion mixture 4 grms., copper carbonate 8·6 grms., and calcium carbonate 7·2 grms., showed that at 800° and at 905° C. none of the true Egyptian blue was formed, the product consisting of uncombined quartz, copper oxide, and an olive-green glass, but at 830° C. considerable quantities of the blue pigment were formed, and on re-grinding and re-heating several times at this temperature, the green glass and copper oxide practically disappeared, leaving a mixture of the blue pigment and uncombined quartz, corresponding to lump samples of frit discovered in Egypt but much richer in the blue. Samples of typical Egyptian blue and of the products prepared as above all proved to consist essentially of a definite crystalline copper silicate as described by Fouqué (this J., 1889, 290). One of the authors' samples contained : SiO_2 63·4, CaO 14·4, CuO 19·5, K_2O 1·19, Na_2O 0·93 per cent. The blue crystals could be obtained without fusion mixture, but it was necessary to heat to a higher temperature (*e.g.* 1050° C.) and then re-grind and reheat at 850° C. When fusion mixture or other alkali salts were used, some of the copper or calcium in the blue crystalline silicate (CaO, CuO, $4SiO_2$) was replaced by alkali metals. The crystalline blue silicate was formed at a temperature far below the fusing point of the whole mixture, the mass merely becoming pasty. At temperatures above 900° C. the blue crystals were converted into a green glass, but the Egyptian blue crystallised out again on re-heating at 850° C.—A. S.

Shellac ; Examination of bleached ——. H. Wolff. Chem. Rev. Fett Ind., 1914, 21, 4—5.

Bleached shellac of diverse origin (65 samples) yielded an ethereal extract ranging from 11·5 to 14·5 per cent. A further test of purity is to determine the amount of benzene extract after previous extractions with petroleum spirit and with ether. The powdered shellac, preferably air-dried or dried at 40° C., is best extracted in a linen bag suspended in the extraction apparatus. Before each extraction it is rapidly ground up with a little of the solvent and sufficient sand to give a dry powder. The extraction with each of the solvents is continued for 3 to 6 hours. In this way a final benzene extract varying between 4 and 5 per cent. was obtained (45 samples gave 4·3 to 4·6 per cent.). The method is not suitable for the quantitative examination of mixtures.—C. A. M.

Japan lac ; The chief constituent of ——. *IV. Derivatives of hydro-urushiol.* R. Majima and J. Nakamura. Ber., 1913, **46**, 4080—4088.

Hydro-urushiol, the crystalline reduction product of urushiol from Japan lac (this J., 1912, 998), yielded a lead salt and various benzoyl derivatives. Its dimethyl ether was converted into a mono-nitro derivative (m. pt. 72°—73° C.), and the latter (by nitration with fuming nitric acid) into a di-nitro compound (m. pt. 83° C.). Both compounds crystallise in needles, and they afford the best means of identifying the dimethyl ether of hydro-urushiol. The behaviour of this ether on nitration was analogous to that of dihydrosafrol. Oxidation of hydro-urushiol in acetone solution by means of permanganate yielded palmitic acid—thus confirming the presence of an alkyl group in the side chain and showing that the latter must contain $C_{15}H_{31}$ instead of $C_{14}H_{29}$ as previously assumed. The constitutional formulæ of all the derivatives of hydro-urushiol must be correspondingly modified. The reactions showed that hydro-urushiol is a higher phenol (see also this J., 1907, 1245 ; 1909, 532, 1212).—C. A. M.

Phenols ; New synthesis of higher ——. [*Isomerides of hydro-urushiol dimethyl ether.*] R. Majima and J. Nakamura. Ber., 1913, **46**, 4089—4095.

Phenols with the constitution of a 3·4-dimethoxy-1-tetradecyl-benzene and a 3.4-dimethoxy-1-pentadecyl-benzene were synthesised as follows :—Myristyl chloride and veratrol were condensed by means of aluminium chloride (yield under 25 per cent.) and the resulting tridecyl-veratryl ketone, $(CH_3O)_2C_6H_3.CO.C_{13}H_{27}$ reduced to a phenol by the following stages. It was first converted into the oxime, and this was reduced by means of ammonium amalgam to the amine, $(CH_3O)_2C_6H_3.CH(NH_2).C_{13}H_{27}$. The phosphoric acid salt of this amine yielded, on dry distillation, tetradecenyl-veratrol, $(CH_3O)_2C_6H_3.CH : CH.C_{12}H_{25}$, and this, when reduced with hydrogen and platinum, was converted into tetra-decyl-veratrol, $(CH_3O)_2C_6H_3.C_{14}H_{29}$. Pentadecyl-veratrol was obtained by a similar series of reactions from tetra-decyl-veratryl-ketone, the latter being prepared by converting myristic acid into pentadecanic acid and condensing the chloride of this acid with veratrol, as described. Hexadecyl-veratrol was also prepared. None of these higher phenols was identical with hydro-urushiol dimethyl ether, although they showed similar reactions and were apparently isomeric therewith (see preceding abstract).—C. A. M.

Rosin size; Examination of ——. J. Marcusson. Chem. Rev. Fett Ind., 1914, 21, 1—3.

In addition to determinations of the alkali, rosin (free and combined) water and impurities, special tests are now required for the numerous substances added to commercial sizes. The older type of rosin size was completely soluble in alcohol, but the modern additions (glue, starch, dextrin, casein, gum, etc.) are insoluble. The insoluble residue should be tested for weighting materials (clay, barium sulphate, etc.), and the ash and nitrogen determined. If no nitrogen is present glue, albumin and casein are absent. Starch may be detected by the iodine reaction and separated almost quantitatively from dextrin and gum arabic by treatment with cold water. Lead acetate precipitates gum arabic from an aqueous solution, whilst dextrin remains in solution. They may also be distinguished by their different optical rotations. Viscose may be identified by being decomposed by dilute acid, with the liberation of hydrogen sulphide and separation of cellulose hydrate. Occasionally vegetable gum ("Pflanzen-schleim") is added to rosin size. In such cases the alcoholic precipitate is flocculent or in threads but is always transparent. The aqueous solution of this precipitate gives a gelatinous precipitate with lead acetate. The principal vegetable gums, including linseed gum and gum tragasol, also give insoluble precipitates with 5 per cent. tannin solution—in which respect they differ from gum arabic, which is also precipitated by lead acetate. If the alcoholic precipitate contains nitrogen, its behaviour towards water and acetic acid is ascertained. Animal glue is completely soluble in water, and the solution does not give a precipitate with acetic acid either in the cold or on heating—in contradistinction to the other nitrogenous products (casein, albumin). Ordinary animal glue contains about 18 per cent. of nitrogen, and about 0·2 to 0·25 per cent. of sulphur. When heated with alkaline lead oxide solution it does not yield a precipitate of lead sulphide, as is given by vegetable glue ("Pflanzenleim"), albumin and casein. With tannin it forms a sparingly soluble compound. Albumin (egg-albumin) is soluble in cold water, but is precipitated on heating or on the addition of acetic acid. Vegetable glue and casein are soluble as alkali compounds. These are decomposed by acetic acid with the precipitation of the protein. Casein is distinguished from the other proteins by containing about 0·8 per cent. of phosphorus and by being precipitated by rennet. For the detection of dextrin and gum arabic (which may be precipitated by alcohol with nitrogenous compounds) an excess of tannin is added to the aqueous solution and the liquid filtered. The filtrate is evaporated to dryness, and the residue taken up with a little water and again filtered. The new filtrate is treated with alcohol in excess, which keeps the tannin in solution and precipitates dextrin and gum arabic. This precipitate is dissolved in water and examined as described.
—C. A. M.

Behaviour of ultramarine in cement ware. Haerting. *See* IX.

Patents.

Oil paints; Process of manufacturing ——. H. Steinherz and F. von Schaller. Fr. Pat. 460,296, April 19, 1913.

Materials of colloidal structure (*e.g.* talc, asbestos, kaolin, etc.) are ground under pressure with driers and liquid "bakelites" until absorption and emulsification is complete. Coloured organic or inorganic pigments may be added to the mixture, and owing to the pressure obtaining in the mill or kneading machine, are perfectly incorporated.—C. A. M.

Turpentine and rosin; Process for extracting —— *from wood.* B. F. A. Saylor, Rome, Ga., Assignor to Standard Turpentine and Wood Pulp Co., Atlanta, Ga. U.S. Pat. 1,081,276, Dec. 9, 1913.

Finely divided resinous wood is placed in a closed cylinder which is then heated externally to about 212° F. (100° C.), the pressure in the cylinder being at the same time reduced to about 4 ins. of mercury. Dry caustic soda is then injected into the cylinder, and steam admitted under pressure. The steam is allowed to escape and carry off some of the turpentine and practically all air, until the pressure is reduced to about 20 lb. per sq. in., when the cylinder is closed. The cylinder is again heated externally, and steam is admitted from the bottom until 100 lb. pressure is attained; this pressure is maintained, by the further injection of steam, while steam is also allowed to escape, carrying with it more turpentine, until all the latter is recovered from the wood. The steam supply is now cut off, and the pressure allowed to fall. The turpentine product is ejected from the cylinder, on opening the latter, by the residual steam pressure, and the wood-pulp is finally removed from the cylinder.—E. W. L.

Resinous and wax-like condensation products and process of making same. British Thomson-Houston Co., Ltd., London. From General Electric Co., Schenectady, N.Y., U.S.A. Eng. Pat. 24,254, Oct. 23, 1912.

Resinous or wax-like substances are produced in two stages consisting in the interaction of a polyhydric alcohol —*e.g.* glycerol—with an amount of a polybasic acid or anhydride—such as phthalic anhydride, succinic, tartaric, glutaric, malic or camphoric acid—insufficient for complete esterification, and the subsequent interaction of the intermediate products with another acid such as those mentioned above, or propionic, stearic, palmitic, oleic, benzoic, lactic, salicylic, glycollic, chloroacetic, chlorobenzoic, or chloropropionic acid, or with a substance having certain acid properties *e.g.*, colophony. For example, 184 parts of glycerol and 296 parts of phthalic anhydride (equimolecular proportions) are heated at 200°—210° C. until gas bubbles cease to rise. To the somewhat thickened mass 118 parts of succinic acid are added and the mixture is heated at 210°—225° C. until it forms a jelly, or nearly so. The transparent mass becomes hard and brittle and free from bubbles on cooling; it is not fusible but becomes plastic on heating. It is apparently not identical with the product of the simultaneous action of phthalic anhydride and succinic acid on glycerol. When solid it may be powdered and moulded under pressure either with or without fillers. The moulded product may be rendered hard, tough and non-plastic under heat by heating for half-an-hour at 200°—210° C. The product obtained when succinic acid (236 parts) is employed in the first stage, and phthalic anhydride (148 parts) in the second, is slightly elastic when cold, but on heating, loses its flexibility and becomes a strong, tough, clear, solid mass, free from bubbles, infusible and insoluble. The product obtained when colophony (279 parts) is used in the second stage is a hard, reddish-brown resin, which is not the equivalent of a simple mixture of the phthalic resin and colophony. When stearic acid is used in the second stage the product is a soft waxy substance with good insulating properties, soluble in some heavy hydrocarbon oils. Lactic acid gives a very plastic product with a relatively low flow-point. The product from glycerol, phthalic anhydride, and monochloroacetic acid in equimolecular proportions has a flow-point of 64·5° C., is pliable and sticky. By increasing the anhydride to 1$\frac{3}{8}$ mol. and reducing the chloroacetic acid to $\frac{1}{4}$ mol. the flow-point is raised to 88° C. and the product is hard and brittle, becoming infusible when heated to 160° C. for 8 hours.—E. W. L.

Phenol and formaldehyde; Process for making an anhydrous reaction product of ——. F. G. Wiechmann, New York, Assignor to Fenoform Corporation, Hastings-upon-Hudson, N.Y. U.S. Pat. 1,080,188, Dec. 2, 1913.

A condensation product which is viscous and syrupy at ordinary temperatures, non-hygroscopic, insoluble in water, and showing no trace of water when tested with anhydrous copper sulphate, is obtained when 100 parts of crystallised carbolic acid are heated with from 10—35 parts of paraformaldehyde (or with formaldehyde), in the presence of a catalytic agent (*e.g.* dry ammonia).—E. W. L.

Condensation product of phenol and formaldehyde; Process of obtaining a ——. Stockhausen Kautschukwerke Ges. m. b. H. Fr. Pat. 460,675, July 23, 1913. Under Int. Conv., Jan. 7, and April 19, 1913.

Condensation products of phenol and formaldehyde are converted into plastic (and finally insoluble) masses by heating for a short time, while in a fluid or still fusible condition, with (say 50 to 100 per cent.) of a compound of a trivalent metal, such as iron chloride or aluminium chloride; sulphur, rubber, filling materials, etc., may be added before or after the addition of the iron chloride. The initial condensation product may be prepared by heating the phenol and formaldehyde in the presence of alkali until the liquid becomes turbid, when the mass is rapidly cooled. Products obtained as described may be used for the impregnation of paper, wood, cork, asbestos, wool, etc.—C. A. M.

Varnish. A. Kuegel, Jersey City, N.J. U.S. Pat. 1,080,461, Dec. 2, 1913.

A solution of a resinous substance in alcoholic ammonia. —E. W. L.

Cellulose nitrates; Process of manufacturing non-inflammable solutions of —— *preferably utilisable as lacquers.* Akt. Ges. für Anilin-Fabrikation. Fr. Pat. 461,034, Aug. 1, 1913. Under Int. Conv., Nov. 15, 1912.

A chloro-derivative of ethane or of ethylene (di-, tri-, or tetrachloroethylene or tetrachloroethane) is added in large proportion to a concentrated solution of cellulose nitrate in a suitable solvent.—C. A. M.

XIV.—INDIA-RUBBER; GUTTA-PERCHA.

Vulcanisation of rubber. F. Ahrens. Gummi-Zeit., 1913, **28**, 490—491.

The author examined old and new samples of a mixing of a low quality rubber. The old sample contained 9 per cent. of free sulphur (by acetone extraction), 13·6 per cent. of total sulphur, and 2·83 per cent. of combined sulphur. The new sample contained 7 per cent. of free, 15·8 per cent. of total, and 5·03 per cent. of combined sulphur. (The sulphur was estimated by a slight modification of the usual nitric acid method, in which the acid mixture, after oxidation, was diluted with water, neutralised by dilute caustic soda solution, then evaporated down and fused as usual.) Hence the combined sulphur in the old sample had actually diminished. This is not the case with samples of good quality, *e.g.*, Para rubber. The author remarks that vulcanisation must depend essentially on the colloidal structure of the rubber; he considers that coagulation from the latex is intimately connected with oxidation, and that further experiments are necessary on the parallelism between vulcanisation and oxidation.—H. E. P.

Patents.

Caoutchouc; Synthetic products resembling or related to ——. J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen-on-Rhine, Germany. Eng. Pat. 975, Jan. 13, 1913.

The synthetic products from butadiene and its homologues may be improved in quality by heating them alone under reduced pressure in an inert atmosphere, provision being made for the removal of volatile products. In some cases the simultaneous employment of nitrogen compounds, such as ammonia, methylamine, aniline, amino-acids, glue, and albumin, is very advantageous. —E. W. L.

Rubber; Process for preparing a product similar to soft ——. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 267,945, Dec. 25, 1912. Addition to Ger. Pat. 266,618.

To produce a product resembling soft rubber, the process described in the principal patent (see Eng. Pat. 11,530 of 1913; this J., 1913, 1078) is carried out at a lower temperature, or for a shorter period.—T. F. B.

India rubber; Coagulation and curing of ——. F. A. Byrne, Birmingham. Eng. Pat. 18,061, of 1913, date of appl., Oct. 30, 1912. (See this J., 1913, 98, 1163.)

The vapours obtained by heating formic acid may be employed for the coagulation and or curing of rubber. —E. W. L.

Raw rubber; Preparation of ——. F. Ripeau. Fr. Pat. 460,689, July 23, 1913.

Latex is distributed in successive layers over the surface of a horizontal revolving drum, which has been previously smoked, each layer of latex being smoked to induce coagulation before applying the next layer. The sheet of rubber is removed from the drum by a longitudinal cut. No pressure is applied to the sheet of rubber during the process.—E. W. L.

Gums [rubber, etc.]; Process and apparatus for extracting —— *from vegetable tissues containing them.* F. Kempler. Fr. Pat. 461,093, Aug. 4, 1913.

The bark, etc., containing rubber or allied gums is coarsely crushed by some method which does not overwork the particles of rubber, and is then fed into an apparatus consisting of a horizontal cylindrical casing, of which the lower half is perforated and acts as a screen, and in which revolves a friction roller. The whole is immersed in a tank in which water can be maintained at the desired level to enable the fine particles of crushed bark, etc., to be carried away through the screen, whilst the agglomerated rubber remains behind.—E. W. L.

Rubber and analogous substances; Vulcanisation of articles made of ——. V. Thomas. Fr. Pat. 460,780, July 26, 1913. Under Int. Conv., July 26, 1912.

Vulcanisation may be effected by the action of the chemically active light rays (*e.g.*, violet and ultra-violet rays from mercury vapour lamps) upon thin films of rubber mixings containing sulphur, or upon solutions of such mixings. The process may be used in combination with the ordinary process of hot vulcanisation, and may be carried out in an inert atmosphere in order to avoid the formation of ozone. A very thin film of Hevea plantation rubber mixed with 6 per cent. of sulphur, prepared by evaporating a 3 per cent. solution in benzine on a transparent quartz plate, was exposed on both sides to the rays from a Heraeus lamp run at 110 volts and 3·5 ampères and distant 13 cm. The rubber was covered with a layer of water to shield it from the heat of the lamp. 2·56 per cent. of combined sulphur was found in the exposed sample. A 3 per cent. solution of plantation rubber and sulphur in benzine exposed in thin layers to the rays from a quartz lamp run at 220 volts and 3 ampères, at a distance of 3—4 cm., vulcanised very rapidly, a rapid passage before the lamp, with a stream of water interposed to cut off heat, being sufficient to bring about the combination of sulphur to the extent of 1·5 to 2·5 per cent. The solution left on evaporation a residue of vulcanised rubber, insoluble in the ordinary rubber solvents.—E. W. L.

Rubber; Process for regenerating ——. C. Harries. Ger. Pat. 267,277, Nov. 28, 1912.

Solutions of rubber waste are treated with gaseous hydrogen chloride, bromide, or iodide, and the products, of the type, $C_{10}H_{16},2HCl$, are heated with bases, such as alkalis, ammonia, or amines; it is stated that rubber of good quality is regenerated by this process, whether from the waste of natural or artificial rubber goods.—T. F. B.

Vulcanisation of natural or artificial caoutchouc substances; Process for accelerating the ——. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 266,619, Dec. 25, 1912. Addition to Ger. Pat. 265,221.

In place of using piperidine or its homologues as described in the principal patent (see Eng. Pat. 11,530 of 1913; this J., 1913, 1078), derivatives of these bases may be used —T. F. B.

Plastic compositions. A. Oetker, Altona-Ottensen, Germany. Eng. Pat. 4663, Feb. 24, 1913.

A plastic composition for elastic padding, floor coverings, etc., consists of waste vulcanised rubber, in the form of small pieces or powder, agglomerated by a binding agent of gutta-percha and fatty matter or paraffin, to which caoutchouc or resin may be added.—H. E. P.

Rubber compositions. J. W. Aylsworth, East Orange, N.J., U.S.A. Eng. Pat. 8757, April 14, 1913. Under Int. Conv., April 18, 1912.

Rubber compositions, soft or hard, are made by vulcanising a mixture of rubber, chloronaphthalene (*e.g.*, liquid monochloronaphthalene or a solid chloronaphthalene) and vulcanising agent, which is preferably added after the previous ingredients have been mixed. Fillers may be added. Metal articles or fibrous materials may be coated with a film by covering them with a varnish made by using liquid monochloronaphthalene or a solvent such as acetylene tetrachloride with the ingredients mentioned above and then baking.—H. E. P.

Rubber; Manufacture of reinforced hard ——. J. T. Szek. Fr. Pat. 460,243, July 11, 1913. Under Int. Conv., Sept. 20, 1912.

In order to protect the fabric used in the production of ebonite "insertion" from the destructive action of moisture and high temperature in the presence of sulphur during vulcanisation, it is first impregnated with a solution of vulcanised asphaltum in carbon tetrachloride, benzene, etc., then dusted with finely divided quartzite, keiselguhr, glass powder, talc, or other similar substance before the rubber mixing is applied to it.—E. W. L.

Caoutchouc; Manufacture of compounds resembling or related to ——. J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. Eng. Pat. 12,980, June 4, 1913. Addition to Eng. Pat. 26,550, Nov. 19, 1912.

See Addition of June 7, 1913, to Fr. Pat. 459,005 of 1913; this J., 1913, 1164.—T. F. B.

Caoutchouc: Vulcanised —— *and process of making same.* F. Hofmann and K. Delbrück, Assignors to Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. U.S. Pat. 1,081,613, Dec. 16, 1913.

See Eng. Pat. 2312 of 1912; this J., 1912, 651.—T. F. B.

Caoutchouc substance and process of making same. F. Hofmann and K. Delbrück, Assignors to Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. U.S. Pat. 1,081,614, Dec. 16, 1913.

See Eng. Pat. 2313 of 1912; this J., 1912, 547.—T. F. B.

Vulcanised glycerol resin. W. C. Arsem, Schenectady. Assignor to General Electric Co., New York. U.S. Pat. 1,082,106, Dec. 23, 1913.

See Eng. Pat. 9985 of 1913; this J., 1913, 1023.—T. F. B.

Obtaining erythrene and other unsaturated compounds. Ger. Pats. 267,079 and 267,080. *See* XX.

XV.—LEATHER; BONE; HORN; GLUE.

Tans; Distinction of bark —— *from fruit and wood tans.* B. Kohnstein. Collegium, 1913, 645—648.

Aqueous or alcoholic extracts of the bark of the pine and other conifers and of willow bark when boiled with hydrochloric acid, cooled and shaken with ether give a green colouration when the ether solution is removed and shaken with ammonia. The reaction is not confined to these barks, but in most cases is masked by the production of phlobaphenes by the action of the hydrochloric acid. The test may also be carried out by placing a drop of the esterified tannin solution on a piece of solid caustic potash on a white tile. In both cases extracts of leaves and bark give a green colour while those of fruits and wood give a brown colour. A green colour is produced by galls, and young valonia gives an olive green colouration.—D. J. L.

Tanning materials; [Apparatus for] Determination of the ethyl acetate figure of ——. J. R. Blockey. Collegium, 1913, 634.

The apparatus consists of a modification of the Soxhlet extractor with an overflow tube at the side instead of the usual siphon tube. The extractor will hold 30 c.c. of liquid up to the level of the overflow tube and contains, inside, a small glass funnel the stem of which reaches to the bottom and is there bent round, or the end of the stem may be in the shape of a small bulb pierced with small holes. 25 c.c. of clear filtered liquor are placed in the extractor and extraction carried out in the usual manner with ethyl or amyl acetate. The condensed solvent flows down through the funnel, then rises through the liquor in small drops and returns to the distilling flask through the overflow tube. Extraction is complete in 3—4 hours. —D. J. L.

Tannin from Turkish and Chinese galls; Constitution of ——. K. Feist and H. Haun. Arch. Pharm., 1913, 251, 468—526.

The crystalline glucogallic acid obtained by Feist (see this J., 1912, 652) from Turkish galls was methylated by means of diazomethane. The methylated product was very resistant to boiling $N/1$ sulphuric acid, but readily hydrolysed by alkali, yielding trimethylgallic acid. As glucogallic acid contains no aldehyde group, the carboxyl group of the gallic acid residue must be combined with the glucose aldehyde group, the substance being thus a mono-galloylglucose. Tannins obtained from Turkish and Chinese galls were methylated by Herzig's method (see this J., 1909, 1051) and the methylated products shown not to be homogeneous, fractions of varying methoxyl content being obtained by treatment with absolute ether and absolute alcohol. The fractions obtained from methylated Turkish tannin showed a higher methoxyl content than the corresponding fractions from methylated Chinese tannin. The fraction insoluble in cold absolute alcohol, obtained from methylated Chinese tannin was found to be identical with Herzig's "methylotannin" (*loc. cit.*). The methoxyl content of this substance agreed with a compound of 1 mol. of glucose with 11 or 12 mols. of gallic acid, whilst the corresponding fraction from methylated Turkish tannin had a methoxyl content agreeing with 1 mol. of glucose to 1 to 3 mols. of gallic acid. The fraction soluble in cold absolute alcohol obtained from methylated Turkish tannin was not homogeneous but a mixture of mono-, di-, and tri-galloylglucose. Molecular weight determinations by the ebullioscopic method, using acetone as solvent, gave lower values for Turkish than for Chinese tannin. (See also this J., 1912, 1044; 1913, 36.)—T. C.

Pistachia atlantica, Desf., from Libia as a tanning material. F. Vignolo-Lutati. L'Ind. Chim., 1913, 13, 355—356.

The air-dried leaves of *Pistachia atlantica*, when examined by Procter's filter-bell method, gave 40·86 per cent. of soluble matter, of which 19·74 per cent. was absorbed by hide-powder, *i.e.*, a considerably greater proportion than that yielded by *P. lentiscus*, a common adulterant of sumach. The extract of *P. atlantica* was light-coloured and the tannin present gave the reactions of a pyrogallol-tannin, whereas that of *P. lentiscus* is a catechol-tannin. Having regard to the low cost of transport from Libya, it is suggested that it would be advantageous to try *P. atlantica* as a tanning material on a commercial scale in Italy.—A. S.

Water; Natural —— and the catalytic action of some colloidal substances at great dilution [in tanning and dyeing]. E. O. Sommerhoff. Collegium, 1913, 635—638.

If the calculated quantity of lime or soda be added to a natural water the precipitation of calcium carbonate is not nearly quantitative and the result will vary greatly according to the scale on which the experiment is performed. In a softened natural water of 3° of hardness, magnesium salts were still present and could not be quantitatively precipitated by sodium phosphate. The calcium and magnesium salts in natural water are probably present partly in a colloidal complex polymerised form, and thus do not take part in the usual ionic reactions. The presence of inorganic colloidal alkaline earth compounds in water used for silk dyeing and leather manufacture may produce good or bad results. Their influence is favourable in quickly coagulating the colloidal tanning matter in the hide and silk fibre during washing and results are obtained with natural water which can never be imitated by the addition of crystalline magnesium salts to soft water. The formation of colloidal calcium and magnesium salts is favoured by the presence of protective organic colloids such as humic acid. The catalytic action of these salts as oxygen carriers may become, under certain conditions, so strong as to result in local destruction or staining of the silk or hide so that some metallic salts which are quite harmless when present in crystalloidal form may have a very harmful effect when in the colloidal polymerised form. An instance is given of the occurrence of red stains in silk dyeing which were explained as due to a catalytic oxidation effect causing local decomposition of albumin. The colloidal metallic salts are very similar in their effects to bacteria. The author regards it as doubtful that salt stains are due entirely to bacteria. Investigation of the stains should be carried out on a practical scale as it is impossible to produce similar conditions in the laboratory.
—D. J. L.

Leather; Free sulphuric acid in ——. J. Paessler. Collegium, 1913, 648—649.

Leather tanned with the synthetic tanning material Neradol D gives erroneous results when tested for free sulphuric acid by the usual tests. The tanning material itself contains sulphur compounds which are taken up by the hide during tanning. Any method of estimating the free sulphuric acid involving the determination of the total sulphur in the leather must give too high results.
—D. J. L.

Leather; Free sulphuric acid in ——. W. Moeller. Collegium, 1913, 649—650.

Besides Neradol many other substances, when present in leather, give rise to erroneous results in the determination of free sulphuric acid by any of the methods previously proposed. Sody (Gerber Courier, 1913, No. 37) has shown that, in most cases, the high percentage of free sulphuric acid found in many samples of leather by the usual methods is not really present but is formed during the course of the analysis from sulphur present in the leather in other forms. The varying amount of the sulphur in the raw skin, the selenium in the water, sulphur-containing salts in the raw skin, sodium sulphide in the limes, sulphites, sulphates and bisulphites in the tanning extracts, sulphonated oils, sulphur dyestuffs, sulphite-cellulose extract, etc., may all contribute to the total sulphur in the leather.—D. J. L.

Patents.

Quebracho; Method of treating ——. J. M. Fiske, New York. U.S. Pat. 1,081,730, Dec. 16, 1913.

Solid extract of quebracho is immersed in water in a closed vessel, and the water is caused to circulate at a temperature not higher than 175° F. (79° C.). The water may be heated by steam. The solution and insoluble matter are drawn off separately.—H. E. P.

Tanning in one operation with mineral and vegetable products. W. A. Klipstein. Fr. Pat. 460,870, July 30, 1913.

Skins are tanned in a mixture of vegetable tanning agents, caustic soda and normal chromium sulphate or other alkalis and chromium salts. For example 70 parts by weight of solid quebracho extract, 8 parts of caustic soda, 75 parts of chromium sulphate and 15 parts of chromium oxide may be used.—D. J. L.

Leather; Treatment of —— for waterproofing and rendering it non-slipping. A. McLennan, Ross, Hereford. Eng. Pat. 21,081, Sept. 16, 1912.

The resistance to water of leather is increased by drumming, for 20 hides of average weight, with a solution of 6 oz. of celluloid dissolved in 5—6 pints of acetone, adding later, at suitable intervals, 10 oz. of gum juniper, 30 oz. of ether, 6 oz. of amber resin and 15 oz. of benzol. The treated leather has a much better grip on a damp or greasy surface than untreated leather. The process is preferably combined with a treatment with rubber solution.—D. J. L.

Leather; Drying japanned or varnished ——. A. Genthe, Worms a/R., Germany. Eng. Pat. 20,795, Sept. 15, 1913.

The ozone produced by mercury vapour lamps when used for the production of ultra-violet rays in the drying of japanned or varnished leather acts injuriously on the varnished surface. The method of removing ozone from the chamber by ventilation (see Eng. Pat. 10,971 of 1912; this J., 1912, 694) fails on moist summer days, but even in such cases, the injurious action of the ozone may be prevented by removing the aqueous vapour as far as possible from the air entering the chamber by suitable chilling.—D. J. L.

Bones; Preliminary treatment of —— for gelatin manufacture. H. Bunzel. Fr. Pat. 460,611, June 26, 1913. Under Int. Conv., Oct. 28, 1912.

The bones, after treatment with hydrochloric or other acids, are treated with a solution of peroxide or percarbonate of sodium or other alkali or alkaline-earth persalts. The process is much quicker than the usual treatment with lime water and a product of better colour is obtained.—D. J. L.

Leather and leather products; Manufacture of ——. W. Spalteholz, Leipzig, and K. Haring, Hersfeld, Germany. Eng. Pat. 28,392, Dec. 9, 1912.

See Ger. Pats. 258,992 and 258,993 of 1911; this J., 1913, 668.—T. F. B.

XVI.—SOILS; FERTILISERS.

Sodium sulphate; Effect of —— on the growth of plants. E. Haselhoff. Landw. Jahrb., 1913, 44, 641. Biedermann's Zentr., 1913, 42, 824—826.

The presence of sodium sulphate in the effluents from soda works, and in atmospheric dust in the neighbourhood of potash and other chemical works, has led the author to try its effect on plants when present in the soil and when dusted on to the leaves. The dust had an undoubted retarding effect on grasses, and soil cultures and water cultures showed in many cases a retarding effect on other plants with 0·5 grm. per litre. The results fluctuated considerably and the individuality of the plant had undoubtedly some effect.—W. H. P.

Nitrogenous fertilisers in U.S.A. J. W. Turrentine, U.S. Dept. of Agriculture. Bureau of Soils, Dec., 1913. [T.R.]

Of the 250,000,000 tons of sodium nitrate exported from Chile in 1911, the United States took 500,000 tons, of which some 70,000 tons were used in agriculture. Surveys of those parts of the U.S.A., the climate of which would permit of nitrate formation, has failed to reveal their presence in workable quantities. For the last five years the annual U.S. production of ammonium sulphate has ranged from 83,400 tons in 1908 to 155,000 tons in 1912. The world's production in 1911 was 1,187,000 tons. The only feasible development lies in the by-product oven. An oil shale from Montana is reported which yields 41·5 lb. ammonium sulphate and six gallons crude oil per short ton. During 1910, 13,531 tons of calcium nitrate were exported from Norway, and the total production was about 22,000 tons. In 1911, 2302 tons were imported into the U.S.A. In 1912 about 12,000 tons of cyanamide were produced at Niagara, 4000 at Nashville, and from 15,000 to 18,000 tons in Europe. Owing to recent additions, the Niagara Works of the American Cyanamid Co. should be able to put out at the rate of some 50,000 tons a year by the end of 1913. Tankage and dried blood contains from 5 to 8 per cent. of nitrogen and from 5 to 12 per cent. of phosphoric acid. Pure dried blood contains 14 per cent. of nitrogen, but as obtained on the market the content varies from 9 to 13 per cent. An ox in good condition yields 12 lb. of tankage and 7 lb. of dried blood; each calf, 2·4 lb. tankage and 0·75 lb. blood; each hog, 4·8 lb. tankage and 1·2 lb. blood; and each sheep, 1·2 lb. tankage and 0·5 blood. These figures do not include bone or concentrated tank water. Had all the materials derived from cattle of all kinds slaughtered in U.S.A. in 1912 been rendered available they would have produced 222,535 tons of tankage and 79,794 tons of dried blood. The present supply depends largely on the output of the large packing houses, for the work from the smaller ones is not so available, and there is little likelihood of much increase. Of the fertilisers used in U.S.A., 215,000 tons are ammonium sulphate, 70,000 tons sodium nitrate, 11,000 tons calcium cyanide, from 100,000 to 150,000 tons tankage, and 70,000 tons fish scrap.

XVII.—SUGARS; STARCHES; GUMS.

[Beetroot] Juice; Purification of —— [by alumina]. M. Lindner. Deutsch. Zuckerind., 1913, 38, 1136—1138.

On digesting beetroot pulp with a suspension of colloidal alumina at 45°—50° C., the juice obtained was only slightly turbid when cold and filtered quite clear. Experiments made on a larger scale with a glass diffusion apparatus gave equally favourable results, the alumina separating easily from the beetroot chips as a black mass. The alumina must be free from salts and ammonium compounds. 50 kilos. of chips required 1 kilo. of colloidal alumina, containing 12 per cent. Al_2O_3. Sugar boiled from the juice thus prepared, without the use of lime, gave the following results:—Polarisation, 98·00, ash, 0·33, water, 0·68, organic non-sugar, 0·99 per cent. The sugar dried easily in the centrifugal machine and, with slight steaming, yielded a product fit for direct consumption: polarisation, 99·80, ash, 0·003, water, 0·180, organic non-sugar, 0·017 per cent. The alumina did not produce the same purification with diffusion juice as when applied direct to the beetroot chips, the reason adduced being that the non-sugars of the beetroot have a labile structure which no longer exists when they are freed in the diffusion juice.

—L. J. de W.

Sucrose; Constants for use in the double polarisation method of determining ——. L. G. L. Steuerwald. Archief Suikerind. Nederl.-Indië, 1913, 21, 1383—1392.

Several investigators have observed when using the double polarisation (Clerget-Herzfeld) method of determining sucrose that the Herzfeld constants are not strictly accurate, a result higher than the truth being given, so that in the examination of raw beet sugars the presence of raffinose may be indicated, when the trisaccharide is absent (International Commission for Uniform Methods of Sugar Analysis, New York, 1912). The author has found the Herzfeld constant to give 0·2—0·3 per cent. more sucrose in the case of high-grade cane sugars than a constant specially determined by him. A new series of constants, the average of values determined at 28°—29° C. and at 20° C., and calculated to 0° C., has now been constructed by him (Table 1).

Table 1.

—J. P. O

Dextrose; Action of alkali and alkaline-earth cyanides on ——. E. Rupp and A. Hölzle. Arch. Pharm., 1913, 251, 553—556.

A mixture of dextrose and potassium cyanide (or barium cyanide) liberated ammonia even without the addition of caustic alkali. The potassium compound of the nitrile of heptagluconic acid was first formed as an additive compound and was converted first into the ammonium salt of heptagluconic acid, and then into the corresponding potassium salt with evolution of ammonia. The mechanism of the reaction was elucidated by determining quantitatively the amount of ammonia formed and the potassium content of the product and the isolation and identification of the anhydride of heptagluconic acid.—T. C.

Betaine hydrochloride from molasses residues ; Preparation of ——. H. Stoltzenberg. Zentralbl. Zuckerind., 1913, **22**, Nos. 4 and 5. Chem. Zentr., 1914, **1**, 22.

In the preparation of betaine from molasses residues (this J., 1912, 788 ; 1913, 301), the ethyl alcohol used need not be pure ; alcohol denatured with methyl alcohol is quite suitable. The method of Urban (this J., 1913, 440) is criticised, especially in regard to the quantity of hydrochloric acid, the use of animal charcoal, and omission of alcohol. The solubilities of betaine hydrochloride, glutamic acid hydrochloride, and potassium chloride in water are nearly equal, and only a mixture can be obtained by evaporation of an aqueous solution of these substances. —A. S.

Patent.

Starch ; Process for treating —— for the production of an adhesive particularly suitable for use as a size. W. J. Mellersh-Jackson, London. From Casein Co. of America, New York. Eng. Pat. 4203, Feb. 18, 1913.

See U.S. Pat. 1,053,719 of 1913 ; this J., 1913, 302.—T. F. B.

XVIII.—FERMENTATION INDUSTRIES.

Brewing barleys ; Direct determination of extract, as a factor in the valuation of ——. R. Seibriger. Woch. Brau., 1913, **30**, 649—650.

The protein-content of barley, valuable as a means of judging how the grain will behave on the malting floor, does not by itself constitute a trustworthy basis for the calculation of extract yield. Barleys of the same protein-content may differ by as much as 4·8 per cent. in their yield of extract. For the valuation of brewing barleys the author therefore recommends the direct determination of extract (see this J., 1910, 893 ; Woch. Brau., 1912, **29**, 297) besides that of moisture, proteins and germinative capacity. When malting is conducted under ordinary conditions there is a fairly constant difference (1—1·5) between the percentage extract of the barley (determined as above) and that of the malt (determined in fine grist by the Congress method) the latter value being the lower. Greater differences than this indicate unsatisfactory methods of malting, and the direct determination of extract in barley serves not only as a basis for the valuation of the grain itself, but, together with the determination of extract in the malt, as a control on the malting operations. Barleys containing less than 77 per cent. of extract (calculated on the dried substance) are as a rule not well suited for brewing.—J. H. L.

Malt ; Influence of dilution of the mash on the yield of extract found in the examination of —— by the Congress method. W. Windisch and W. Glaubitz. Woch. Brau., 1914, **31**, 1—4.

In the determination of extract in malt by the Congress method in use on the Continent, the extract-content of the filtered wort (about 8·5 per cent.) is found from its density by reference to Balling's table. The results obtained vary slightly according to the dilution of the mash, and these discrepancies depend to some extent on the character of the malt, but are smaller and more constant when instead of Balling's table, that of K. Windisch is used (cp. O. Saare, this J., 1902, 557). For example, if the mash is so diluted as to give a 12 per cent. instead of an 8·5 per cent. wort, the values found for the yield of extract in the malt are higher by 0·75—0·8 per cent. or 0·4 per cent., according as Balling's or K. Windisch's table is used. These differences are due mainly to the state of dilution of the wort and not to the amount of matter extracted from the malt. Similar discrepancies are encountered when a wort (or a pure sucrose solution) is diluted to different extents, and the extract-contents calculated from the degree of dilution are compared with those deduced from the actual densities by reference to Balling's table ; but if K. Windisch's table is used the discrepancies almost if not quite vanish. The authors recommend that in order to approach technical conditions as closely as possible, the Congress method of mashing should be so modified as to yield a wort of 11—12 per cent. extract, and also that Balling's table should be replaced either by that of K. Windisch (15° C.) or by that of Mohr (17·5° C.).—J. H. L.

Pyruvic acid, a product of the vital activity of yeast. A. Fernbach and M. Schoen. Comptes rend., 1913, **157**, 1478—1480.

The quantity of acid produced in yeast fermentations was considerably increased by adding calcium carbonate to the medium. Using a Champagne yeast in a sugar solution containing mineral salts and 1·5 grm. of peptone per litre, a quantity of calcium salts insoluble in alcohol (*i.e.* free from acetate) equivalent to 5·5 per cent. of the sugar fermented was obtained, whilst with the myco-yeast of Duclaux the yield rose to 25 per cent. Among the acids produced pyruvic acid was identified.—A. S.

Invertase ; Formation of ——. H. Euler and H. Cramér. Z. physiol. Chem., 1913, **88**, 430—444. (See also this J., 1912, 245, 654.)

The marked production of invertase which occurs when yeast is kept for some days in sugar solutions (see *loc. cit.*, and Meisenheimer and others, this J., 1913, 838) is not a consequence of increased general vitality of the cells, for it is sometimes accompanied by diminished fermentative activity. It takes place in solutions of sucrose, dextrose or mannose, but not in those of mannitol, sodium formate or sodium lactate ; yet the effect of sugar is somewhat increased by the presence of sodium lactate and diminished by sodium formate. The authors conclude that the formation of invertase requires conditions favourable to the production of protoplasm, and the energy required for both processes must be supplied by fermentation.—J. H. L.

Emulsin free from proteins ; Production of ——. K. Ohta. Biochem. Zeits., 1913, **58**, 329—338.

Commercial emulsin (Kahlbaum's) was digested with 1/10 of its weight of pancreatin and 100 parts of water rendered slightly ammoniacal, for 5—16 days at 37° C. in presence of toluene. The clear filtered solution was dialysed against water for 5—10 days and afterwards concentrated at a low temperature and mixed with several times its volume of alcohol. The precipitated enzyme, washed with alcohol and ether, and dried, amounted to only 2 per cent. of the original material. It still contained nitrogen but was free from proteins (biuret and triketohydrindene tests negative). It gave a positive pentose reaction, contained organically combined phosphorus, reduced Fehling's solution strongly after boiling with mineral acids but not at all before, and on incineration yielded an ash containing calcium and magnesium but no sulphates or chlorides. It hydrolysed amygdalin and salicin, the former more readily than did the commercial emulsin, and its activity remained unimpaired after six months.—J. H. L.

Lactic acid ; Determination of free and combined —— in wines. T. Roettgen. Z. Unters. Nahr. Genussm., 1913, **26**, 648—650.

For the determination of free lactic acid 50 c.c. of the wine (grape or fruit) are freed from volatile acids by distillation (200 c.c. of distillate), and the residue extracted for 24 hours with ether. The ethereal extract is mixed with 30 c.c. of water, the ether evaporated, and the aqueous residue treated with barium hydroxide solution in slight excess, and heated for 15 minutes on the water-bath. A current of carbon dioxide is now passed through the still alkaline liquid and the heating continued until the residue is concentrated to 10 c.c. It is then made up to 150 c.c.

by the addition of 40 c.c. of water and 100 c.c. of 95 per cent. alcohol, filtered, and 100 c.c. of the filtrate titrated with $N/4$ hydrochloric acid. Results thus obtained are in close agreement with those given by the more tedious methods of Kunz and Möslinger, which may however be used for the determination of the total lactic acid.
—C. A. M.

Spirits; Regulations of Dominion of New Zealand regarding methylation of ——. Board of Trade J., Jan. 8, 1914. [T.R.]

A Ministers' Order (No. 1058), dated 28th October last, prescribes regulations to be observed under Section 35 (10) of the Customs Law Act of 1908, for the manufacture, use, and sale of methylated spirits in the Dominion. The regulations provide, *inter alia*, that no spirits shall be methylated which are of a lower strength than 50 per cent. overproof, and that no wood naphtha or pyridine shall be used for the purpose of methylation which has not been approved by the Secretary of Customs. No wood naphtha will be approved which is of a less strength than 60 o.p. by Sikes' hydrometer, whilst pyridine must comply with certain prescribed tests. The regulations further specify the kinds of methylated spirit which may be manufactured for sale and used in certain industries.

Patents.

Wines and spirits, Ageing or maturing ——. J. Da V. Vianna, Lourenço Marques, Africa. Eng. Pat. 23,548, Oct. 17, 1913.

The wine, or spirit, is stored in closed casks and subjected to a continual rocking movement for some months at a temperature of about 110° F. (43° C.).—W. P. S.

Wine; Process of clarifying ——. A. Ornstein, Vienna. U.S. Pat. 1,081,623, Dec. 16, 1913.

See Eng. Pat. 4597 of 1913; this J., 1913, 548.—T. F. B.

XIXa.—FOODS.

Carabao's milk; Composition of ——. E. R. Dovey. Philippine J. Sci., 1913, **8**, 151—157.

Analyses of the milk from 19 different carabaos (a kind of buffalo) yielded the following results :—

	Minimum.	Maximum.	Average.
Sp. gr. at 17·5° C.	1·0307	1·0418	1·0364
	per cent.	per cent.	per cent.
Total solids	17·61	27·85	21·55
Fat	5·62	15·93	10·35
Solids-not-fat	9·92	14·22	11·20
Proteins (N × 6·25)	4·86	9·79	5·88
Lactose	3·50	5·32	4·32
Ash	0·71	0·95	0·84

The composition of the ash, etc., is also recorded. Determinations of the total solids and fat in the milk from a further 105 animals showed that the fat averaged 10·44 per cent. and the total solids 21·42 per cent. It is suggested that 8·5 per cent. of solids-not-fat and 8·0 per cent. of fat be adopted as minimum standards for the milk.—W. P. S.

Rennet; Conditions of activity of the enzyme of ——. L. Michaelis and A. Mendelssohn. Biochem. Zeits., 1913, **58**, 315—328.

The optimum concentration of hydrogen ions for the precipitation of casein by acids in pure solutions or in milk is $2{\cdot}5\times10^{-5}$. The presence of calcium salts displaces this optimum in the direction of greater acidity (*e.g.*, to 3×10^{-4} in $M/10$ solutions of calcium chloride) and renders it less definite. The optimum concentration of hydrogen ions for the precipitation of casein by rennet in presence of calcium salts lies between the values 4×10^{-7} and 1×10^{-6}. There is thus a zone of relative inactivity (10^{-6}—10^{-5}) between the optimum concentration of hydrogen ions for acid precipitation and that for precipitation by rennet. The action of rennet is therefore specific, and not simply a particular case of acid precipitation. The calcium ions necessary for the action of rennet cannot be replaced by hydrogen ions.—J. H. L.

Butter; Adulteration of —— by addition of cocoanut oil. [Presence of cocoanut oil in genuine butter.] R. Ledent. Bull. Soc. Chim. Belg., 1913, **27**, 325—330.

Certain of the constants of samples of butter, undoubtedly genuine and obtained from the milk of cows which had been fed on cocoanut oil cake, appear to indicate definitely the presence of cocoanut oil.—T. F. B.

Patents.

Flour; Milling of ——. H. Leetham and Sons, Ltd., and S. Leetham, York. Eng. Pats. 28,375, Dec. 9, 1912, and 6043, March 11, 1913.

Flour, at any point of the milling process, is subjected to the action of a spray of water charged with ozonised air. Ammonium carbonate or lime may be added to the water.—W. P. S.

Cattle foods; Manufacture of ——. J. J. Eastick and J. J. A. de Whalley, London. Eng. Pat. 29,648, Dec. 24, 1912.

Peat moss, either alone or mixed with from 0·5 to 5 per cent. of its weight of sulphurous acid, is heated in an autoclave to 160° C. for 30 minutes; the excess of acid is then removed or neutralised, and the product is dried, if desired. It may be used as a fodder directly, or may be ground to a meal, pressed into cakes, or mixed with other foodstuffs.—W. P. S.

Milk; Process of sterilising ——. C. E. Bonine, Philadelphia, Pa. U.S. Pat. 1,081,483, Dec. 16, 1913.

Milk is heated in a closed vessel under pressure to about 130° C.; the volume of the milk should be such as will occupy about 90 per cent. of the capacity of the vessel, and it is continually agitated while being heated and subsequently cooled.—W. P. S.

Butter suitable for long storage; Process of obtaining ——. G. Zmeskall. Fr. Pat. 460,525, July 19, 1913.

Fresh milk is heated to boiling and the "cream" which rises to the surface in the form of a skin is separated and churned into butter.—W. P. S.

Margarine suitable for cooking purposes; Process of manufacturing ——. P. A. Schmitt. Fr. Pat. 460,614, June 28, 1913. Under Int. Conv., June 28, 1912.

Ten parts of a mixture of alkali-casein solution (100), and egg albumin (20 parts) are incorporated with 90 parts of a mixture of vegetable fats and milk or water.
—W. P. S.

Alimentary substances; Process of preserving and sterilising ——. Ges. fur Sterilisation m. b. H. Fr. Pat. 460,912, July 31, 1913.

The substances are treated with an organic or mineral acid and a halogen. For instance, meat is treated with

0·3 per cent. of its weight of hydrochloric acid and 0·05 per cent. of bromine dissolved in alcohol; vinegar may be preserved by the addition (per 100 litres) of 6 grms. of bromine dissolved in 6 grms. of potassium bromide and 60 grms. of water. After 24 hours, the excess of the halogen is destroyed by the addition of a sulphite or thiosulphate, and the acid may be neutralised by means of an alkali carbonate or bicarbonate.—W. P. S.

Baking powder. C. H. Boehringer Sohn. Ger. Pat. 266,377, April 4, 1912.

An aluminium salt of lactic acid is mixed with an alkali or alkaline-earth carbonate or bicarbonate, particularly sodium bicarbonate. Baking powders prepared with normal or basic aluminium lactate are said to be stable. —T. F. B.

Flour; Processes and machines for treating ——. C. Herendeen, Chicago. Eng. Pat. 17,330, July 28, 1913.

See U.S. Pats. 1,073,985 and 1,073,986 of 1913; this J., 1913, 987.—T. F. B.

Condensation or concentration of milk and other liquids by filtration; Process for the ——. E. W. Kuhn, Brussels. Eng. Pat. 19,420 of 1913, date of appl., Sept. 9, 1912.

See Fr. Pat. 448,160 of 1912; this J., 1913, 445.—T. F. B.

Milk-separating machine; Centrifugal ——. S. C. Hauberg, Copenhagen. U.S. Pat. 1,081,304, Dec. 16, 1913.

See Eng. Pat. 19,154 of 1912; this J., 1913, 503.—T. F. B.

Alimentary products from soy-beans; Process of manufacturing ——. F. Gössel, Stockheim, Germany. U.S. Pat. 1,082,118, Dec. 23, 1913.

See Fr. Pat. 451,447 of 1912; this J., 1913, 621.—T. F. B.

XIXb.—WATER PURIFICATION; SANITATION.

Plumbo-solvent-water, Treatment of —— by means of mechanical filters. F. J. Dixon. Inst. of Water Engineers. Engineering, 1914, **97**, 55—56.

A description of the plant installed for the Ashton-under Lyne, Stalybridge, and Dukinfield (District) Water Works Joint Committee. The water comes mainly from peaty moorland gathering grounds; it is generally acid, discoloured, and contains low forms of animal and vegetable matter in suspension. It is purified by treatment with whiting (basic calcium carbonate) and aluminium sulphate and passage through mechanical filters. The latter consist of closed cylinders having a false bottom of steel which is riveted to the outer shell and pierced by holes into which phosphor-bronze nozzles are fixed from the underside. On the false bottom rests the filtering bed, 3·5 feet deep, of graded quartz crystals. A central vertical tube, extending nearly to the false bottom, contains a spindle to which propeller blades and two water-jets are attached for cleansing purposes. At the outlet end of the filter-house is a tintometer consisting of two glass tubes connected respectively with the raw water inlet pipe and the filtrate outlet pipe. According to an appendix to the paper, prepared by S. Delépine, the plumbo-solvent power of the water (grains of lead dissolved per gallon by the water in contact with new lead for 24 hours) has been reduced from 0·7 to 0·07 or less. Since Jan., 1913, there have been used 0·385 grain of lime and 0·320 grain of aluminium sulphate per gallon of water, the cost of chemicals per million gallons of water being, on the average, 1s. 11d., and the total cost of treatment 7s. 10d.—A. S.

Carbon monoxide; Laws of absorption of —— by blood in vitro. M. Nicloux. Comptes rend., 1913, **157** 1425—1428.

The displacement of oxygen from blood by carbon monoxide and inversely of carbon monoxide by oxygen may be expressed by the reversible equation:

$$HbO_2+CO\rightleftarrows HbCO+O_2,$$

where Hb represents hæmoglobin. Hence if blood be placed in contact with a mixture of the two gases, an equilibrium between the oxygen and carbon monoxide compounds, respectively of hæmoglobin should be established, depending upon the relative concentrations of the two gases in the plasma surrounding the blood corpuscles, which concentrations in turn would depend upon the partial pressures of the two gases in the gaseous mixture. Experiments with hog's blood saturated with carbon monoxide and with oxygen respectively and exposed to mixtures of carbon monoxide and oxygen or air showed that these views are correct. (In the case of air the partial pressures of the carbon monoxide and oxygen are calculated for a mixture of carbon monoxide and oxygen alone in the proportions present.) If the concentration of the carbon monoxide compound of hæmoglobin be termed y, and the percentage of carbon monoxide in the gas, x, then the concentration of the oxygen compound of hæmoglobin will be $100-y$ and of oxygen $100-x$, and the reaction constant

$$K=\frac{(100-y)\times x}{y\times(100-x)}$$

The mean value found experimentally for K was 0·0045. —A. S.

Lime, sulphur and salt wash; Composition of the ——. J. K. Haywood. J. Amer. Chem. Soc., 1905, **27**, 244—255.

Methods are suggested for the determination of sulphur in various states of combination when present in the same solution. Sulphide sulphur is determined by treating the solution with ammoniacal zinc chloride, heating, filtering, treating the precipitate with potassium hydroxide solution and hydrogen peroxide, and precipitating the sulphate by means of barium chloride. The first filtrate is neutralised with hydrochloric acid and titrated with sodium iodide, this furnishing a figure for sulphur as sulphite and thiosulphate. The residual liquid is now acidified and barium chloride added; this gives a measure of the sulphate and sulphite. Finally the sulphite-sulphur is determined from the acidity to sodium hydroxide of the solution remaining after the sodium iodide titration.—T. F. B.

Natural water and the catalytic action of some colloidal substances at great dilution [in tanning and dyeing]. Sommerhoff. *See* XV.

Gravimetric determination of nitrites. Busvold. *See* XXIII.

Patents.

Water, sewage and the like; Means [floating filter] for filtering ——. A. Mitchell, Longside, Aberdeenshire. Eng. Pat. 3751, May 21, 1913.

A floating vessel or pontoon is divided into three compartments by longitudinal partitions: the two outer compartments are enclosed and act as floats whilst the middle compartment contains the filtering material which is supported on a perforated false-bottom. The bottom of the pontoon under the middle compartment is provided with a number of openings for the admission of the liquid, and these openings are covered by transverse strips or bands of fabric which pass under the pontoon and are attached to drums on the upper parts of the latter. When the fabric over the openings becomes clogged, a fresh portion may be brought over the openings by rotating the drums. A rubber band, operated in the same manner may be employed for closing the openings when it is desired to cleanse the filter. The filter compartment is also divided into sections by transverse partitions, so that any section may be put out of use without interfering with the others, and each section is fitted with a separate outlet connected with a common discharge pipe.—W. P. S.

Sewage; Method of treating ——. A. Priestman, Philadelphia, Pa. U.S. Pat. 1,080,926, Dec. 9, 1913.

The sewage is delivered into a settling tank, the denser portion being discharged in small quantities at intervals from the bottom of the tank into a second tank and thence, subsequently, into a third tank. The discharge is controlled by the overflow of the liquid sewage from the first tank.—W. P. S.

Liquids; Purification of ——. R. H. McKee, Orono, Maine, U.S.A. Eng. Pat. 4139, Feb. 18, 1913. Under Int. Conv., March 27, 1912.

See Fr. Pat. 455,408 of 1913; this J., 1913, 954.—T. F. B.

Sewage and the like; Apparatus for purifying ——. P. Bunzel, Coethen, Germany. Eng. Pat. 17,304, July 28, 1913.

See U.S. Pat. 1,079,391 of 1913; this J., 1914, 39.—T. F. B

Water; Process for clarifying —— *and purifying it from germs.* R. Gans, Pankow, Assignor to J. D. Riedel A.-G., Berlin. U.S. Pat. 1,082,315, Dec. 23, 1913.

See Fr. Pat. 423,388 of 1910; this J., 1911, 645.—T. F. B.

XX.—ORGANIC PRODUCTS; MEDICINAL SUBSTANCES; ESSENTIAL OILS.

Alkaloids of the morphine group and phenanthrene; Absorption of ultra-violet rays by ——. M. Gompel and V. Henri. Comptes rend., 1913, **157**, 1422—1425.

A comparison of the absorption of ultra-violet rays by morphine, codeine, and apomorphine and by phenanthrene gave results in agreement with the view that these alkaloids are derivatives of phenanthrene. The absorption of the rays by apomorphine was much more intense than by morphine and more nearly approached that by phenanthrene. Morphine and codeine gave almost identical results, there being a single marked absorption band at $\lambda = 2850$; it is possible to determine spectrographically 0·1 mgrm. of either of these alkaloids in 1 c.c. to within 5 per cent. In the case of apomorphine there are three small absorption bands at $\lambda = 3200$, 3078 and 3026 respectively and a large absorption band at $\lambda = 2785$; 0·01 mgrm. of the alkaloid can be determined spectrographically. (See also this J., 1913, 671.)—A. S.

Brucine; Some new oxidation products of ——. H. Leuchs and H. Rauch. Ber., 1913, **46**, 3917—3922.

On oxidising brucine with an acetone solution of permanganate (see this J., 1914, 40) small quantities of certain non-acidic substances were formed in addition to dihydrobrucinone and brucinonic acid. The first substance had the composition, $C_{23}H_{24}O_7N_2$, and when dissolved in glacial acetic acid, it was optically inactive, but in hydrochloric acid it had $[\alpha]_D = +87{\cdot}4°$. It was insoluble in benzene and ether and sparingly soluble in chloroform, acetone, alcohol and ether. It melted at 336° C. with decomposition. The composition of the second substance was $C_{23}H_{26}O_7N_2$ It had $[\alpha]_D = +5{\cdot}66°$ in glacial acetic acid. It could be crystallised from water and melted at 240° C. Glacial acetic acid and chloroform dissolved the substance readily. The third substance had the composition, $C_{21}H_{22}O_6N_2$, and had $[\alpha]_D = +72{\cdot}8°$ in glacial acetic acid. After crystallising from water, it melted at 290° C. with decomposition. All these substances gave the brucine reaction with nitric acid.—F. Shdn.

Genisteine, a new volatile alkaloid. Valeur. J. Pharm. Chim., 1913, **8**, 573.

Genisteine, $C_{16}H_{28}N_2$, m.pt. 60·5° C., b.pt. 177°—178° C. (uncorr.) at 22 mm., was isolated from the mother-liquor from the crystallisation of commercial sparteine sulphate. It forms a hydrate, $C_{16}H_{28}N_2,H_2O$, which melts with loss of water at 117° C. The hydrate has the rotatory power $[\alpha]_D = -52{\cdot}34°$ in absolute alcohol (4 per cent. solution). The alkaloid is a saturated base, not reducing permanganate in acid solution, it does not contain a methoxyl group attached to a nitrogen atom. It is a di-acid base (mono-acid to phenolphthalein), yielding a picrate, $C_{16}H_{28}N_2$, $2C_6H_2(OH)(NO_2)_3$, m.pt. 215° C., with decomposition, and a platinichloride, $C_{16}H_{28}N_2.2HCl.PtCl_4 + 2{\cdot}5H_2O$, which loses its water at 110° C. and decomposes at 235° C. without melting. —A. S.

"Rhein cryst."; Commercial ——. O. A. Oesterle and E. R. Haugseth. Arch. Pharm., 1913, **251**, 550—552.

In commerce "*Rhein cryst.*" is regarded as synonymous with "*Acid. chrysophanic. ver.*" Three samples obtained from different sources were found to be identical in composition. They consisted of almost pure chrysophanic acid and contained no rhein (1.8-dihydroxyanthraquinone-3-carboxylic acid) and no emodin monomethylether. It is recommended that the name rhein should be reserved for 1.8-dihydroxyanthraquinone-3-carboxylic acid.—T. C.

Perfumes of lichens. E. M. Holmes. Perfum. and Essent. Oil Record, 1913, **4**, 408—409.

Attention is drawn to the need of investigation of the odorous principles of lichens, with a view to using them in perfumery. As a basis for retaining odours in *pot pourri* and sachets, the common reindeer lichens, *Cladonia rangiferin* and *C. sylvatica*, appear very suitable. The tree lichen, *Evernia prunastri*, known in France as *Mousse de chêne* (oak moss), has been used for some years as a basis for perfumes. It is generally found admixed with other less fragrant lichens, but may be readily distinguished by the frond being grey on the outside and white on the under or channelled side. According to Gattefossé the odorous principle is a phenol, *lichenol*, isomeric with carvacrol, and soluble in a 3 per cent. solution of sodium carbonate; and a suitable basis for perfumes is obtained by extracting the lichen with a volatile solvent, and distilling the extract *in vacuo*. Other fragrant lichens mentioned are *Lobaria pulmonaria* ("oaklungs." *mousse de la base du chêne*), *Conocephalu-conicus* (having a bergamot odour), *Hygrophorus agathosmu* and *Clitocybeodora* (having an odour of aniseed).—A. S.

Mosses in perfumery; Use of ——. H. Mann. Amer Perfumer and Essent. Oil Rev., 1913, **8**, 248—249.

At the present time oak moss (*Lichen Quercius viridis* known in France as "Mousse de chêne" is almost univer sally used in perfumery. It is usually extracted wit light petroleum, and the residue obtained is dilute with about 200 times its weight of alcohol. In some case an alcoholic infusion of the dry moss is made. This ca be used as a base for fine perfumes and for toilet soap The moss residues are sometimes incorporated with th latter where special mechanical cleansing properties a desired.—F. Shdn.

Essential oils; Constituents of ——. The sesquiterpene fraction of Java citronella oil. F. W. Semmler and K. E. Spornitz. Ber., 1913, **46**, 4025—4029.

A fraction of Java citronella oil containing sesquiterpene was washed repeatedly with 60 and 70 per cent. alcohol. It then boiled at 153°—156° C. at 15 mm., had the sp. gr. 0·8659 at 20° C. and n_D = 1·50386. The fraction consisted of a mixture of sesquiterpene and sesquiterpene alcohol. After distilling over sodium, and again fractionating, sesquicitronellene, $C_{15}H_{24}$, was separated. The characters were, b. pt. 138°—140° C. at 9 mm., sp. gr. 0·8489 at 20° C., n_D = 1·53252, $\alpha_D = +0° 36'$. This substance was reduced by means of sodium and alcohol to dihydrosesquicitronellene, $C_{15}H_{26}$, b. pt. 131°—133° C. at 12 mm., sp. gr. 0·8316 at 20° C., n_D = 1·4800 and $\alpha_D = \pm 0°$. Reduction in ethereal solution with platinum and hydrogen led to the formation of octohydrosesquicitronellene, b. pt. 115°—117° C. at 9 mm., sp. gr. 0·7789 at 20° C., n_D = 1·43518, $\alpha_D = \pm 0°$. The sesquiterpene was inverted to *cyclo*-sesquicitronellene by means of concentrated formic acid. The substance then boiled at 129°—132° C. at 15 mm., had the sp. gr. 0·8892 at 20° C., n_D = 1·5069, $\alpha_D = +56°$ and could not be reduced by means of sodium and alcohol. The original oil contained a small quantity of a paraffin boiling at 165°—167° C. at 15 mm.—F. Shdn.

Patchouli oil. M. Lehmann. Chem.-Zeit., 1913, **37**, 1589.

Oils distilled during the last six months have shown a much lower sp. gr. (0·95 to 0·96), optical rotation (—42° to —59° C.), and solubility in alcohol (6 vols. of 90 per cent. alcohol for clear solution) than the oils of previous years. The aroma of the recent oils is superior, and the alteration in the properties is to be attributed to climatic conditions during the growth of the plants. The following limits are suggested for the constants of this year's patchouli oil:—Sp. gr. 0·95 to 0·97: optical rotation, —40° to —59°; refractive index, 1·504 to 1·515; saponification value, 4 to 18; saponif. value of acetylated oil, 35 to 80; soluble at first in equal vol. of 90 per cent. alcohol. After the addition of 2 to 5 vols. the solution becomes turbid, but should become permanently clear again after the addition of 6 vols.—C. A. M.

Calamus oil; Constituents of ——. H. Thoms and R. Beckstroem. Ber., 1913, **46**, 3946—3948.

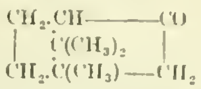
A fraction of terpene-free calamus oil of Japanese origin gave results different from those of Semmler and Spornitz (this J., 1914, 40). The oil contained a little calameone and about 66 per cent. of asarone. A fraction of the composition, $C_{15}H_{24}O$, was treated with cold concentrated arsenious acid solution and washed. The residue consisted of a hydrocarbon, $C_{15}H_{22}$, which had the characters, b. pt. 146° C. at 19 mm., sp. gr. 0·9330 at 18° C., α_D = +6·5° at 18° C. in a 2 cm. tube. The hydrocarbon was present as such in the original oil, and was not produced by the dehydration of an alcohol.—F. Shdn.

Mastiche [Pistachia lentiscus] leaf oil. Vimard, Dhumez and Monschein. Perfum. and Essent. Oil Rec., 1913, 4, 403.

The oil had the sp. gr. 0·887, optical rotation +3°, esters 5·8 per cent., total acetylisable constituents 13·5 per cent. It did not distil below 160° C., but yielded 20 per cent. below 170° C., 50 below 180° C., 58 below 190° C., 66 below 200° C., 74 below 210° C., and 78 per cent. below 220° C. When distilled under reduced pressure and collected in four fractions of 20 per cent. and then one of 15 per cent., the sp. gr. of the fractions increased from 0·855 to 0·925 and the refractive index from 1·4680 to ·4795, whilst the optical rotation fell from +11° to nil. The first two fractions contained pinene. The oil had a eculiar odour somewhat resembling that of rue and savin ils.—A. S.

l-Epicamphor (l-β-camphor). J. Bredt and W. H. Perkin, jun. Chem. Soc. Trans., 1913, **103**, 2182—2225.

Epicamphor,



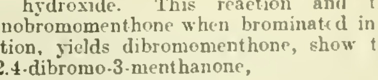
was prepared independently by Lankshear and W. H. Perkin (Chem. Soc. Proc., 1911, **27**, 167) and by Bredt and his co-workers (Chem.-Zeit., 1911, **35**, 765). The product obtained by Wagner (Chem.-Zeit., 1903, **27**, 271; Ber., 1903, **36**, 4602) and described as epicamphor was apparently a mixture consisting largely of impure camphor. A better method for the preparation of epicamphor than those referred to above consists in treating methyl-*d*-bornylene-3-carboxylic acid with hydroxylamine in the presence of sodium methoxide, whereby *d*-bornylene-3-hydroxamic acid, $C_8H_{14}<\genfrac{}{}{0pt}{}{C.C(OH):N.OH}{\ddot{C}H}$ is produced almost quantitatively and this acid readily yields epicamphor under a variety of conditions. Preferably the reaction mixture, without isolating the acid, is shaken continuously for 12 hours with *p*-toluene sulphonyl chloride, whereby molecular rearrangement takes place with formation of bornylene-3-isocyanate, and the latter is extracted with ether and converted into epicamphor by distillation with steam in presence of hydrochloric acid. Epicamphor has an odour very similar to, but distinct from, that of ordinary camphor; it melts at 182° and distils at 213° C. and its optical rotation (in benzene solution at a concentration of 13·1205) is $\alpha_D^{18} = -58·21°$: its oxime (α_D = +100·5° for a benzene solution containing 0·6293 grm. per 10 c.c.) melts at 103°—104° C. and its semicarbazone at 237°—238° C. On oxidation it yields *d*-camphoric acid, whilst when reduced with sodium in boiling alcoholic solution it yields *l*-epiborneol, m. pt. 181°—182·5° C. Physiological experiments carried out by Van der Velden and Leyden showed that epicamphor has a much less pronounced and less persistent action than camphor on the beat of the heart: the action of camphor is toxic at the concentration necessary for favourable action in the case of epicamphor.—A. S.

Dibromomenthone; Structure of ——, and a new synthesis of buchu camphor [diosphenol]. G. Cusmano. Atti R. Accad. dei Lincei, Roma, 1913, **22**, II., 569—575.

Dibromomenthone, m. pt. 78°—80° C., which can be readily obtained, in good yield, by the action of bromine vapour mixed with air, on menthone, is converted into buchu camphor (diosphenol),

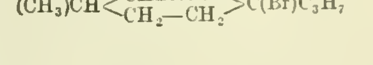
$$(CH_3)CH<\genfrac{}{}{0pt}{}{CH(OH).CO}{CH_2—CH_2}>CH.C_3H_7$$

when treated with a 2·5 per cent. aqueous solution of potassium hydroxide. This reaction and the fact that 4-monobromomenthone when brominated in chloroform solution, yields dibromomenthone, show that the latter is 2.4-dibromo-3-menthanone,



$$(CH_3)CH<\genfrac{}{}{0pt}{}{CHBr.CO}{CH_2—CH_2}>C(Br)C_3H_7$$

and not



$$CH_3(Br)C<\genfrac{}{}{0pt}{}{CH_2.CO}{CH_2.CH_2}>C(Br)C_3H_7$$

as stated by Beckmann and Eickelberg (this J., 1896, 470). The semicarbazone of buchu camphor melts, with decomposition, at 219°—220° C.—A. S.

Sylvestrene; Synthesis of d- and l- ——. W. N. Haworth and W. H. Perkin, jun. Chem. Soc. Trans., 1913, **103**, 2225—2237.

The acid obtained by the elimination of hydrogen bromide from 1-bromo-1-methylcyclohexane-3-carboxylic acid in the course of the synthesis of carvestrene (*dl*-sylvestrene), and supposed to be 1-methyl-Δ^1-cyclohexene-3-carboxylic acid, is now shown to consist of a mixture of this acid with the isomeric 1-methyl-Δ^6-cyclohexene-3-carboxylic acid. By the resolution of this *dl*-mixture of acids by means of brucine and *l*-menthylamine, there were obtained finally the dextro Δ^6-acid ($\alpha_D = +108°$) and the lævo-Δ^1-acid ($\alpha_D = -49{\cdot}7°$), and from these, by methods similar to those used in the synthesis of carvestrene (*loc. cit.*), *d*-sylvestrene (the terpene of Swedish oil of turpentine), b. pt. 174°—176° C., sp. gr. 0·8485 at 18° C., $n_D = 1{\cdot}4752$, $\alpha_D = +67{\cdot}5°$, and *l*-sylvestrene, b. pt. 175°—178° C., $\alpha_D = -66{\cdot}5°$, were prepared. *l*-Sylvestrene was also synthesised from *l*-1-methyl-Δ^9-cyclohexene-3-carboxylic acid obtained by the resolution of *dl*-acid (see Fisher and Perkin, Chem. Soc. Trans., 1908, **93**, 1878): the specimen thus obtained had the b. pt. 176°—178° C., sp. gr. 0·848 at 19° C., $n_D = 1{\cdot}4761$, $\alpha_D = -68{\cdot}2°$. A mixture of equal quantities of *d*- and *l*-sylvestrene dihydrochlorides when recrystallised from methyl alcohol yielded carvestrene dihydrochloride. (See also this J., 1913, 766.)—A. S.

Geranyl chloride. M. O. Forster and D. Cardwell. Chem. Soc. Trans., 1913, **103**, 1338—1346.

GERANYL chloride, $C_{10}H_{17}Cl$, prepared by the action of thionyl chloride on a mixture of geraniol and pyridine, was a colourless liquid with a marked odour of hops, b. pt. 103° C. at 14 mm., sp. gr. 0·918 at 25° C., $n_D = 1{\cdot}4741$. The same product was obtained in a similar manner from linalool, and it is probably identical with the linalyl chloride of Dupont and Labaune (this J., 1910, 716, 1132). The chloride gave a nitrosate, $C_{10}H_{17}O_4N_2Cl$, m.pt. 101° C., which proved a convenient means of identifying it. On treatment with ethyl sodioacetoacetate, it yielded ethyl geranylacetoacetate, identical with the ester prepared by Dupont and Labaune from linalyl bromide. This ester when boiled with alcoholic baryta and the product treated with hydrochloric acid, yielded geranylacetone (dihydro-ψ-ionone), identical with the ketone prepared by Kerschbaum (this J., 1913, 711) from the nitrile of farnesinic acid, and proved by the work of Harries and Haarmann (this J., 1913, 711) on farnesol, to have the constitution, $CH_3.C(CH_3):CH.(CH_2)_2.C(CH_3):CH.(CH_2)_2.CO.CH_3$. The production of this ketone proves that the compounds prepared by the authors contain the geranyl and not the linalyl radical, and hence that when linalool is converted into a chloride, the latter contains the geranyl radical. Besides the compounds mentioned, ethyl geranyl ether, geranylamine, ethyl geranyl malonate, geranylacetic acid, and a hydrocarbon, $C_{10}H_{18}$ (b. pt. 161° C. at 763 mm., 65° C. at 20 mm., sp. gr. 0·768 at 25° C., $n_D = 1{\cdot}4458$, were also prepared, the last-named by the action of zinc dust and acetic acid on geranyl chloride.—A. S.

Oleanol; Derivatives of ——. F. Tutin and W. J. S. Naunton. Chem. Soc. Trans., 1913, **103**, 2050—2060.

OXIDATION of the crystalline compound oleanol, $C_{31}H_{50}O_3$, from olive leaves (this J., 1908, 641) by means of potassium permanganate yielded a dihydroxy compound, $C_{29}H_{46}O_4$, which contained a carbonyl group, and was termed *oleanone*. It yielded mono- and diacetyl derivatives. On heating oleanone with glacial acetic acid and diluting the mixture with water, a pink colouration changing to green and then to fugitive violet was obtained, the changes of colour closely resembling those given by a phytosterol when treated with sulphuric acid and acetic anhydride. In this reaction of oleanone an acetyl derivative was formed, and this on hydrolysis gave the corresponding alcohol, $C_{50}H_{76}O_5(OH)_2$. An analogous reaction occurred when diacetyloleanone was heated with acetic acid containing hydrochloric acid, the mono-acetyl derivative, $C_{50}H_{76}O_7(CO.CH_3)_2$, being formed. Oxidation of oleanone with chromic acid gave a compound, $C_{29}H_{42}O_4$ (m. p. 275° C.), which yielded only a mono-acetyl derivative. A mixture of carboxylic acids was also produced in the chromic acid oxidation.—C. A. M.

Yatrene. O. Anselmino. Apoth.-Zeit., 1914, **29**, 10—11.

YATRENE was found to be a mixture of 8-hydroxy-7-iodoquinoline-5-sulphonic acid with aboot 20 per cent. of sodium bicarbonate.—F. SHDN.

Acetylation of organic compounds. E. Knoevenagel. Annalen, 1914, **402**, 111—148.

THE acetylation of hydroxyl groups with acetic anhydride can be accelerated and often carried out almost quantitatively at ordinary temperatures by the addition of 1 to 5 per cent. of certain substances (ferric, zinc and stannous chlorides, phosphorus trichloride, sulphuric acid, copper sulphate, ammonium sulphate, etc.) which behave, not as dehydrating agents, but in some unexplained way as catalysts. Substances containing carbonyl oxygen, and ethereal or anhydride-like bodies such as ethers, polysaccharides, celluloses and starches, and oxygen ring compounds as epichlorhydrin, cineol, etc., can also by the breaking of an oxygen linkage be similarly converted into diacetates (called "acetolysis" in contradistinction to hydrolysis). The catalysts appear to be specific in their action, so that by using a suitably selected catalyst with, for example, cellulose it may be possible either to acetylate hydroxyl groups, or split the molecule by acetolysis at specific positions favourable for attack by the catalyst employed. The acetylation of a number of different types of substances has been studied in detail using the catalysts mentioned above. All except ammonium sulphate convert aldehydes into diacetates. Quinone and unsaturated ketones react best in presence of ferric chloride. Diethyl ether and three-membered oxygen carbon rings react only with ferric chloride, the former at 100° C., the latter at the ordinary temperature. In contrast to this, six-membered rings, such as cineol, readily yield acetates, in presence of nearly all the catalysts, by the splitting of the ring at the oxygen atom. Salicylic aldehyde with acetic anhydride and phosphorus trichloride, copper sulphate or zinc sulphate, was converted into disalicylic aldehyde, whilst the other catalysts yielded mainly the triacetate.—G. F. M.

Hydroxy-acids; Decomposition of —— *with soda-lime.* L. Carpenter. Chem. News, 1914, **109**, 5.

MIXTURES of sodium lactate and sodium citrate respectively with soda-lime when destructively distilled under reduced pressure in an iron tube heated to just below redness, yielded mainly acetone and mesityl oxide, $(CH_3)_2.C:CH.CO.CH_3$.—A. S.

PATENTS.

Diaryl ethers; Process for the formation of ——. F. Fritzsche und Co., Hamburg, Germany. Eng. Pat. 9797, April 25, 1913. Under Int. Conv., June 29, 1912.

A SOLUTION of dry alkali phenolate (phenoxide) in excess of the corresponding phenol is heated to about 200° C. under pressure with monohalogen substitution products of aromatic hydrocarbons. Phenyl ether can be prepared in this way from potassium phenoxide and chlorobenzene. —F. SHDN.

Emetine; Manufacture of ——. H. S. Wellcome, London, F. H. Carr and F. L. Pyman, Dartford. Eng. Pat. 14,677, June 25, 1913.

EMETINE can be prepared by suitably methylating cephaeline, for instance, by boiling the latter with sodium methylate (methoxide) and methyl sulphate in methyl alcoholic solution.—F. SHDN.

Arsenic antimony compounds; Manufacture of ——. Farbwerke vorm. Meister, Lucius, und Brüning, Höchst on Maine, Germany. Eng. Pat. 19,778, Sept. 1, 1913 Under Int. Conv., Oct. 4, 1912.

THE method of manufacture of aromatic arseno-compound described in Eng. Pat. 11,709 of 1911 (this J., 1912, 256

can be modified by using an antimony compound in place of one of the arsinic acids or one of the arsenoxides. In this way, arsenic-antimony compounds are produced.
—F. Shdn.

Chemical process [preparation of diacetone-alcohol]. A. Hoffman, Brooklyn, Assignor to Alco Deo Co. U.S. Pat. 1,082,424, Dec. 23, 1913.

A liquid containing a "comparatively large percentage" of acetone is heated to a temperature below 150° C. but sufficiently high to evolve acetone vapour; the vapours are condensed and allowed to pass through a granular mass of calcium hydroxide or other sparingly soluble catalyst heated to a high temperature, whereby a small percentage of the acetone is converted into diacetone-alcohol. The liquid thus obtained is added to a quantity of previously distilled liquid, the mixture is distilled to remove some of the acetone and to produce a more concentrated solution of the alcohol, and the acetone evolved is again submitted to the action of the catalyst.—T. F. B.

Erythrene and other unsaturated compounds; Process for obtaining ——. A. Gerlach and R. Koetschau. Ger. Pats. 267,079 and 267,080, Sept. 24 and 26, 1912.

(1) Oleic acid, or oils, fats, or waxes containing acids of the oleic series or compounds thereof, are heated by means of electrically heated wires, etc., in an apparatus, the walls of which are kept at a temperature about the boiling-point of the mass. An agent which facilitates decompostion may be added. The erythrene and other unsaturated compounds are separated from the products of the reaction by physical or chemical methods. (2) In the above process, the oleic acid may be replaced by wool-grease or other substances containing cholesterol. It is advisable that the wool grease be free from water. By this process it is possible to obtain a yield of 50 per cent. of product boiling below 200° C. Free cholesterol, or analogous substances such as phytosterol, are said to give similar results.—T. F. B.

2-Phenylquinoline-4-carboxylic acid and its homologues; Process for preparing esters of ——. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 267,209, Nov. 3, 1912.

The acetol esters of 2-phenylquinoline-4-carboxylic acid or its homologues are obtained by treating the acids with halogen derivatives of acetone. The physiological effects of the esters resemble those of the free acids, but the esters are tasteless.—T. F. B.

Amino- and diaminoketones; Process for preparing aliphatic ——. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 267,347, Nov. 8, 1912. Addition to Ger. Pat. 254,714 (see this J., 1913, 380).

The reactions described in the principal patent and also in Eng. Pat. 14,231 of 1913 (see this J., 1913, 1128) can be carried out in presence of solvents not miscible with water, and also of inorganic or organic salts, preferably under pressure. It is said that by appyling this modification to the condensation of acetone or its homologues with ialkylamino-oxymethanes or with tetra-alkyldiaminomethanes, the formation of by-products is prevented to a large extent, and the reaction is very complete.—T. F. B.

arbohydrate phosphoric acid esters; Process for forming ——. S. Carlson, Nadhammar, Sweden. Eng. Pat. 11,653, May 19, 1913. Under Int. Conv., May 20, 1912.

ee Fr. Pat. 458,096 of 1913; this J., 1913, 1031.—T. F. B.

zonides; Gaseous —— and their production. W. J. Knox, New York, Assignor to Knox Terpezone Co. of America. U.S. Pat. 1,081,617, Dec. 16, 1913.

e Eng. Pat. 27,371 of 1912; this J., 1913, 924.—T. F. B.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

Patent.

Colour-screens [for colour photography], Process for the manufacture of ——. C. Späth, Steglitz, Germany, Assignor to Eastman Kodak Co., Rochester, N.Y. U.S. Pat. 1,081,341, Dec. 16, 1913.

See Eng. Pat. 23,138 of 1910; this J., 1911, 109.—T. F. B.

XXII.—EXPLOSIVES; MATCHES.

Explosives; Composition of newly permitted ——. Chem. Trade J., Dec. 27, 1913. [T.R.]

An Order, No. 1217, of November 25, 1913, authorising additions to the permitted list of explosives to be used in coal mines, has been made by the Home Secretary under Section 61 of the Coal Mines Act. The composition of these new explosives as given in the Order is as follows:—

Ingredients.	Parts by weight.	
	Not more than	Not less than
Ammonite No. 3 (Miners' Safety Explosive Company, Ltd.)—		
Nitrate of ammonium	72	68
Nitrate of sodium	23	21
Tri-nitro-naphthalene	4	3
Chloride of ammonium	4·5	3·5
Moisture	1	—
Expedite (Explosives and Chemical Products, Ltd.)—		
Nitrate of ammonium	36	33
Nitrate of potassium	34	32
Chloride of ammonium	21	19
Tri-nitro-toluol	13	11
Moisture	1·5	—
Negro Powder No. 2 (Roburite and Ammonal, Ltd.)—		
Nitrate of ammonium	58	55
Chloride of sodium	29	26
Tri-nitro-toluol	16	14
Graphite	1	0·5
Colouring matter	0·1	—
Moisture	1	—
New Fortex (Explosives and Chemical Products, Ltd.)—		
Nitrate of ammonium	36	33
Nitrate of potassium	34	32
Amido compound	13	11
Chloride of ammonium	21	19
Moisture	1·5	—
Permon Powder (Carbonite Syndicate, Ltd.)—		
Nitro-glycerine	13	11
Collodion cotton	0·5	0·2
Glycerine	5	3
Flour of potatoes (dried at 100° C.)	10·5	8·5
Nitrate of ammonium	57	54
Nitrate of sodium	1·5	0·5
Chloride of sodium	18	16
Moisture	3	—
Pitsea Powder, No. 2 (British Explosives Syndicate, Ltd.)—		
Nitro-glycerine	7	6
Nitrate of ammonium	56·5	53·5
Nitrate of potassium	11	9
Woodmeal (dried at 100° C.)	10	8
Oxalate of ammonium	19·5	17·5
Moisture	2	—
Sheppey Powder (Cotton Powder Company, Ltd.)—		
Nitro-glycerine	28	26
Nitrate of potassium	32	30
Woodmeal (dried at 100° C.)	33	30
Oxalate of ammonium	7	5
Moisture	6	3
Sunderite (Nobel's Explosives Company, Ltd.)—		
Nitro-glycerine	10	8
Nitrate of ammonium	54·5	50·5
Perchlorate of potassium	10	8
Woodmeal (dried at 100° C.)	9	7
Oxalate of ammonium	21	19
Moisture	2	—

The usual stipulations are made in each case as to markings, quality, etc.

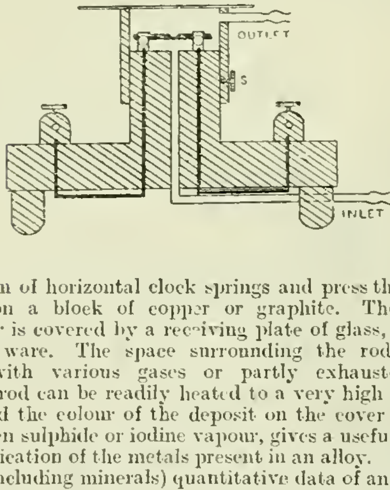
PATENT.

Preparation of alkaline oils [for protecting ordnance from the effects of smokeless powder]. Fr. Pat. 460,419. *See* XII.

XXIII.—ANALYTICAL PROCESSES.

Electric micro-furnace; Fractionation of alloys and minerals in the ——. A. L. Fletcher. Chem. Soc. Trans., 1913, **103**, 2097—2108.

THE furnace (see fig.) consists of a brass drum sliding on a solid slate cylinder of 5—8 cm. diameter which bears a pair of terminals for a carbon rod. The terminals take the form of horizontal clock springs and press the carbon down on a block of copper or graphite. The sliding cylinder is covered by a receiving plate of glass, silica, or biscuit ware. The space surrounding the rod can be filled with various gases or partly exhausted. The carbon rod can be readily heated to a very high temperature and the colour of the deposit on the cover in air or hydrogen sulphide or iodine vapour, gives a useful qualitative indication of the metals present in an alloy. In many cases (including minerals) quantitative data of an approximate nature may be obtained from very small specimens by weighing the deposit and the residue.—W. H. P.



High temperatures; Methods of research at —— and the high temperature microscope. E. Kittl. Oesterr. Zeits. Berg- u. Huttenw., 1913, **61**, 745—748.

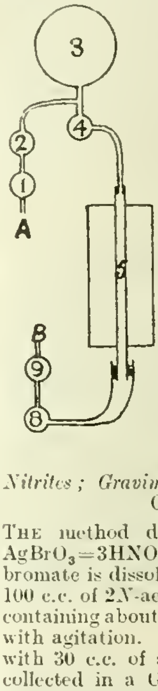
CHIEFLY a description, with drawings, of Doelter's high temperature microscope, an ordinary mineralogical polarising microscope the stage of which is fitted with a small electrical resistance furnace, 5½ cm. or 10 cm. high, giving internal temperatures up to 1300° C. and 1600° C. respectively. A small quartz or platinum capsule contains the substance to be examined, and is lowered to the centre of the furnace; and a plate of glass or other transparent substance covers the top of the central tube, thus protecting the objective, and allowing the use of indifferent gases other than air in the furnace. The lower part of the microscope tube and the objective are water-cooled, and the magnification possible is from 13 to 15 diameters.—J. T. D.

Chromium; Determination of —— by alkaline oxidation. F. Bourion and A. Sénéchal. Comptes rend., 1913, **157**, 1528—1531.

THE method depending upon the oxidation of a chromic salt to chromate by means of hydrogen peroxide in alkaline solution and subsequent estimation of the chromate has been carefully examined. The presence of iron does not affect the process; but small amounts of nickel, cobalt, or manganese vitiate the results owing to rapid catalytic action on the peroxide. The addition of a small amount of sodium sulphate (1/100 grm.-mol.) after oxidation has been effected greatly facilitates the decomposition of the excess of peroxide.—J. R.

Iron and aluminium; Separation of ——. H. Borck. Chem.-Zeit., 1914, **38**, 7.

AN apparatus for the separation of iron and aluminium by heating the ignited oxides in hydrochloric acid gas (this J., 1912, 460) comprises a series of washing flasks, 1, 2, 4, 8 and 9, and a Kipp's apparatus, 3, for the production of the hydrochloric acid gas from ammonium chloride and sulphuric acid. The flask, 1, is left empty, 2 is charged with concentrated sulphuric acid or with mercury, 4 with about 30 c.c. of concentrated hydrochloric acid, 8 with 50 c.c. of water, and 9 with 50 c.c. of 30 to 40 per cent. potassium hydroxide solution. The oxides are heated in a quartz boat, in the tube, 5, whilst a mixture of hydrochloric acid gas and air (drawn through A by means of a pump at B) is passed through the tube. After the ignition any traces of chlorine absorbed by the quartz boat are expelled by continuing the ignition for a short time in a current of air alone. The same apparatus may be used for the rapid separation of tungsten, molybdenum and uranium from silica and thoria.—C. A. M.

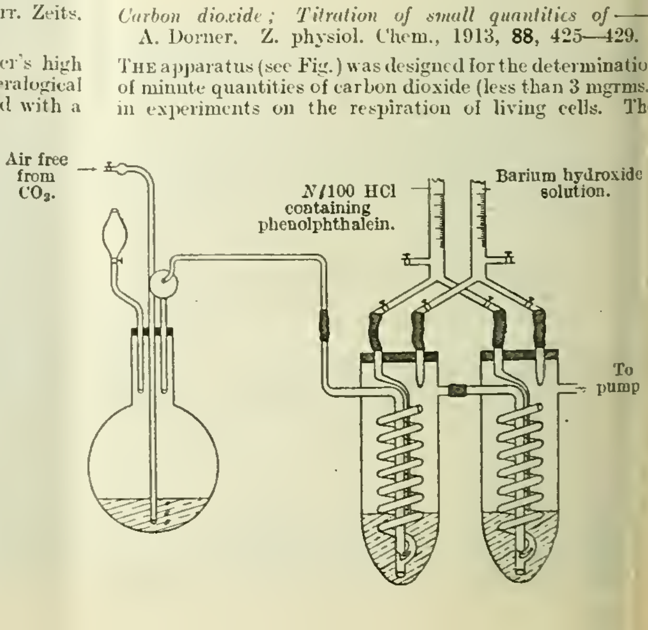


Nitrites; Gravimetric determination of ——. N. Busvold. Chem.-Zeit., 1914, **38**, 28.

THE method depends upon the reaction: $3HNO_2+AgBrO_3=3HNO_3+AgBr$. About 1·4—1·5 grm. of silver bromate is dissolved by warming in 100 c.c. of water and 100 c.c. of 2*N*-acetic acid and the nitrite solution (200 c.c. containing about 1 grm. of sodium nitrite) added gradually, with agitation. The mixture is heated to 85° C., treated with 30 c.c. of sulphuric acid (1 : 4), the silver bromide collected in a Gooch crucible, washed, dried at 130° C. and weighed: 0·907 grm. AgBr is equivalent to 1 grm. $NaNO_2$. The method is accurate to within ±0·1 per cent.; in presence of chloride the quantity of silver chloride in the precipitate must be determined and a correction applied.—A.S.

Carbon dioxide; Titration of small quantities of —— A. Dorner. Z. physiol. Chem., 1913, **88**, 425—429.

THE apparatus (see Fig.) was designed for the determinatio of minute quantities of carbon dioxide (less than 3 mgrms. in experiments on the respiration of living cells. Th



Air free from CO_2.
N/100 HCl containing phenolphthalein.
Barium hydroxide solution.
To pump

absorption vessels, which are constructed on the principle of the Walter's apparatus for washing gases, are of ordinary glass and are not heated during absorption (cp. Warburg, this J., 1912, 1049). At the commencement of a determination they are swept out by air free from carbon dioxide, and then about 30 c.c. of barium hydroxide solution are run into each. During absorption the gas is drawn through at the rate of 150 c.c. per min. The current of air is continued during the subsequent titration with acid.—J. H. L.

Organic matter; Destruction of large quantities of —— in the Kjeldahl process. E. Carpiaux. Bull. Soc. Chim. Belg., 1913, **27**, 333—334.

The following method has been found to give satisfactory results in the determination of nitrogen in samples weighing from 20 to 30 grms.:—The sample (say 30 grms.) is introduced into a 500 c.c. flask, 30 c.c. of sulphuric acid is added, and the whole is well shaken and allowed to stand for an hour; the mass becomes hot and forms a spongy carbonaceous product. Carbonisation may be accelerated by moderate heat. When the mass appears to be dry, mercury and sulphuric acid are added and the oxidation is proceeded with as usual. To remove any undesirable excess of sulphuric acid after the oxidation, pure sugar may be added to the boiling liquid. Nitrogen, phosphoric acid, and calcium may be determined in the resulting liquid. It is stated that this method obviates the difficulties due to excessive frothing which occur in the usual process.—T. F. B.

Boron; Determination of extremely small quantities of —— in organic substances. G. Bertrand and H. Agulhon. Comptes rend., 1913, **157**, 1433—1436. (See this J., 1910, 375.)

For very small quantities of boron, strips of turmeric paper of definite size are partly immersed under standardised conditions in the solutions containing boron as sodium borate and rendered acid with hydrochloric acid and in standard solutions of known boron content and of the same degree of acidity. The solution rises in the paper by capillarity and after a certain time (1—2 hours at 35° C., 10—24 hours at the ordinary temperature), the upper portions of the papers, exposed to the air, will have become coloured to a length depending upon the quantity of boron present. For quantities of boron between 0·0005 and 0·1 mgrm., the quantity of boron may be estimated accurately from the length of the coloured portion of the paper. Even in pure water a brown colouration may appear on the paper, but this is not changed to blue by ammonia as are the colourations due to boron.—A. S.

Alloys and other chemical substances; Method and instrument for the separation, detection, and estimation of elements in ——. A. L. Fletcher, Dublin. Eng. Pats. 29,537 and 29,538, Dec. 23, 1912.

The material is heated electrically near a moving surface, such as the surface of a revolving drum. As the drum revolves, resistances are cut out of the electrical circuit so that the material is heated continuously to higher temperatures. Substances volatilised at different temperatures are thus received on different portions of the moving surface.—T. St.

Heating bodies; Process and apparatus for determining the calories given off from ——. M. Arndt. Fr. Pat. 460,248, July 11, 1913. Under Int. Conv., July 13, 1912.

A volume of air measured at atmospheric pressure is forced by a body of mercury moved by the action of a water pressure tube and intermittent siphon into a hollow vessel in contact with the heating body. The air expands and causes the mercury contained in a second vessel to rise to a corresponding degree. A float in the mercury also rises and by means of a cord passing over a pulley actuates the recording mechanism which indicates the number of calories given off and also closes an electric circuit which causes a bell to ring or some other signal to be shown. —W. H. C.

Heating value of fuels; Method and device [*calorimeter*] *for measuring the ——.* H. Junkers, Aachen, Germany, Eng. Pat. 22,514, Oct. 6, 1913. Under Int. Conv., Oct. 16, 1912.

The heat liberated by the combustion of solid, liquid, or gaseous fuels is transmitted by known heat-exchanging devices to a stationary liquid having a coefficient of expansion which is as nearly as possible constant at the temperatures under consideration, and the heating value calculated from the increased volume of the liquid. The effect of a uniform coefficient of expansion is that the increase in volume of the liquid is the same whether the temperature is uniform throughout or not, so that no stirring is necessary. Petroleum satisfies the necessary conditions but water is unsuitable. In the form of apparatus shown, the heat is transmitted from a burner, *c*, to petroleum in the vessel, *o*, by means of gills, *d*, in the flue and gills, *f*, in a liquid circulating passage, *g*. The top of the apparatus is made conical to avoid presence of air bubbles, and a heating or cooling coil, *i*, is provided to enable the calorimeter to be brought quickly to the temperature of the room to avoid radiation corrections. The increase of volume of the liquid is measured by means of a tube, *h*, and the heating value obtained by multiplying by a factor and dividing by the amount of fuel used. In another form of apparatus the tube, *h*, is replaced by an expansible chamber operating a pointer.—H. H.

DR. R. F. RUTTAN IN THE CHAIR.

THE RUBBER AND RESIN CONTENT OF THE DESERT RUBBER-PLANT "GUAYULE," IN RELATION TO RAINFALL.

BY FRANCIS E. LLOYD, M.A.

In an earlier paper* the view has been advanced that the amount of rubber secreted by the guayule, *Parthenium argentatum* Gray, varies within wide limits, inversely with the amount of soil water available. It was shown, however, that the amount of rubber which may ultimately occur within the secreting cells (which are chiefly those of the parenchyma) may be quite as great in those cultivated plants which receive a maximum water supply, as in feral plants, while the amount calculated to the total dry weight of the plant remains small. This is explained by the great changes in the character and especially in the volume relations undergone by the various tissues when the plant accommodates itself to the change from xerophytic to mesophytic conditions. The most obvious of these changes is seen in the thickness of the cortex (" bark "), which is relatively much less in well-watered plants, this constituting an important factor in determining the amount of rubber relative to total dry weight.

Correlated with the soil water supply is also the rate of secretion within the cell, which is much slower in well-watered plants. Thus a feral plant will show a much larger amount of rubber within the cells at the close of the normal wet season, say three months after the earliest effective rainfall of summer (in Chihuahua), than will an irrigated plant after six months of rapid growth, while the latter, during a subsequent period of enforced drought, will make marked advance toward attaining a full complement of rubber.

From the study of plants grown under such extreme conditions as regards water supply, it was to be inferred that variations in rainfall, either from season to season in the same locality, or as correlated with geographical conditions, would be accompanied by variations in structure and rate of rubber secretion in the same directions in plants in their normal habitats. Indeed, one striking example was afforded and has been described elsewhere† as well as in the publications above cited, but, at the time, no analyses were available, so that the divergencies of structure and rubber content had to be described in histological terms only.

Since then, the writer has received samples of plants in three lots from as many separate localities which bear out in a striking way the inference made, both in regard to the general habit of the plant and as to the rubber content in terms of total dry weight. These were very kindly furnished me by Sr. Ramon Muñoz, accompanied by the following data. The material was collected in December, 1912. During that year and during the latter half of 1911 the rainfall had been " very abundant," and in consequence an " abundant and rapid reproduction and growth " in all he guayule fields was reported. It is not possible to say n exact terms what "abundant" means, but we may uppose that, in a country where 12 to 15 inches is not considered meagre, 20 inches would fall somewhere near he mark. However this may be, it is more to the present purpose to point out that the region where the plants of Lot 3 grew is recognised as having a distinctly more abundant rainfall than those lands lying farther to the west. It lies on the eastern border of the guayule area, partly in the states of Nuevo Leon and partly in San Luis Potosi. These plants have a very different appearance from those of the other lots, namely, Lot 1 and Lot 2, both from guayule fields situated well within the area of distribution, and, indeed, markedly different from that of any guayule which I have seen growing in the field. Rather do they resemble irrigated plants in their slender twigs, yellowish bark, and greater shrinkage upon drying, the last-named character becoming evident in deep longitudinal folds. The plants of Lot 1 were four small seedlings, of which one was three years old and the remainder two, and except for a growth rate (viz., about 6 cm. yearly) somewhat greater than usual (about 3·5 cm. yearly) presented nothing unusual. The plants of Lot 2, also four in number, were of a type of guayule generally recognised as the " best." They were stocky plants, with fewer and thicker branches and twigs, grey in colour and generally conforming to the popular conception of " macho " (male) guayule, while the plants of Lot 3 are regarded as " hembra " (female). This distinction I have discussed elsewhere (*l.c.*), but briefly the alternative views are that we are dealing either with distinct races (elementary species) or with merely environment types. The latter view is strongly indicated by the evidence, which is not of the kind to be pertinent to this paper, but whichever of the interpretations is true, the present record will have its value. The great difference between the two samples (Lots 2 and 3) of plants which we are discussing is indicated by the weights. The plants of Lot 2 were 5 to 7 years old and had an average weight of 45·7 grms.; while of those of Lot 3 four, which were of a similar range of ages, had an average weight of only 29·2 grms. The average heights above soil were 22 and 19 cm. respectively, from which it appears that their growth rates were not connected with their transverse measurements. This is the one discrepancy which makes itself evident in a comparison of the plants of Lot 3 with irrigated ones, which may, however, be due to temperature effects, if we may assume, as seems proper, that the soil conditions need not be called into the question. That, however, a greater rainfall for 1911–1912 made itself felt more especially where it occurred, in probably greater abundance, appears to be indicated by a more rapid average growth rate for the plants of Lot 3.

The number of measurements (11 to 13) is admittedly rather too small to justify much reliance upon them, but they are given for their probable worth.

Average growth in height.

Lot No.	1911.	1912.
	cm.	cm.
2	3·6	4·4
3	4·8	5·3

All these measurements are somewhat in excess of the average growth rate of 3·5 cm. per annum, as established by numerous measurements by myself (*l.c.*). Nevertheless, they are not excessive nor greater than observed by me for particular localities. The seedlings comprised in Lot 1, however, also show a greater amount of growth in length than is usual during years of less rainfall than occurred in 1911-12, being, for the two years, about 10 cm. against a normal of about 6 cm. (*loc. cit.*). The samples, the analysis of which is given below, indicate therefore a rainfall of more favourable quantity, in harmony with the testimony of Sr. Muñoz, while those of Lot 3 conform to a type of guayule which resembles the irrigated plant.

The analyses were carried out by Mr. E. H. Pound in this laboratory in the following manner. The finely ground material was dried for 24 hours at 105° F. It was then extracted with acetone (6 hours) followed by petroleum ether of 60° (2 hours). The extracts were dried for one hour at 105° F. Parallel series were run. The plants of Lot 1 were entirely incorporated with the samples extracted; those of Lots 2 and 3 were divided into tops (the growth of the last two years) and stocks (the remaining basal portion). The following are the results and their averages:—

Average	2·41	12 61	1·43	12·82

NOTE.—For analyses of mature plants, see Whittelsey, J. Ind. Eng. Chem., April, 1909.

From these figures it appears that the plants of Lot 2 have about 62 per cent. more rubber in the tops and 13 per cent. in the stocks than those of Lot 3. The amount in the latter is about the same as I observed for field seedlings (exclusive of leaves) which had grown rapidly in response to a rather favourable season. In the seedlings of Lot 1 the amount is less than would be expected (namely, 1·52 per cent. against 1·80, leaves included) (Lloyd, *l.c.*), in view of the alleged considerable rainfall. But, as rain is usually local in the desert, especially on "bajadas" or footslopes, one has to admit the absence of exact information. The resin content, on the other hand, is little variable, and this fact is cited in support of a view earlier expressed that there is no connection between the occurrence of rubber and that of resin, for which view histological evidence had been given. That rubber may break down into resins is of little value as evidence that the resin in guayule is used in the building up of the rubber.

Concerning the anatomical structure of the plants in question, the same differences as between field and irrigated plants, such as I have heretofore described (*l.c.*) occur, but in smaller measure. These need not be mentioned here in detail, it sufficing to mention merely the greater development of cork, mechanical elements (stereome) and of the tracheids, together with a reduction of medulla and medullary rays, in the plants of Lot 3, those, namely, which received the greater rainfall. Microscopical examination does not discover any discrepancy in the amount of rubber in the individual cells, except to some extent in the smallest twigs, so that we must therefore conclude that the differences in the total amount of rubber produced must be referred chiefly to the differences in the volumes of tissues which secrete rubber as compared with those which do not. That, in the case of field plants, these differences may account for a considerable difference in favour of plants of the type of Lot 2 is seen in the ratios presented by the squares on the radial dimensions of the "wood" (that is, the whole cylinder of tissue bounded by the cambium layer) and the "bark" (those tissues on the outside). This, for stems of the same sizes are:—

	Ratio $\frac{\text{Bark}}{\text{Wood}}$.	
Total diameter:—	2·82	1·95
Lot 1	1·02	0·98
Lot 3	0·76	0·76

That is, in the better watered plants, the "bark" is considerably thinner.*

These ratios, however, indicate only a difference of 34 per cent. (for larger twigs) and 29 per cent. (for smaller twigs) in favour of the field plants, while the analyses show a 60 per cent. difference of rubber content for tops (which would include all the twigs of the sizes measured here together with somewhat larger ones). It is evident that an error of large size has been introduced, due as a matter of fact to ignoring the amount of cork, which is barren of rubber, and of pith, which is rich equally with the living cortex. The relative volumes of these tissues in twigs of the same diameter (about 5—6 mm.) are indicated by the following numbers, representing areas in transverse sections:—

Lot.	Pith.	Wood.	Cortex.	Cork.
2	95	394	984	236
	19	522	788	380

from which is it seen that the pith is smaller and the cortex thinner, while the wood and cork are thicker. By eliminating the cork and introducing the pith into the calculation, the ratios of volume of rubber producing tissue (still ignoring the medullary rays) to "wood" turns out to be for Lot 2, 2·74 and for Lot 3, 1·55, showing a difference of 76 per cent. in favour of the plants of Lot 3. This difference would not be realised in the extractions, since, aside from the imperfections of the method, the tissues of the smaller twigs of the two lots were not, as microscopic examination revealed, equally loaded with rubber, while larger twigs were included under the heading "tops" than the size chosen for measurement, two conditions which would disturb the relative amount of rubber recoverable.

Aside from the rate of secretion, there are two ways in which the amount of rubber produced by plants is affected by water supply, namely, by altering the volumes of rubber-bearing tissues, and by affecting the total amount of secretion within them. The evidence is clear that, in speaking of the effect of soil water, this difference must be recognised. Records show that both conditions occur, either in combination, as in the plant here under discussion, or severally. The latter only has been observed in the case of latex-plants. Olson-Seffer,† and Collins and Pittier‡ have noticed that *Castilloa* produced less rubber when it had been subjected to larger amounts of water by irrigation, and Fox, quoted by Neish,§ observed that milkweed (*Asclepias syriaca* and *incarnata*) gives a higher yield of rubber when it has grown in dry soils. It is obvious that the question is one of very great practical as well as theoretical importance, quite aside from the guayule problem, the importance of which is, at present, on the wane. The rubber planter will be compelled to study this relation whenever the problems of irrigation and drainage present themselves.

Conclusion.—The determinations of rubber for tw samples of feral guayule plants grown in their natura habitats under diverse conditions of soil-water, show tha a relatively abundant amount of rainfall results in a plan which simulates in many ways one grown under irrigatio the likeness extending to the amount of rubber produce and the relative volumes of bearing and non-bearin tissues. The departure from the normal, as indicated by typical desert plant producing a maximum yield of rubbe is such as to result in a plant which yields a distinctly less amount of rubber. Within the normal habitat of the guayule plant, therefore, the amount of rubber varies in an amount at least as great as that above indicated, namely, 62 per cent.

---

* The different values of this ratio for larger stems are illustrat by tables in Publ. 139, Carn. Inst. Wash., above cited.

† Year Book, 1908. Rubber Planters' Assoc., Mexico.

‡ In O. F. Cook. Bull. U.S. Dept. Agric., No. 49, Oct., 1903

§ This Journal, 1913, **32**, 72.

The amount of resin secreted appears not to be affected by the amount of soil-water, and evidence is yet lacking that rubber and resin secretion are causally related in the plant.

Such differences, which are attributable to physiological causes are of great theoretical and practical importance.

London Section.

Meeting held at Burlington House on Monday, January 5th, 1914.

PROF. W. R. HODGKINSON IN THE CHAIR.

THE VISCOSITY OF OILS.

BY J. L. STREVENS.

(Taranaki Oil Fields, New Zealand.)

Considerable work in connection with viscosity and lubrication has been carried out during the past few years chiefly with a view to determine true (or absolute) viscosity through a large range of temperature in a simple and convenient manner (Dunstan and Strevens, this J., November 30th, 1912) and more recently (Higgins, this J., June 16th, 1913) on behalf of the International Commission for the Unification of Tests on Petroleum Products.

This communication, which may be regarded as a continuation of the first paper mentioned above, does not deal with the connection between lubrication and viscosity to any further extent beyond the statement that the lubricating capacity of any oil from a purely mechanical point of view depends entirely on the viscosity. Where special circumstances attend the use of a lubricant such as in a steam cylinder, air compressor, or gas engine, the rôle played by the extraneous bodies with which it comes in contact and the affecting conditions must be taken into account, as also its chemical characteristics. Under similar circumstances oils of equal viscosity at the working temperature of a bearing, even when there are constitutional and other physical differences, possess the same coefficient of friction in the bearing (Ubbelohde, "Theory of Lubrication"). Hence the necessity for absolute viscosity temperature curves in the study of lubrication.

The first determinations made by the author in collaboration with Dr. Dunstan contained certain errors which arose unavoidably from an interpolation of Scarpa's viscosity figures for phenol, at that time the only source available from which to calculate the viscometer constant. Later figures by Dunstan and Thole (this J., Nov. 30th, 1912) resulted in a different phenol viscosity curve from which the oil-viscometer constant curve was replotted. The result was a comparatively small variation through a large range of temperature as the following logarithmic values show :—

Before correction.		After correction.	
Temp.	log. Kt.	Temp.	log. Kt.
15·5° C.	$\bar{3}$·175	15·5° C.	$\bar{3}$·030
100° C.	$\bar{4}$·965	100° C.	$\bar{4}$·990
200° C.	$\bar{4}$·715	200° C.	$\bar{4}$·950

Consequently previous figures for all viscosities below [illegible]° C. (the temperature corresponding to the junction of the uncorrected and corrected "constant" curves) are too high and those above too low.

As a check on the result a similar viscometer was recalibrated showing a corresponding curve and both instruments were used in the investigations.

Many new oils have been investigated which, with the exception of some of vegetable and animal origin, are all lubricants well known to the oil trade.

The previous viscosity curves are materially altered, especially in the high temperature region, which for some oils approximates to their actual working temperatures.

Until more is known of the actual constitution of the various lubricating oils of commerce, to what extent the viscosity is affected cannot be stated, but from analogous work on bodies of known constitution it may be generally inferred that (1) Increase of mol. wt. favours increase of Zt., *e.g.*, rape oil (trierucin) $>$ olive (triolein). (2) Hydroxyl formation favours increased Zt., *e.g.*, castor oil and the blown oils. (3) Polymerisation (see 1), *e.g.*, "Elektrion" oils. (4) Solution of solid bodies in oils (*e.g.*, "soaping") tends to a high viscosity-temperature coefficient. (5) Unsaturation tends to lower the viscosity and, broadly, the $>$ iodine value $<$ Zt., *e.g.*, linseed and perilla oils less than nut or olive oil. (6) Combined high mol. wt. and conjugated doubled bonds mean a high Zt., *e.g.*, tung oil.

Some of the figures obtained are lower than those obtained by Higgins, *e.g.* :—

	Strevens.	Higgins.	Temp.
Russian engine ……	1·9	2·05	25° C.
Olive ……………	0·95	1·07	15° C.

This must be attributed to several causes, including difference in method of investigation and probable difference in origin of oil—long period of flow—as well as a substance of considerably lower viscosity than oils being the calibrating agent. On the other hand, the percentage rate of change of Zt. per 1° C. in the neighbourhood of 25° C—50° C. for Russian engine oil is 5·7 against 5·6 (Higgins).

The author, in conclusion, would like to draw the attention of the International Commission for the Unification of Tests on Petroleum Products to the possibility of standardising the viscosity of an oil (or oils) by Higgins' method and using the same as calibrating liquid for the determination of the viscometer constant detailed in the above investigations. Moreover, the oil trade could use with perfect reliability and uniformity instruments thus calibrated and similar to the simple type detailed in the previous paper (this J., Nov. 30th, 1912) with all confidence in their exactitude under a guarantee certificate and constant-curve drawn up by a responsible scientific authority such as the National Physical Laboratory.

The Redwood figures given above show the range usually met with in the commercial oils. The numbers are those obtained by the author from examination of some hundreds of such products during the past few years.

It is possible to obtain the ratio of the times of flow on a standard technical viscometer to the actual absolute viscosity by the formula :—

$$Zt = (aT - \frac{b}{t})t$$

where a and b are constants differing slightly at various temperatures, and T=time of outflow in seconds.

The adoption of certain "standard temperatures" at which to ascertain the viscosity of an oil for comparison purposes is not satisfactory owing to the difference in the ratios of the viscosity of oils over a wide range of temperature. The only really satisfactory method is by means of viscosity-temperature curves over a range depending on the kind of oil and its proposed use. Thus for light oils, engine oils, and lubricants which are not likely to be subjected to high temperatures in their ordinary practice, a range from 15° C.—100° C. would be ample, whilst valuable information should be obtainable for cylinder oils and gas engine oils, from a viscosity curve over a much higher range.

DISCUSSION.

Mr. ARNOLD PHILIP said he thought Dr. Beilby ha shown some years ago that the solution of paraffin wa under certain circumstances in mineral oils actually lowere their viscosity, whilst in experiments carried out Portsmouth he had found that the solution of naphthale in ordinary mineral oils usually very remarkably lower their viscosity.

Mr. J. H. Coste emphasised the great need for standardisation of viscosity tests. They knew the reading of the Redwood viscometer did vary, and it was very desirable that any viscometer used should be definitely standardised.

ON THE OXYGEN CONTENT OF THE GASES FROM ROASTING PYRITES.

BY LEWIS T. WRIGHT.

About 40 years ago, Scheurer-Kestner (Bull. Soc. Chim., 1875, 23, 437) called attention to the fact that the gases from roasting pyrites did not contain nearly enough oxygen to justify satisfactorily what I may term the normal reaction, $2FeS_2+11O=Fe_2O_3+4SO_2$. Friedr. Bode (Dingl. 218, 322) then called attention to the existence of ¾ to 1½ per cent. of sulphur as sulphate of iron in the cinder as helping to explain this observed shortage of oxygen, and pointing out that Winkler and others had shown how SO_3 was formed by the action of incandescent ferric oxide on SO_2 and oxygen. Scheurer-Kestner (Dingl., 219, 512), in reply to Bode, entered into further detail, and showed that the quantity of oxygen in the cinder as sulphate was in any case trifling, but that even if all the sulphur in the cinder existed as sulphate, and all the missing oxygen were disposed of as SO_3 either in the cinder as sulphate, or as SO_3, then the sulphur in a case he cites would have been thus disposed of: 65·5 per cent. sulphur as SO_2 in the burner gas; 32·5 per cent. as SO_3, and 2 per cent. as sulphate in the cinder.

This was followed by Lunge and Salathe's work on the action of red hot ferric oxide on 1 vol. SO_2 and 2 vols. air (Ber., 10, 1824). They were able to get experimentally as high as, for 100 parts by weight of sulphur as SO_2, 22 parts of sulphur as SO_3. This is less than would be inferred by Scheurer-Kestner's reasoning for the case from practice he had presented. The matter was apparently left to rest there with an observation by Lunge that perhaps an error in the estimation of oxygen by pyrogallate had influenced the result.

If the matter has no further interest, so far as the sulphuric acid industry is concerned, I believe it may have in connection with the increasing attention now being given to the efficiency of air used in copper smelting processes, and I venture to revive it.

If the whole of the pyrites were burned according to the "normal" reaction, $2FeS_2+11O=Fe_2O_3+4SO_2$, and if 100 vols. of the air furnishing the oxygen supply contained 20·90 vols. of oxygen and 79·10 vols. nitrogen, and further the reaction could proceed to the exhaustion of the oxygen of the air employed, then there would be for 100 vols. of air used, 15·2 vols. SO_2, 5·7 vols. of oxygen disappearing from the gas and forming Fe_2O_3, and 79·10 vols. of nitrogen, and the furnace gas would have this composition: SO_2, 16·1 per cent., N, 83·9 per cent.

I had frequently tried to ascertain how much SO_2 I could "soak" into the burner gas by closing up pyrites oasting furnaces against the admission of further air at a time when they were running well and hot, and then aking a series of gas analyses for SO_2. This would ise till about 11·5 to 12·5 per cent. SO_2 appeared, and hen cease. The average maximum of rather less than 2 per cent. SO_2 which was found on these tests I regarded s a working maximum, and attributed the deficiency rom the 16·1 per cent. which would obtain if all the yrites were burned by the above reaction with 100 per ent. air efficiency, partly to the SO_2 forming an "extincive" atmosphere. It did not occur to me then that the ee oxygen might have been entirely used up. I was ware that a deficiency of oxygen had been generally oted, but it did not occur to me that this was more han relatively unimportant, and I now regret that I did ot on those occasions also have the burner gas examined r free oxygen.

I was satisfied that about 12 per cent. of SO_2 was a actical maximum. On examining a number of analyses wing both SO_2 and oxygen in burner gas from works under my control, and afterwards other analyses published at various times by different observers, I noticed certain peculiarities to which I would like to call attention.

The analyses are dealt with in the following manner. The difference between the total of the SO_2 and oxygen is treated as nitrogen. From this nitrogen the original oxygen is calculated on the basis of 20·90 oxygen to 79·10 nitrogen (by multiplying the nitrogen by the factor 0·264). The difference between the original oxygen and that in the SO_2 and the oxygen found in the gas is the oxygen which has disappeared from the gas. This I call "oxygen absorbed." According to the "normal" reaction it combined with the iron to form Fe_2O_3. For instance, if the reaction had been exclusively the "normal" one, then as said before, for an original 20·90 vols. oxygen, 15·2 vols. of oxygen would remain in the gas, and 5·7 vols. would be absorbed by the iron, and the ratio, oxygen absorbed to SO_2 would equal 0·375.

In the accompanying table are given analyses of burner gas so discussed as well as the "normal gas" of Lunge, which has a ratio of oxygen absorbed to $SO_2=0·37$. It may be convenient to call this the "normal" ratio.

It will be noticed (1) that in no case is the "normal" ratio approached; (2) that the results of each observer are not only generally concordant in themselves, but also with those of other observers, and (3) that the highest SO_2 results have the lowest ratios and the lowest SO_2 the highest ratios, and generally as the percentage of SO_2 increases the oxygen absorbed to SO_2 ratio decreases.

If there were any constant error in these analyses that made, for instance, the absorbed oxygen 1 too high, the "normal" ratio would be increased by 0·5 in the case of gas with 2 per cent. SO_2 and 0·125 with gas of 8 per cent. SO_2. Also if 80 per cent. of the pyrites were burned by the "normal" reaction, and the balance by secondary reactions, the average effect of which could be expressed by the equation $FeS_2+7O=FeSO_4+SO_3$, then the ratio, oxygen absorbed to SO_2 would be 0·81.

I am not prepared to say how much of the defect from the "normal" reaction is caused by the undoubted occurrence of other reactions by which metallic sulphates and SO_3 are formed, or by some constant error in the method of analysis, but I do want to point out that if the remaining oxygen in ordinary burner gas were used up in the combustion of pyrites, we could never reach a "normal" gas containing so much as 16·1 per cent. of SO_2, and the maximum must be 12 per cent. SO_2 when the free oxygen is all exhausted.

If we consider the burner gas, SO_2 found, 8·6; O found, 5·5; N by diff., 85·9; O original, 22·7; O absorbed, 8·6; ratio, 1; and the remaining oxygen could be disposed of in the same ratio, then the SO_2 would increase by one-half of the remaining oxygen and the other half of the oxygen would be "absorbed"—the final result would be, SO_2 found 11·35, O found none, N by diff. 85·9, O. absorbed 11·35, ratio 1, or correcting for shrinkage of volume, 11·67 per cent. of SO_2.

In the case of the burner gas containing 8·4 per cent. SO_2 and the "ratio" 0·9, SO_2 found 8·4, O found 6·5, N by diff. 85·1, O absorbed 7·6, ratio 0·9; and of the remaining free oxygen, viz., 6·5 were disposed of at the same ratio of 0·9, the resulting gas would be: SO_2 found 11·8, O found none, N by diff. 85·1, O absorbed 10·7, ratio 0·9 and correcting for shrinkage of volume the resulting gas would contain 12·2 per cent. of SO_2 as a possible maximum

The gas with a percentage content of 16·1 per cent. SO_2 is therefore, so far as our experience goes, not attainable in pyrites roasting furnaces.

In closing this paper I would like to offer a tribute to William Crowder, whose "Observations made on the Working of Vitriol Chambers" is the most complete account of the progressive change in the composition of the gases in the chamber sulphuric acid process with which I am acquainted. His expressed wish that the information he then gave to the world might prove to be useful memoranda will already, I believe, have been amply fulfilled.

Discussion.

Sir **William Ramsay** asked whether it was certain that the formula of the oxide of iron produced was Fe_2O_3. The main argument seemed to be conceived on a difference of oxygen, an error in the estimation of which would make that difference greater or smaller.

Mr. J. H. **Coste** said that sulphur trioxide was always produced when coal gas was burned without chilling the products.

Sir **William Ramsay** asked whether it was allowed for.

Mr. J. H. **Coste** said that the gases from a calorimeter, like Boys' or Junker's, always showed sulphur dioxide, apparently because the product had been chilled; but if gas were burned in the Referees' apparatus for determining sulphur practically the whole of the sulphur came off as sulphur trioxide. Sulphur dioxide was not usually found.

The **Chairman** said that that might account for the expected discrepancy in the analyses in the second column.

Mr. D. M. **MacKechnie** said, with regard to Sir William Ramsay's remarks on the degree of oxidation of the iron present, ferrous oxide was admittedly present and might be there in quantity.

Mr. **Lewis Wright**, in reply, said in regard to the matter raised by Sir William Ramsay, the amount of sulphur trioxide formed under these circumstances, would hardly, in his opinion, account for the ratios shown. Of course some magnetic oxide was formed and tha affected the ratio. He did not know if anyone had determined that; but there were other well-known secondar reactions taking place. Some of the claims which ha been made to the production of a burner gas containin nearly 18 per cent. of SO_2 in special types of furnace could hardly be explained in the face of the analys which came from all kinds of practices, not only from h own but that of many other chemists engaged in th manufacture of sulphuric acid. On the question of tl possible analytical error in the absorption of oxyg which was suggested by Dr. Lunge, when they we dealing with gases of such extreme dilution, it was obvio any of the many possible errors in technical gas analys might happen and would then affect the ratio. If aft a burner gas was taken away through various channe air was allowed to enter, that was to say, if there was mixture of burner gas and false air, or if a dilute g was taken off directly from roasting pyrites, the sa high ratio was found in each case.

THE HEAT TEST OF EXPLOSIVES.

BY A. C. EGERTON.

It is satisfactory to find that interest has been tak in the paper on the heat test published in this Journ. 1913, 331, Robertson and Smart having criticised seve of the deductions therein (see this J., 1913, 967).

The results of certain experiments, described in the fore-mentioned paper, were only explicable, in the opinion of the writer, by considering that an explosive can attain a state of equilibrium within a closed heat test tube. In fact, it was suggested that the dissociation pressure of the explosive compound was measurable, and would act as a good guide to its stability. Such a statement has been considered untenable, because decomposition of an explosive can proceed to completion—it is not a reversible process.

Explosives to which the heat test is applicable, on heating at a constant temperature for a long time, gradually deteriorate and eventually decompose; in fact on heating they are all liable to ignite of their own accord. This could not be so if the products of decomposition were in equilibrium with the explosive; indeed the products of decomposition tend to accelerate the rate of decomposition. What then is the evidence for the assertion made in the author's last paper?

It was found that the heat test time was little altered by the presence of two test papers, or even two drops, although calculation from the formula derived from the assumption of a regular rate of increase of the concentration of the nitrogen peroxide and its removal by absorption in the drop or paper, would require that the heat test time should be considerably greater: the continuous tests show that for quite a long period the heat test times remain practically constant.

These two facts appear only to be explicable on the hypothesis that equilibrium establishes itself within the tube. For how otherwise would the results of a continuous test not give decreasing times, or the presence of two drops instead of a single one not cause an increase in the time of the first test?

It will be well to consider other possible reasons. Firstly the concentration of "reacting" gas may be greater than expected and the absorption by the drops or paper less; an upper limit for the value Tc=K for the drops and papers was found (for the drops $K = 156 \times 10^{-6}$), but even this is not great enough to account for the similar results obtained when two drops are exposed; the value for the absorption by the papers was confirmed, and that for the drops was found to be nearly four times as great. This, then, will not account for the facts. Secondly, during a continuous test the drops or papers may absorb the reacting gases as fast as they were formed, or leakage and dilution of the atmosphere within the tube may occur when the drops are changed; this, however, is also disproved, because, if a continuous test is run alongside a similar sample which is kept in a closed tube and only tested at long intervals, after the same period of time has elapsed from the commencement, nearly the same heat test times are obtained. There remains Dr. Robertson's suggestion that during a continuous test the nitrogen peroxide is reduced to nitrogen, this action increasing as time goes on much in the same proportion as the nitrogen peroxide is evolved. If this were so, two tubes treated similarly and heated for a certain time, should contain the same amount of nitrogen peroxide; if they were then tested the one with one drop or paper and the other with two, the results should be very different; they are, however, nearly the same. There is also direct evidence that this is not a plausible explanation, as will be shown later: indeed, from the results of the Will test it would be exceedingly unlikely that the reduction would be sufficient to account for the constant heat test results, especially as the temperature at which a heat test is carried out is so much lower than that for the Will test.

Smart has pointed out that oxygen, nitrous and nitric acids, nitrogen trioxide and peroxide, and nitric oxide are all reacting gases so far as the heat test is concerned: if constant continuous test results were only obtained for the potassium iodide paper, it would be easy to understand, for the reaction on the paper is an oxidising action and that on the drop is due to nitrous acid. It appears conceivable that the nitric oxide found by reduction of nitrogen peroxide might act as a carrier of oxygen, being alternately reduced and oxidised, and this might account for the constant results; but as the nitrogen peroxide increased, one would expect the nitric oxide to increase, and the test times to decrease. It does not seem that such considerations throw any light on the matter.

As none of these explanations suffices to explain the experimental results which had been obtained, it was thought advisable to confirm them, and the following table gives the results of some of the further experiments.

TABLE I.

Guncotton "Conditioned."

KI paper. 70° C.				Naphthylamine drop. 75° C.			
1. Single paper 10′ interval.	2. Two papers 10′ interval.	3. Single papers 30′ interval.	Time.	1. Drops exposed successively.	2. Two drops (in cases marked*).	3. Single drops 30′ interval.	Time.

4 " " " " " " " " " ..	3′

while with the drops after 1½ hours

When 8 drops have been exposed, heat test time is ..	11′
6 " " " " " " " " " ..	10½′
2 " " " " " " " " " ..	8½′

It has been shown in the other papers that the presence of two papers or two drops during the first test should alter the time of the test considerably; but in fact, experiments show that the time of the first test does not alter.

On the other hand, a simple calculation shows that if the rate of evolution of nitrogen peroxide is about 1·0 ×

10^{-6} mgrm. NO_2 per minute per c.c., the amount of nitrogen peroxide in a heat test tube after two hours should be about $1{\cdot}6 \times 10^{-3}$ mgrm., a number which would give a very quick heat test time, and which would not be affected appreciably by the exposure of several papers within the tube.

If the amount remained about 5×10^{-4} mgrm., as the continuous tests seem to show, the difference in tests on exposing different numbers of papers should be about that observed; one can quite realise that the approximate equilibrium would hardly establish itself quickly enough to prevent this effect being observed. The drops absorb much more nitrogen peroxide in colouring up to tint, and if it were not that results after the exposure of very few drops are not greatly different from those where many drops have been exposed during the continuous tests, it would be possible to explain the constant results obtained by absorption in the drop, but that possibility is excluded.

One point to be noticed is that the heat test rises after a certain time, and that this rise occurs sooner, the greater the number of drops or papers introduced. The suggestion of Smart that at the commencement of the continuous test the nitrogen peroxide is reduced by foreign substance, more nitrous acid being thereby obtained, might possibly explain this fact; but it is more probable the result of a slower rate of evolution of nitrogen peroxide after the explosive has been heated some time.

Other experiments were made which confirmed the above results. One experiment was carried out with a sample of dry guncotton at 70° C. for 36 hours (using a drop of *α*-naphthylamine as indicator). The drops were exposed at intervals of an hour. The test times obtained were practically constant, and no gradual increase in concentration in nitrogen peroxide was detectable.

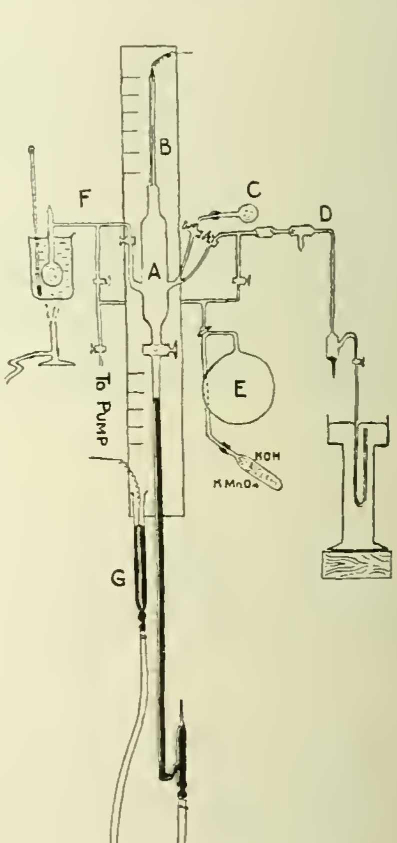
These results confirm those described in another paper, and show that the reacting gases do not increase regularly as time goes on, but that their concentration remains practically constant. Excluding the idea that reduction to NO and nitrogen might account for these constant results, it does not seem possible to explain them otherwise than by assuming that the explosive is behaving like an ordinary dissociable substance in an enclosed space.

How, then, can the two views be brought into line, and how does an explosive behave when kept at a temperature about 70 to 80° C.?

The explosive, if it were an ordinary substance at a constant temperature (*e.g.*, copper nitroxyl), would get into equilibrium with the products of decomposition. There is little doubt that this is the main condition of affairs; at the same time, in order to account for the instability of an explosive and its liability to decompose rapidly, there must be a second process going on. Certain few molecules (especially in the case of explosives of non-homogeneous structure) are decomposed more completely than those which are merely dissociating, and these are decomposed irreversibly with evolution of considerable heat; at certain centres, then, within the explosive this action begins and may spread rapidly and cause spontaneous ignition. The two actions may be looked on as separate; and the results of heating an explosive, as in a continuous test, are those of the two supposed actions. When the explosive is first heated, the explosive may be somewhat more disturbed than after a considerable heating. The explosive would show sudden increases in the concentration of the "reacting" gases; but no marked increase should occur until the explosive has practically reached a condition in which it is likely to explode. These remarks are borne out by the results of continuous tests.

Leakage or absorption by the reagent have been shown not to account for the approximately constant results of a continuous test. As it is not apparently impossible to prove satisfactorily by means of experiments, such as have been described, whether or not reduction of nitrogen peroxide is sufficient to account for the constant results obtained in continuous tests, another method has been devised for this purpose. The method is based on Ramsay's apparatus for measuring small quantitica of gases.

The gas burette, A, ends in a fine capillary tube, B. The side tubes communicate through taps with a bulb containing potash, C, a tube of phosphorus with a mercury inlet, D, and a tube, F, containing the guncotton which can be heated at a constant temperature. The upright tube communicating with the mercury reservoir can be closed by a tap so that the mercury can be shut off from the inside space. The bulb, E, contains pure oxygen. The guncotton in F is heated for some definite time in pure oxygen, and in the meantime the burette, etc., are completely evacuated. The tap to the burette is then opened so that the gas passes chiefly into A (the bulb, F, being small); after closing this tap, that to D is opened and the oxygen burnt up by the phosphorus, and the oxides of nitrogen are decomposed giving nitrogen. The result would be a mixture of CO_2, CO, hydrogen, and nitrogen.



The CO_2 can be partially got rid of by opening to the potash bulb. To get rid of hydrogen a little oxygen is let into the burette, A pumped out and sparked. Then it is let back into the apparatus through the inlet to the phosphorus tube, the nitrogen and CO_2 remaining pass into the burette on opening the tap thereto. The CO_2 can be cooled out by a cup of liquid air over the capillary tube and the residue examined by passing the electric discharge through, by connecting to the mercury reservoir and the small platinum wire at the top of the capillary tube. Its volume can also be measured in the capillary tube.

After two hours' heating, if the rate of evolution of N, NO, and NO_2 from the explosive is constant, the volume of nitrogen obtained should be greater than two cubic millimetres for an ordinary guncotton according to the calculation from the formula giving the rate of evolution of nitrogen peroxides. It is possible, however, to detect a very much smaller quantity of nitrogen by this method.

The results of preliminary experiments have shown that a very much smaller quantity (about $\frac{1}{50}$ cubic mm.) than this is obtained and that this quantity does not seem to increase on prolonged heating for several hours. In fact the results so far obtained support the contention that the explosive substance behaves, in part, like an ordinary dissociable substance.

The method is somewhat difficult to work, but if it can be perfected it should be valuable as an absolute method of measuring the stability of an explosive by the analysis of the gases evolved on heating for different periods of time at different temperatures.

Another experiment was made, in which the bulb, E, was filled with pure CO_2, instead of oxygen: the guncotton being heated in an atmosphere of CO_2, as in the Will test. The gas is then passed into the burette, the CO_2 and NO_2 absorbed in the potash bulb, C, and the hydrogen got rid of by washing out with oxygen and sparking as before. If the nitrogen oxides had been reduced by the guncotton the nitrogen (or nitric oxide which would give nitrogen after this process) should be detectable; but the result obtained was quite negligible even after 4 hours' heating. These experiments seem to prove that for several hours, with temperatures as low as 80° C., a normal nitro-compound explosive does not decompose to any great extent but behaves like a dissociable substance, which gets its equilibrium with the products of dissociation. This process, however, is not alone taking place, but there is also the tendency to decompose irreversibly, which tendency is increased by rise or change of temperature, by the presence of impurities or by the production of acids. At the temperature of the Will test, where even the nitrogen peroxide is itself partially decomposed owing to the high temperature, the latter process is much more prominent. The two processes are independent: the apparent equilibrium is only an approximately constant state of affairs. Other points in the last paper have been called to notice, but these do not require so much discussion.

The reaction on the indicators.—In the above remarks, the expression "reacting gases" has been used, because it was immaterial to the argument what gas was in equilibrium with the explosive. But when interpreting the differences shown by the test paper (which is coloured by oxidation) and the drop (which detects only nitrous acid), it is important to take these differences into account. This difference was recognised, and it was considered to be an argument in favour of a "nitrous acid detecting" reagent, over the ordinary heat test paper, as with the former it becomes possible to interpret the results in a reliable manner. At the same time, Smart quite rightly points out that the starch iodide paper by reason of the back reaction ($2\ KOH + I_2 = KI + KOI + H_2O$) gives a great range between good and bad, and an apparently greater sensitiveness.

Relation between concentration (*C*) *and time* (*T*).—In the determination of the value of K (when TC = K) the higher value obtained by the writer can hardly be due to depletion owing to the size of the vessel. One drop introduced into an atmosphere containing 0·017 mgrm. of nitrogen peroxide would hardly deplete it sufficiently to account for the different value of K obtained, for one drop absorbs only 4×10^{-4} mgrm. of N_2O_4, but for times of 50′ or longer, no doubt the effect is appreciable. Local depletion of NO_2 in the neighbourhood of the drop might have accounted for the difference, but it was found that stirring the gas during the absorption by the drop made little difference to the time. However the results were not satisfactory and the errors were no doubt due to condensation on the side of the vessel; this effect appeared to be more prominent than that of absorption by alkalinity of the glass, as a silica globe gave much the same results.

The other method employed was the measurement of the vapour pressure of nitrogen peroxide. The vapour pressure of nitrogen peroxide at 90° is about 0·009 m.m., the time of colouring of a drop in an atmosphere exhausted with NO_2 from nitrogen peroxide at this temperature is 11′. The value for TC K would consequently be about 140×10^{-6}; measurements at other temperatures below 80°, agree approximately with this value for K, which is not very different from that obtained by the other method.

Heat tests on guncotton.—A long series of experiments, which will be published in full, have all led to the idea that nitric acid, or at any rate H ions, formed in the moisture in the guncotton has an accelerating influence on the decomposition, and that as the water is removed, the rate of evolution of gases becomes slower. It does not seem possible to explain otherwise the results of continuous tests, tests done after drying or evacuation, and tests done in the presence of other substances. The evolution of moisture follows a similar curve to the evolution of other gases. In looking through all the evidence for the view which has been held about the nitric acid, there does not appear to be any better hypothesis, for it fits in well with all the facts.

Continuous tests.—The suggestion made by Smart about the curious difference in the behaviour of iodide paper and of the α-naphthylamine drop at the beginning of continuous tests on cordite offers a possible explanation; but owing to change of temperature, the rate of evolution of gases is probably greater at first, when the unstable portions of the substance are broken up: the drop which absorbs more, may therefore deplete the atmosphere of gases too quickly and give rise to the anomalous maximum in the curve obtained with the drop reagent. This seems to the writer a more probable explanation, but further work would be needed to clear up this point.

Absorption of NO_2 *by guncotton.*—The writer pointed out that there seemed to be contradiction in the results of experiments with guncotton and nitroglycerin respectively which had been described by Robertson and Smart. The contradiction is due, in Smart's opinion, to the physical difference of the guncotton and the nitroglycerin comminuted on silica fibres. No doubt this physical difference exists, but it should tend to give an effect in the opposite direction. In the writer's opinion, the contradiction is due rather to the fact that the nitrogen peroxide is absorbed differently in the two cases; in the guncotton it is absorbed chiefly, not wholly, by the moisture in the guncotton, and in the nitroglycerin it is dissolved in that substance itself. Therein is the physical difference.

There is no doubt, however, that physical difference in the nature of explosives is a very important matter from the practical point of view. A single heat test, for this reason, often gives an unreliable result; a continuous test, on the other hand, might overcome such difficulties.

The practical use of the heat test.—In the discussion of these details, the main problem must not be lost sight of, that is, so to improve the heat test that it may become a thoroughly reliable stability test.

The vagaries of the test are due to differences in the moisture content of the explosives, the presence of foreign substances (like acetone), the physical condition of the explosive and the unreliability of the reaction on the starch iodide paper. None of these would matter, if the differences caused by each effect could be ascertained. It is the writer's opinion that the suggestion made in the last paper would attain this object, namely that a continuous test on the sample of the explosive should be carried out alongside that on a standard sample, and a comparison made of the results obtained. The continuous tests need not last more than 2 or 3 hours, and tests need only be made every ½ hour. It is suggested, also, that the tests should be done with a nitrous acid indicator in the drop form, as well as with the iodide indicator on paper: in this way a reliable knowledge of the stability of the explosive could be established, for the effect of the various disturbing factors could be ascertained.

The values of the first test are important, because if it is short the explosive contains oxides of nitrogen from previous decomposition, or it shows its instability owing to the change of temperature to which it has been submitted; subsequent tests should make it possible to distinguish between these two sources. A single Abel heat test is doubtless a valuable indication of the stability of the explosive, and it has the advantage of being carried out under conditions very similar to those to which the explosive is normally exposed, and it is easy to carry out; its unreliability however, owing to various influences, is its chief drawback. The writer hopes that this drawback will be removed by his suggestion.

Discussion.

Dr. R. Robertson understood Mr. Egerton to hold that while at some higher temperature (say at that of the Will test) the dominant action was that of decomposition, it was possible at the lower temperature of 80° C. for an equilibrium to be set up between the explosive and its products of decomposition. Apart from the known catalytic effect of these on the explosive heated under dry conditions, it might be recalled that even down to a temperature of 40° C. Vieille had found guncotton to decompose in a continuous and regular manner (Mém. Poudres et Salpêtres, **15**). He gathered that in the apparatus illustrated on the board, less nitrogen had been obtained than might have been expected. That might possibly be due to absorption of nitric peroxide by traces of liquid water in the small space in which the products of decomposition were evolved, for he had found in experiments on the decomposition of guncotton *in vacuo* (J. Chem. Soc., **91**, 772) that this space must always be sufficiently large to prevent the deposition of liquid water, proceeding either from decomposition of the guncotton or constitutionally combined, or possibly oxides of phosphorus may have absorbed some of the oxides of nitrogen. In contact with heated guncotton the oxides of nitrogen were reduced to nitrogen, and the more readily the greater the opportunity for reaction between them and the heated explosive. This reduction, noticeable in the Will test, where the products were carried off in a stream of CO_2, became much more pronounced in a closed space, and might have more bearing on the results obtained in the continuous test with guncotton, than the conception of an equilibrium in an instance where the products were found to exercise a catalytic influence on decomposition and where the decomposition had been followed down to a fairly low temperature.

Mr. W. Macnab said that up to a point the heat test was an extremely useful means of testing explosives, but when it was pushed too far and asked to do too much, he thought one got into an unknown land. On the other hand, work like that of Mr. Egerton and Dr. Robertson was all to the good, and ultimately they would get a clear idea of what the heat test could do.

Mr. Egerton in reply said that, with regard to Dr. Robertson's remarks as to the Will test, he thought those results were not very different in a way from what he (Mr. Egerton) had got. Will in his experiments had mentioned the other irreversible effect, and as Dr. Robertson had said those experiments lasted several years. He had noticed especially with cordites that the results of his continuous tests remained constant for a time and then dropped, then remained constant a bit and dropped. He, the speaker, had never gone on for more than 36 hours even with guncotton; but if one went on long enough he had no doubt the same effect would be observed with guncotton. The apparatus he had shown was evacuated with a pump. The guncotton was admitted and the pump had a phosphorus pentoxide tube in connection with it so that the guncotton was fairly dry. After long heating the guncotton gave off the water of constitution; but he had not seen a sufficient quantity in the tube so he did not think nitrous acid could account for these results. On the other hand, he criticised the apparatus himself and he could improve it for the purpose. The mercury was bound to get left in the burette to a small extent, and of course the mercury would absorb the nitrogen oxide at once. Besides that, there was a small amount of grease in the taps which would take some nitrogen oxide, but he did not think that could account for it all disappearing. Finally, he thanked Sir William Ramsay for allowing him to use the apparatus, which was one of Sir William's masterpieces.

Manchester Section.

Meeting held at the Grand Hotel on Friday, December 5th, 1913.

MR. JULIUS HÜBNER IN THE CHAIR.

THE ACTION OF STRONG NITRIC ACID ON COTTON CELLULOSE.*

BY EDMUND KNECHT AND ADOLF LIPSCHITZ.

The remarkable action of strong nitric acid (68 per cent.) on cellulose appears to have been first noticed by Francis (Chem. Soc. Trans. 1885, 183), who proposed to utilise this action for the toughening of filter papers intended for use in filtering under diminished pressure. In 1893, Horace Koechlin pointed out that cotton on being steeped in strong nitric acid did not undergo any diminution in strength, but that it acquired an affinity for basic colours (rhodamine). He also found that after washing the fibre retained a certain amount of fixed nitrogen. In 1896, one of the present authors showed (Soc. Dyers and Col., **12**, 89) that when bleached cotton is treated with nitric acid of 82° Tw. it contracts considerably, becomes much stronger and evinces a greatly increased affinity for direct cotton colours; no increase in its affinity for methylene blue could, however, be observed. On the other hand it was noticed that the treated cotton showed a marked affinity for some acid colours (*e.g.*, Brilliant Scarlet 2 R. Berlin). It was further shown in 1904 by the same author (Ber., **37**, 549) that the mercerising action of nitric acid on cotton only began at ordinary temperatures at 76° Tw. and that the most suitable strength of the acid for the purpose was 83° Tw. Acid of 62°, 42°, and 22° Tw. was found to exert a tendering action on the fibre. These results were partly corroborated by the researches of Hübner and Pope (this Journal, 1904, **23**, 406), who showed that the amount of benzopurpurin taken up by cotton which had been treated with acid of 65° Tw. was very small as compared with that taken up by cotton which had been treated with acid of 83° Tw.

It was further shown by one of the present authors (l.c.) that the mercerising action was preceded or accompanied by the formation of a labile cellulose nitrate which approximated to the composition $C_6H_{10}O_5.HNO_3$ and which was instantly decomposed by contact with water into nitric acid and cellulose, showing in this respect an analogous behaviour to the phenanthrenequinone nitrate of Kehrmann and Mattisson (Ber., 1902, **35**, 343).

It has been shown by Vieille (Compt. rend., 1882, **95**, 132) and by Häussermann (Z. ges. Schiess- u. Sprengst.-Wesen, 1908, **3**, 121) that by the action of nitric acid of sp. gr. 1·52 on cellulose, actual nitration takes place, with the formation of a nitrate containing as much as 12·65 per cent. of nitrogen, *i.e.*, an amount approximating to that of a fully nitrated product (guncotton).

According to C. Hoitsema (Z. angew. Chem., 1898, 173) it is not possible to obtain a more highly nitrated product than that corresponding to the formula $C_{12}H_{14}O_4(NO_3)_6$, which demands 14·14 per cent. of nitrogen.

According to H. Koechlin, cotton treated with ordinary concentrated nitric acid forms a cellulose dinitrate, and this was corroborated by Knecht (l.c.). It has however, since been ascertained that the amount of fixed nitric acid in the treated cotton is considerably less than that demanded by a dinitrocellulose. The former conclusions of one of the authors were based mainly on the results of nitrogen estimations by the Dumas method, and it is probable that the copper spiral employed was not long enough, for subsequent experiments showed that it is necessary, in the estimation of nitrogen in nitrocelluloses to use a spiral at least three times as long as in ordinary nitrogen estimations, in order to avoid the formation of NO. In all the new experiments, the estimation of the nitrogen was made in the Lunge nitrometer.

---

* Excerpt from the dissertation of A. Lipschitz, presented fo the degree of Doctor of Technical Sciences at the Federal Technica High School, Zürich.

In any case the action of strong nitric acid on cotton cellulose is found to take place in two stages. The first and almost instantaneous reaction probably consists in the formation of the labile nitrate. The secondary reaction, which is comparatively slow, consists in the formation of stable nitrates, the nitrogen content of which increases up to a certain maximum and then, by continued contact with the acid, decreases down to a negligible quantity. In this connection it should be mentioned that Chardonnet proposed the use of nitric acid of sp. gr. 1·32 for the denitration of artificial silk (Germ. Pats. Nos. 46, 125, 1888, and 56,655, 1890).

The extent of the action of nitric acid on cellulose depends upon three factors, viz., concentration of the acid, time, and temperature. If the concentration is kept constant, it is found that by increasing the temperature the time required to produce a given result is shortened. Thus, whereas in using an acid of 83° Tw. the maximum of firmly combined nitric acid was obtained after three hours' steeping at a temperature of 31° C., the raising of the temperature in another experiment to 61° resulted in the expulsion of the whole of the nitrogen and the formation of oxycellulose. The properties of this beta oxycellulose are described below.

One of the most characteristic properties of cotton that has undergone treatment with strong nitric acid is its increased affinity for all classes of colouring matters. Of these, methylene blue forms a remarkable exception, and it is for this reason that one of the authors did not find himself in agreement with H. Koechlin, who appears to have used rhodamine as a typical basic dyestuff. In many cases, *e.g.* the direct cotton colours, the mercerising action of the nitric acid is sufficient to account for the increase in the affinity for dyestuffs. In the case of the basic colours, the presence in the fibre substance of the stable nitrate may account for this property, while in other cases again (*e.g.* certain vat dyes and sulphide colours) the oxidising action of the combined nitric acid on the reduced dyestuff is at least a contributory cause to the increased affinity of the fibre for such dyestuffs. Only in the case of acid dyes, such as naphthol yellow, have we been unable to afford any satisfactory explanation from the chemical point of view as to why there should be increased affinity of the mercerised and nitrated cotton.

In connection with the behaviour of mercerised cotton in dyeing a point arises which has never yet received a satisfactory explanation. It is well known that cotton mercerised with caustic soda shows an increased affinity for most colouring matters, and Justin-Müller (Z. Farben-Ind., 1904, **3**, 251), as well as Dreaper (Chem. News, 1904, **90**, 179), have sought to explain this by the assumption that the swelled fibre substance approaches the colloidal condition. If this were the only cause for the increased affinity shown by mercerised cotton for direct colours, mercerisation with caustic soda should give a fibre with a much greater affinity for these colours than mercerising with nitric acid, for the contraction, increase in strength and increase in weight of the air-dried material are much greater in the case of the former reagent. Experience has shown however that exactly the opposite is the case (see also J. Soc. Dyers and Col., 1908, 69) and some other explanation will consequently have to be found for the increased affinity of mercerised cotton for such colouring matters.

In connection with the marked affinity shown by Chardonnet silk for basic colours, it is still a moot point as to what this is due to. It might be caused by the presence in the fibre substance of small quantities of combined nitric or sulphuric acid. On the other hand, Häussermann (Z. ges. Schiess- u. Sprengst.-Wesen, 1906, **1**, 39, 305), maintains that on denitrating the nitrate obtained from cellulose and nitric acid of 1·47 sp. gr., the acid-cellulose of Bumcke and Wolffenstein is formed. Denitrated collodion silk would therefore appear to be of the nature of an acid-cellulose, and this would at least in part account for its affinity for basic colours.

Experimental.

The substance used in the following experiments was a well-bleached two-fold cotton yarn containing only 0·073 per cent. of ash. Mr. C. F. Cross kindly determined the alpha-cellulose in a sample of the material and found this to be 96·6 per cent. The nitric acid employed in all cases was of 83° Tw. strength (sp. gr., 1·415) and the proportion of acid to cotton taken was 100 c.c. of acid to about 5·5 grms. of cotton. After steeping for the required length of time in the acid, the cotton was taken out, well washed in running water until free from acid and was then further examined.

The influence of time was tried at two different temperatures, and the results are given in the following tables:—

TABLE I.

Showing the amount of nitric acid (expressed in terms of nitrogen) which combines with cotton cellulose at –5° C.

The results are also shown in the curves in Figs. 1 and 2. The main line A in Fig. 1 shows the results obtained at the ordinary temperature, while the dotted line B shows those obtained at –5° C. Fig. 2 gives a graphic representation of curve A in Fig. 1, in which a day is taken as unit of time.

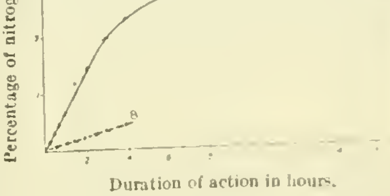

FIG. 1.

The formation of oxycellulose which begins at the same time as the decomposition of the nitrate (denitration) must be accompanied by a corresponding formation of nitrous acid. This was tested for by means of the Griess-Illosvay-Lunge reagent (sulphanilic acid and alpha-naphthylamine, dissolved in acetic acid). After 30 hrs. no trace of nitrous acid could be found, but after 35 hrs. it was found to be present, while after 4 days the amount found was 0·04 grm. (the weight of cotton used in this experiment was 11 grms.). Substances other than oxycellulose are however simultaneously formed, and these are evidently soluble in water, for there is a loss after 7 days' steeping, of 35 per cent. in the weight of the cotton immersed.

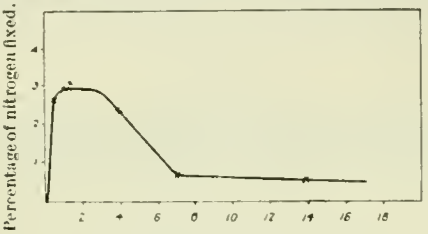

Fig. 2.

The influence of temperature in the nitrating process is as important as that of time and is shown in the following tables, of which Table III. gives the amounts of nitric acid (expressed in terms of nitrogen) taken up at different temperatures during an immersion of 30 seconds' duration.

The results are shown graphically in Fig. 3.

In relation to the results shown in Table V. it is interesting to note that the highest percentage of combined nitric acid is obtained at 31° C., and that at this point the formation of oxycellulose commences. The first indication of the presence of nitrous acid was obtained after 2 hrs. 30 mins. immersion. In its appearance the fibre had however lost the characteristics of mercerised cotton and had lost much in tensile strength. At 44°, the presence of nitrous acid was evident after 80 mins. immersion and after 2 hrs. 30 mins. the nitric acid showed a yellowish colouration, while the cotton was disintegrated into small fibres. At 61° the formation of oxycellulose was indicated by the appearance after 1 hr. 30 mins. of brown fumes and the resulting oxycellulose, which constituted not more than one-fifth by weight of the original cotton showed the same properties as the product obtained by the action of nitric acid after two months' steeping at the ordinary temperature.

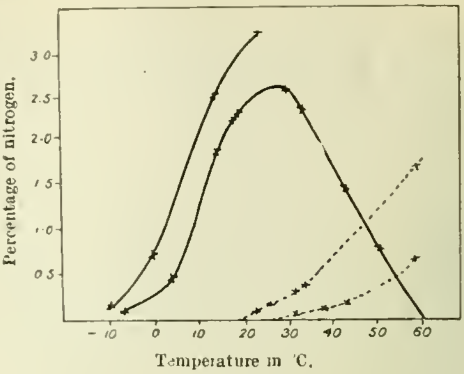

Fig. 3.

Physical properties of the treated cotton.

It has already been shown by one of the authors that cotton yarn after being steeped in nitric acid of 83° Tw. shrinks some 13 per cent. As in the case of caustic soda, the action is very rapid, most of the shrinkage taking place in the first 20 seconds. Generally speaking, the shrinking action is also more marked at low than at more elevated temperatures.

Previous work has shown that the strength of cotton yarn is influenced by steeping in nitric acid of 83° Tw. In the new experiments it is now shown that time and temperature are important factors. Thus, a considerable increase in strength is obtained by steeping for periods up to 15 minutes at the ordinary temperature, but this is not maintained after 30 minutes, and after 32 hours the tensile strength of the treated yarn is less than one third of that of the original. The other results are shown

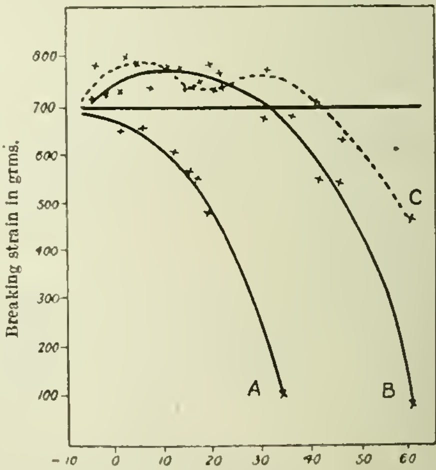

Fig. 4.

in Fig. 4, in which curve A shows the effect of a 3 hours' treatment at different temperatures, curve B the effect of 5 minutes' and curve C that of 30 seconds' treatment.

Cotton yarn which had been steeped in nitric acid for 30 seconds and 3 hours respectively was examined under the microscope in the ordinary way and in section and was compared in this way with the untreated yarn. The result of this examination showed that the effect of nitric acid on the structure of the fibres was very similar to that of strong caustic soda (mercerising).

Chemical properties of the treated cotton.

The ultimate analysis of the product formed by steeping cotton for three hours at the ordinary temperature in nitric acid of 83° Tw. gave the following figures :—

	Per cent.
C	40·23
H	5·91
N	2·14
O	51·72
	100·00

Its behaviour towards acetic, sulphuric and hydrochloric acids does not appear to differ from that of ordinary cotton. In 20 per cent. caustic soda it readily dissolves at the temperature of the water-bath. This reaction is evidently accompanied by a considerable amount of oxidation as about one-third. of the nitric acid originally present in combination with the cellulose was found as nitrous acid in the decomposition products.

It is interesting to note that the product after being denitrated by ammonium sulphide differs from that obtained by the denitration of gun cotton (with 13 per cent. N) in that it is neither soluble in weak nor in concentrated caustic soda.

Treated with N/50 solution of iodine in potassium iodide, the following behaviour was noticed :—

Bleached cotton	Very faint brownish colouration.
Witz's oxycellulose	,, ,, ,, ,,
Hydrocellulose	Slightly more pronounced.
Cotton steeped 40″ in HNO_3	Strong brown colouration.
,, ,, 5′ ,,	Very strong brown colouration.
,, ,, 3 h. ,,	Brown-black
,, ,, 16 h. ,,	Brown-black, but deeper.
Cotton steeped 5′ and denitrated	Strong brown colouration.
,, ,, 3 h. ,,	Very strong brown colouration.
Chardonnet silk	Blue black.
Nitrocellulose (13 per cent. N)	Faint yellow.
Mercerised cotton.	Slightly darker than bleached.

The behaviour of these various products was also studied towards ammoniacal silver nitrate. The reagent was made up as follows :—50 c.c. of a 2 per cent. solution of silver nitrate, 10 c.c. conc. ammonia and 0·5 c.c. of a 5 per cent. solution of caustic soda.

1. Bleached cotton	——
2. Witz's oxycellulose	Yellow.
3. Hydrocellulose	Faintly yellow.
4. Cotton steeped 40″	Turns slowly yellow, then yellowish brown.
5. ,, ,, 5′	
6. ,, ,, 3 h.	Turns slowly yellow, then yellowish brown. Sol. light yellow.
7. ,, ,, 16 h.	
8. Steeped 5′ and denitrated	Brownish colouration.
9. ,, 3 h. ,,	As No. 8, but stronger.
10. Chardonnet silk	,, ,, ,,
11. Nitrocellulose (13 per cent. N)	As No. 5.
12. Mercerised cotton	As No. 3.
13. Sol. of cotton steeped 8 months.	Black.

The product of the action of nitric acid of 83° Tw. on cellulose when tested by Schwalbe's process (Z. angew. Chem., 1910, 23, 924 ; this J., 1910, 688) was found to give a high copper number (31—33 at 20° C.).

Schiff's reagent (Magenta solution decolourised with sulphurous acid) gives a strong red colour with samples of cotton which had been steeped for 40 seconds, 3 hours and 16 hours, and the same behaviour was shown by cotton which had been steeped for 5 minutes and had been subsequently denitrated. From this behaviour, coupled with the fact that cotton steeped for 4 hours gives (with paranitro phenyl hydrazine a yellow colouration ten times deeper that that obtained with ordinary cotton would appear to indicate that treatment with nitric acid imparts to the cellulose the character of an aldehyde. This is all the more remarkable as Lunge and Bébié (Z. angew. Chem., 1901, **14**, 511) state that nitrocellulose prepared by the action of mixed acids is indifferent towards Schiff's reagent. It may be that in the nitrocelluloses formed in the two ways there are constitutional differences.

Behaviour towards colouring matters. It was known already to Kuhlmann (Comptes rend. 1856, **42**, 711, and **43**, 900) that a preliminary treatment of cotton with nitric acid increased its affinity for mordant colours. The best results obtained by this author were obtained by steeping the cotton for 20 minutes in nitric acid of 62° Tw. (sp. gr., 1·31). Later, one of the present authors showed that cotton treated with nitric acid of 83° Tw. showed a greatly increased affinity for the direct and for certain acid colours. The behaviour of cotton treated with nitric acid towards benzopurpurin has also been studied and reported upon by Hübner (this Journ., 1907, **91**, 1064), while Grandmougin (Z. Farbenind., 1907, **36**) maintains that by using an acid of 67° Tw. at higher temperatures the affinity for direct colours decreases (possibly through formation of oxycellulose).

Direct colours. The following points are of interest in connection with the increased affinity of the treated cottons towards these colours :—

Benzopurpurin 4B. The affinity for this colour is very strong and gradually increases up to a certain point with the duration of the period of steeping. When this point is reached the amount of colouring matter taken up diminishes, so that after 16 hours' steeping the shade obtained is lighter than that obtained after 3 hours' steeping. This result is probably due to oxidation of the dyestuff by the combined nitric acid. The denitrated product takes up less colouring matter than the nitrated but nevertheless much more than untreated cotton.

Chrysophenin behaves similarly to benzopurpurin, likewise diamine sky blue, though in the latter case there is a material difference in its behaviour towards cotton which has been steeped for 16 hours. The depth of shade obtained in dyeing under this condition is only about half of that obtained on ordinary cotton. This is possibly due to the fact that diamine sky blue is easily destroyed by oxidising agents. In the case of Erika which represents another class of direct cotton colour, the maximum depth was obtained on cotton which had been steeped for 3 hours. The comparative behaviour of this dyestuff towards cotton which had been steeped for 3 hours and had then been denitrated and towards Chardonnet silk is noteworthy in that the latter is only dyed a faint shade while the former dyes about twice as deep as untreated cotton.

In the case of Heliotrope BB, with the formula :—

$$\begin{array}{l} CH_3O.C_6H_3.N : N.C_{10}H_5(SO_3Na)NHCH_3 \\ \quad\;\; | \qquad\qquad\qquad\qquad\qquad (7) \qquad\; (2) \\ CH_3O.C_6H_3.N : N.C_{10}H_5(SO_3Na)NHCH_3 \end{array}$$

there is about the same increase in affinity up to 3 hours' steeping as with other direct colours, but it is noticeable that as nitration proceeds, the shade becomes redder, and this is very pronounced after 16 hours' steeping. This behaviour is analogous to the effect of light on Crystal Violet and may be due to the oxidation of the methyl groups, which are the cause of the blue shade of the original dyestuff.

In the table, it has been attempted to give a rough summary of the results obtained with six typical direct colours. The amounts of colouring matter were not estimated accurately, but were judged by the depth of shade of the dyed patterns. In each case the shade obtained on ordinary cotton is taken as standard or unit, 2 for instance indicating twice the depth of that obtained on ordinary cotton.

Table showing the relative amounts of direct cotton colour taken up in dyeing :—

	Benzopurpurin 4 B.	Chrysophenin.	Diamine Sky Blue.	Erika BN.	Heliotrop BB.	Oxamine Green MN.
Ordinary cotton	1	1	1	1	1	1

,, ,, ,, 3h. and denitrated.	2	2	2	2	3	3
Chardonnet silk	2	1·25	1	0·5	0·1	1·25

Basic colours. In comparing the behaviour of these colours towards the treated cotton, the dye trials were carried out at the boil for one hour.

Auramine II. is not taken up by cotton steeped for 3 hours and then denitrated in larger amount than by ordinary cotton. This finding is in conformity with that of Hübner and Pope (this Journ., 1903, **22**, 70), in regard to the behaviour of all basic colours towards cotton mercerised with caustic soda. It is remarkable that the amount of Auramine taken up by cotton which has been steeped 21 hours is comparatively greater than with any other basic colour tried ; nevertheless it is not as pronounced as the affinity of Chardonnet silk for this dyestuff. Rhodamine B does not dye Witz's oxycellulose any deeper than it does ordinary cotton ; in other respects it resembles Auramine. It is noteworthy that the steeped and denitrated cotton has even less affinity for Rhodamine than ordinary cotton. Brilliant Green resembles Rhodamine except in its extraordinary affinity for Chardonnet silk. With Safranine and Bismarck Brown the shades become brighter in the presence of combined nitric acid. In both cases, Chardonnet silk is dyed very deep shades. In the case of Methylene Blue. it is characteristic that very little increase in the affinity is shown after steeping even for 3 hours.

The results obtained are shown in the following table :—

	Auramine II.	Safranine FF extra.	Rhodamine B	Bismarck Brown extra.	Brilliant Green extra.	Methylene Blue B.	Spirit Blue.
Untreated cotton	1	1	1	1	1	1	1

,, 5' and denitrated	1	1	0·75	1	0·75	1	—
,, 3 hrs. ,, ,,	1	1	0·75	1	0·75	1	0·5
Chardonnet silk	8	8	3	8 >	10 >	10	—

Acid colours. Kuhlmann observed, as far back as 1856 (Comptes rend., **42**, 711) that by nitrating or by the moderated action of nitric acid, the cotton fibre acquired an affinity for picric acid. We find that by simply steeping for a short time in nitric acid of 83° Tw., no affinity has been produced for this dyestuff. After steeping for at least one hour, the fibre begins to take up picric acid and the amount taken up increases with the time of steeping which was prolonged to 21 hours. It is evident that the presence of the combined nitric acid is the cause of this remarkable behaviour, for denitrated cotton no longer shows any affinity for the dyestuff. Acid Violet 3 BN showed a similar behaviour, but in the other cases, the denitrated cotton still dyed deeper shades with acid dyes than ordinary cotton.

The results are shown in the following table :—

	Picric acid.	Naphthol Yellow S.	Crystal Scarlet 6 R.	Eosin A.	Naphthylamine Black 4 BN.	Acid Violet 3 BN.	Lanacyl Blue R.
Ordinary cotton	1	1	1	1	1	1	1
Witz's oxycellulose	1	1	0·1	1	0·2	0·5	0·1
Cotton steeped 40"	1	2	1	2	2	1	2
,, ,, 5'	1	2	1·5	2	2·5	1	2·5
,, ,, 3 hrs.	5	10	4	4	4	6	3
,, ,, 21 ,,	8	9	3	4	grey-black	6	1
,, ,, 5" denitrated..	1	2	1·5	2	2	1	2
,, ,, 3 hrs. ,, ..	1	2	1·5	2	2·5	1	2·5
Chardonnet silk	1	1	0·1	1	0·5	2	0·0

Sulphide colours. In their behaviour towards ordinary and treated cotton, these dyestuffs behave like the direct colours, and according to the researches of Biltz (Ber., 1905, **38**, 2973) and of Minajeff (Z. Farbenind., 1907, **6**, 313) on the laws of adsorption should be classified as such.

	Katigen-Brilliant Green G.	Thion Yellow G.	Sulphur Brown G.	Immedial Sky Blue.
Ordinary cotton	1	1	1	1
Steeped 40"	2	2	2	2
,, 5'	3	2·5	2	2
,, 3 h.	3	3	2	1·5
,, 16 h.	1·5	2·5	1·5	1·25
,, 3 h. and denitrated	2·5	1·5	1·5	1·75

Saposchnikoff and Minajeff (*ibid.*, 1905, **4**, 81) showed by quantitative experiments that the affinity of cotton mercerised by caustic soda was one and a half times as great as that of ordinary cotton. It is now found that by mercerising with nitric acid, the affinity of cotton for these colours is somewhat more than doubled. Prolonged steeping has, like in many other cases, the effect of diminishing the affinity, and this was found to be especially marked in the case of Immedial Sky Blue, which began to show a decreased affinity even after 3 hours' steeping.

Some typical results are given in the preceding table.

Feydion blue which constitutes, as it were, a link between the sulphide and vat dyes, behaves in a similar manner.

Vat dyes. According to Saposchnikoff and Minajeff (l.c., 1903, 2, 257) mercerised cotton dyed against ordinary cotton in the vat takes up one and a half times as much indigo as the latter. By mercerising with nitric acid and then dyeing in vat dyes, it is found that still larger amounts of colouring matter are taken up than by mercerising with caustic soda. This increase in affinity is evidently due to two causes, one of which is the mercerising *per se*, while the second contributory cause is to be found in the oxidising action of the combined nitric acid in the fibre. (See also Knecht, Journ. Soc. Dyers and Col.)

It is seen, namely, that in dyeing in the vat, especially with indigo and thioindigo red, the dyestuff and not its leuco compound is fixed *in the vat*. Algol Red B forms an exception to the general behaviour of the vat dyes tried, in that it falls off considerably in intensity on cotton which has been steeped for 3 hours. The results are shown in the following table :—

	Ciba Scarlet G.	Algol Red B.	Helindone Red B.	Helindone Blue BB.	Indanthrene S.	Indigo.	Thioindigo Red B.
Ordinary cotton	1	1	1	1	1	1	1
Witz's oxycellulose	0·75	0·75	0·75	0·75	1	1	1
Cotton steeped 40″	2	2·5	2·5	2·5	2	3	2·5
,, ,, 5′	2·5	2·5	2·5	2·5	2·2	3·5	3
,, ,, 3 hrs.	3	0·9	3	3·5	1·8	6	4
,, ,, 16 ,,	3	0·9	3	3	1·7	10	5
,, ,, 3 hrs. and denitrated	2	2	2	2	2	1·5	1·5

Some further experiments were done in the case of indigo with a view to ascertain the strength of acid which would give the best results. To this end bleached calico was spotted with nitric acid of different strengths, washed and then dyed in the vat. It was thus found that the action only began with acid of 80° Tw. (sp. gr. 1·4) and increased up to 86° Tw. (sp. gr. 1·43) beyond which strength the experiments were not continued. This mode of experimenting may, however, be open to an objection in that the amount of acid being limited, it is diluted by the natural moisture in the cotton.

The colours obtained on cotton treated with nitric acid show the same fastness to light, rubbing and washing as those obtained on untreated cotton.

Aniline Black. A copper black dyed in a full shade on cotton which had been steeped in nitric acid for 3 hours showed a red shade, but by previously denitrating the cotton, this did not occur. If, however, the Aniline Black liquor was used more dilute, so as to yield only a thin black on ordinary cotton after ageing and chroming, it was found that the nitric acid treated cotton yielded only a dirty grey and this is probably due to excessive oxidation of the aniline by the chlorate present in the liquor on the one hand and the combined nitric acid in the fibre on the other.

Tannic acid. Previous experiments have shown (Knecht and Kershaw, this Journ., 1892, **11**, 129, and Saposchnikoff and Minajeff, Z. Farbenind., 1904, **3**, 164) that cotton mercerised with caustic soda takes up one and a half times as much tannic acid as ordinary cotton. It is now found that towards cotton mercerised with nitric acid (steeping 40 seconds) tannic acid shows at least twice the affinity as towards ordinary cotton. With cotton steeped for 3 hours there is a decrease in the amount of tannic acid fixed, but this is evidently due to destruction by oxidation as denitration of the cotton caused it to take up more tannin again.

DISCUSSION.

Mr. **William Thomson** asked whether, in denitrating cotton, the nitro-compound went into solution, as he understood the author to state that nitrated cotton lost considerably in weight by the process. What was the nature of the solution of the partially nitrated cotton in caustic soda? He had treated filter paper with sulphuric acid, and afterwards exhausted the paper thoroughly with water, and determined the amount of acid remaining in the paper. He found on each occasion he did not get the quantity of acid from the paper which was originally put into it, the presumption being that the acid remained in combination with the cellulose.

Dr. **G. J. Fowler** inquired whether Professor Knecht had made special experiments as to the degree of nitration best adapted for fixing acid dyes on cotton, whether he had any theory as to the action which took place; further, if he had tried any other reducing agents than ammonium sulphide, and if there was any likelihood of other reagents being effective. It was known to be possible to decompose cellulose by organisms, both in the presence and in the absence of nitrates, and it was a matter for enquiry as to whether nitrated cellulose could be fermented by itself and what the action would be. He was aware Professor Knecht had experimented on the action of enzymes on cellulose, and would like to learn whether he had incidentally tried the action of enyzmes or of bacterial ferments on nitrated products.

Dr. **H. Levinstein** asked whether the dye tests were made cold or hot. He would imagine from the appearance of the direct dyestuffs they were dyed cold. Had Professor Knecht made a comparative washing test of the Acid Violet on what he called "animalised cellulose" and on ordinary animal fibre. It would be interesting to know whether Acid Violet was fixed on the nitrated cellulose with the same tenacity it was fixed on wool.

Dr. **M. Wyler** asked what was the special lightfastness of treated and untreated cotton dyes.

Mr. **Hübner** enquired as to the relationship of the fastness of an acid colour and eosine, as in the case of an eosine some light would be thrown upon the problem of dyeing. He also asked whether any experiments had been made by viewing the fibres in polarised light. He believed the late Mr. Guttmann had first drawn attention to the difference between guncotton and ordinary cotton when examined in polarised light.

Mr. **L. E. Vlies** asked whether Professor Knecht had observed any increased resistance to weak mineral acids of cotton treated with nitric acid, and if so what was the best strength of nitric acid and temperature to use. This information would be valuable in connection with the treatment of cotton filter cloths with mixed acids, or nitric acid alone, to give resistance to the action of weak, hot, mineral acids.

Mr. **R. des F. Shepherd** enquired whether the nitrated cellulose was inflammable.

Dr. **T. J. I. Craig** asked whether nitrated cotton behaved differently to unnitrated cotton with regard to stripping agents; also had Professor Knecht any information regarding the action of nitric acid on artificial silk, and had it the same effect upon the strength of the silk as it had upon that of the cotton.

Professor **E. Knecht**, in reply, stated he was not in a position to say what became of the nitro-compound when it went into solution. He did not think a certain amount of the fibre dissolved in water as a nitrate. The question had been partly studied by Berl, who, in the course of his investigations on the action of caustic soda on guncotton obtained a most complicated mixture of acids, some nitrogenous and some not nitrogenous, but nearly all belonging to the fatty series. The whole molecular complex was broken up when this treatment was carried out hot: but if guncotton was treated with cold caustic soda, then some soluble nitro acids were obtained, which were precipitated by acids from the solution. He was very much interested in Mr. Thomson's experiment with filter paper treated by sulphuric acid. The point had recently been investigated by Heermann, who sought to show that Chardonnet silk contained combined sulphuric acid. He, personally, did not feel quite satisfied upon the point, that esters did actually exist in a fibre like Chardonnet silk. He had not put forward the processes described in the paper as actually of commercial value. He had not gone systematically into the question of the best temperature for fixing acid dyes on cotton. In the majority of cases there was a considerably increased affinity for colouring matter, the main cause being the mercerisation. Naphthol Yellow, which could be taken as a typical acid dye, gave a very strong shade. Cotton mercerised with nitric acid showed a much stronger affinity for colouring matters than cotton mercerised with caustic soda. As yet there was no explanation for the increased affinity of ordinary mercerised cotton, and he was equally unable to offer an explanation for the behaviour of cotton mercerised with nitric acid. There was no doubt that combined nitric acid in many cases was a contributory factor to the absorption of colouring matter. This was evidently the case with the basic and the sulphide colours, and particularly with the vat dyes, where the oxidising action of the combined nitric acid made itself evident in fixing the larger proportion. He took it, it was similar to the increased affinity shown by cotton dyed Manganese Bronze for vat dyes. It was known that if cotton were dyed Manganese Bronze, and then dyed with indigo or other vat dyes, it took up a very much larger percentage of colouring matter. He had gone into the question of reducing agents referred to by Dr. Fowler, and had tried all sorts of reducing agents to reduce the nitric acid in cellulose, but had not found anything which would take the place of ammonium sulphide, though perhaps sodium sulphide would act in the same way. He had tried hydrosulphite of soda, both in the presence of a little caustic soda or in the presence of ammonia, with the result that in either case it rotted the fibre and did not denitrate it. This was remarkable as hydrosulphite was known to possess in other respects a far more powerful reducing action than ammonium sulphide. Stannite of soda was without action. He had not gone into the question, but he thought that it would be very interesting to ascertain whether either the nitrated or the denitrated product was capable of undergoing any process of fermentation. The specimen cotton hanks exhibited were treated quite roughly at a boiling temperature, except the vat dyes, which were treated cold. He was somewhat afraid the experiments rather complicated the theory of dyeing for he was quite at a loss to explain certain of the phenomena observed. With regard to comparative washing tests of Acid Violet on nitrated cotton and on wool, it had been shown that the colour was not so fast as in the case of wool. He had not made any test with regard to the fastness to light of the colours, not having thought the process of any technical value. He was, however, very glad the suggestion had been made and would make some trials. He had not made any experiment with regard to eosine and Acid Violet, nor with regard to polarised light, although the latter test was apparently quicker and more reliable than a determination of the nitrogen in the nitrometer. They had made some general tests as to the effect of weak mineral acids on the product, and there was not much difference between the nitrated product and ordinary cotton. He was of opinion that in order to obtain an acid-proof fibre it would be necessary to nitrate very much higher than he had done. The inflammability of the material was not greater than that of ordinary cotton. In reply to Mr. Craig, he had not tried the action of stripping agents on colours dyed on the nitrated cotton, but he imagined it would require a larger amount of stripping agent to strip colours from nitrated cotton than from ordinary cotton.

Scottish Section.

Meeting held at Glasgow on Tuesday, November 25th, 1913.

DR. THOMAS EWAN IN THE CHAIR.

THE COMPOSITION AND AGRICULTURAL VALUE OF CARBONATE OF LIME FROM CAUSTICISING PLANT.

BY JAMES HENDRICK, B.SC., F.I.C.

In the aggregate enormous quantities of carbonate of lime from causticising plant are produced and allowed to go to waste. There are, I understand, about 58 paper mills in Scotland alone, most of which have causticising plant. The production by these of waste carbonate of lime, dry, is probably not less than 20,000 tons per annum. In the case of works known to the writer there are dump heaps containing thousands of tons of this substance, while in other cases expense is incurred in carting it to hollows which are filled up with it and other waste of the works. Occasionally it is got rid of by running it into a river or other watercourse.

Much burnt lime and carbonate of lime are used for agricultural purposes, and much more ought to be used. Formerly lime, both in the form of burnt lime and carbonate of lime, was used to a far greater extent than at present. For a variety of reasons the use of lime began to fall off about 40 years ago, and between 1870 and 1900 the practice of liming became almost non-existent over a great part of Scotland. Since 1900 liming has been increasing again, but only to a limited and partial extent, and one may say that over large parts of Scotland farmers have been living, so far as lime is concerned, on the capital laid up in the soil by their predecessors. With the gradual exhaustion of the store of available lime the soil is becoming sour, and various evils, such as weeds which are favoured by sour, lime-deficient soils, and the disease of finger and toe in turnips, are becoming more prevalent.

It has been shown by drainage experiments that every cultivated soil is constantly losing lime. Hall and Miller * have estimated that the loss of lime in the drainage of unmanured plots at the Rothamsted Experiment Station is equal to 1000 lb. of carbonate of lime per acre per annum. The loss is greater from manured plots. Similar results have been obtained on the Continent, where Creydt † and his co-workers estimated from drainage experiments on a cultivated and manured field that the loss of lime in the drainage was 630 kilos. of CaO per hectare, which is almost exactly 1000 lb. of carbonate of lime per acre.

It is estimated that the average loss per acre per annum throughout England and Wales is not less than 500 lb. of carbonate of lime. If we take it at this figure for Scotland also, and for cultivated and manured land, it is probable that this is an under-estimate: at least 500 lb. of carbonate of lime, or 280 lb. of quicklime, per acre per annum should be applied to all cultivated land. In other words, at least 1 ton of commercial burnt lime of good quality or 1¾ tons of good quality chalk or ground limestone, should be applied once in seven years merely to maintain the lime of the soil. Only a fraction of this amount is used at present.

For many purposes at any rate it is safer and better to use carbonate of lime than to use burnt lime. Formerly great quantities of soft chalks, marls, shell sands, and other easily friable forms of carbonate of lime were applied to the soil, and in recent years a considerable amount of hard limestone rock has been ground for application to the soil as "ground limestone." While expense is thus being incurred in grinding limestone to a comparatively coarse powder, the very fine precipitated carbonate of lime of causticising plant, which is specially valuable on account of its very great fineness of division, is being thrown away.

Samples of the waste carbonate of lime as it comes from the dump heaps of different paper works were obtained, and analyses of a number of these are shown in Table I.

TABLE I.

Analyses of Wet Waste Carbonate of Lime.

	I.	II.	III.	IV.	V.
	Inverurie.	Inverurie.	Culter.	Culter.	Stoney-wood.
	per cent.	per cent.	per cent.	per cent.	per cent.
Moisture ...	49·64	47·84	38·29	47·97	43·78
Carbonate of lime	37·31	44·04	51·93	45·64	49·91
Lime in other forms	9·35	3·30	0·87	0·32	6·80
Alkalinity (as NaOH) ..	8·25	2·89	2·24	1·61	3·65
Silica	0·64	2·15	2·86	2·78	1·70

Nos. I., II. and V.: The alkalinity was due to free lime.
Nos. III. and IV.: The alkalinity was due to carbonate of oda and caustic soda. There was no free alkaline lime.

The amount of moisture in, and the composition of these samples, vary somewhat according to the nature of the process used, and the methods used in removing the carbonate of lime from the caustic lye. In some works the process is comparatively crude and rough, while in others it is carried out with greater precision and with more perfect appliances. In crude samples the moisture is nearly 50 per cent., but in samples which have been well drained or treated in a vacuum filtering apparatus, it is considerably less than 50 per cent.

Several paper works known to the writer have for years offered this substance free of charge to farmers who will take it away, but in no case has any substantial quantity been taken. The objection seems to be that it is sticky and difficult to spread when wet. Further, farmers are unfamiliar with it, and are very doubtful if it is of any value at all. It is quite possible to use it in the undried state, and much of it might be used in this way by farmers in the neighbourhood of paper works, for if it is scattered about in lumps and left exposed for a short time to dry weather or to frost, it readily falls to powder and can then be spread. Where it has to be carried any considerable distance before use it will probably be found better to dry it.

It is easily dried by artificial means, and at the suggestion of the writer some paper works have experimented on drying it, and one at least is now drying it on a large scale and is selling it to farmers in this state at a price sufficient to cover the costs of drying and marketing. Even if nothing more is obtained, this is a saving as compared with incurring expense merely to dispose of it as a waste product. When dried, it is more easily disposed of to farmers, and the firm in question has got rid of hundreds of tons during the past few years.

Table II. gives analyses of a number of dried samples obtained from different sources.

TABLE II.

Analyses of Dried Waste Limes.

	I.	II.	III.	IV.	V.
	per cent.	per cent.	per cent.	per cent.	per cent.
oisture	4·02	1·23	12·27	9·51	13·48
arbonate of lime	66·50	88·33	68·08	60·84	74·20
me in other forms	13·89	3·48	3·74	11·60	1·45
kalinity (as NaOH)	16·08	0·63	4·37	6·76	0·92
ica	2·40	1·65	3·48	2·48	4·97

No. I. contained alkaline lime equal to 11·26 per cent. CaO; ual to 14·87 per cent. $Ca(OH)_2$, and practically no soda.
No. II. contained no free alkaline lime, and very little soda.
Nos. III. and V.: The alkalinity was due to soda and carbonate soda.
No. IV.: Like No. I., contained much alkaline lime.

In addition to carbonate of lime, which is the chief substance present, and which may constitute upwards of 90 per cent. of a well-dried sample, there are smaller quantities of other substances present. The material is sometimes very alkaline, in other cases very little alkalinity is exhibited (Nos. II. and V., Table II.). In some cases the alkalinity is due to alkaline lime (Nos. I., II., and V., Table I.; and Nos. I and IV., Table II.), which shows that considerable excess of lime had been added in the causticising tanks. In other cases the alkalinity is due to the presence of sodium hydroxide and sodium carbonate (Nos. III. and IV., Table I.; and No. III., Table II.), which indicates that the soda lye had not been efficiently drained from the precipitated lime. There is always a small quantity of silica present, chiefly as silicate of lime, and some organic matter. On the whole, however, the dried samples contain as much available lime, as carbonate of lime and hydrate of lime, as is contained in ordinary commercial ground limestone, and they contain more than half as much available lime as is contained in ordinary commercial burnt lime. By "available lime" is meant lime available to neutralise acids, and therefore in a form which will be of use for the purposes for which lime is needed in the soil.

Field Experiments.—The field experiments carried out by the writer with paper works waste lime were not undertaken primarily to determine the value of this substance for field use. Their main object was to demonstrate the value of lime as a remedial agent in combating the disease of finger and toe in turnips. At the outset the writer was inclined to the common view that burnt lime is far more effective for the object in view than carbonate of lime. The paper works carbonate of lime was included among the different kinds of lime used, as it was a waste product extensively produced locally, the value of which it was thought it might be worth while to test in comparison with other forms of lime more generally used by farmers. Further study of the subject has shown that one of the principal reasons which led to the general use of burnt lime in agriculture was that such lime can readily be brought into a fine state of division by slaking and can thus be thoroughly incorporated with the soil. Another important reason for the use of burnt lime was that carriage was saved by its use. In former days, before means of transport were developed to the present extent, this was a consideration of even more importance than at present. In course of time it has been forgotten that these were the main reasons for the adoption of the use of burnt lime in agriculture and not any essential superiority for most agricultural purposes of calcium oxide or calcium hydrate over calcium carbonate. If we look back to the agricultural records of the first half of the nineteenth century we find that wherever soft chalks, marls, or shell sands could be obtained, they were used extensively in the surrounding districts without being burnt to quicklime, but on the other hand, where only hard limestone rock could be obtained or where lime had to be carried from a distance, burnt lime was used. There is little doubt that for nearly all purposes carbonate of lime is, weight for weight of lime, as valuable as burnt lime, and that on certain soils and under certain conditions carbonate of lime is a safer and better substance to apply to the soil than quicklime. The results of the four experiments described below are in favour of this view.

These experiments are only part of a series which is at present in progress, and they are very incomplete. Such experiments should be carried out not for one or two years only but over a considerable period of years, so as to cover more than one rotation of crops on the same land. But it is very difficult to arrange this except on an experimental farm, and till now this has not been available to the writer. When carried out on the lands of private persons, and especially of tenant farmers, for obvious reasons it is generally impossible to have the experiment continued for more than a short period.

In some of the experiments mentioned below the lime was applied only a few months before the turnips were drilled. It would have been better had it been possible to commence the liming at least a year or two before the land came into turnips. Also had one had complete control of the land and been able to keep in view merely the experiment without considering the natural wish of the farmer not to risk the loss of a crop, much larger quantities of lime would have been applied to some of the plots than were applied. Experiments covering all these points are at present in progress; meantime the results already obtained are quoted because they illustrate the value of paper works waste lime.

Field experiments suffer from the disadvantage that the probable error of a single experiment is very great. In measuring differences, therefore, which are not very great it is necessary to repeat the experiment over and over again on a large number of plots in order to obtain significant figures. In the experiments here described the differences found in the incidence of disease and also in the weight of crop obtained are so great that the figures may safely be regarded as significant.

The experiments were carried out on soils which were known to be badly infected with finger and toe, and on which the turnip crop had been seriously injured by the ravages of the disease the last time the land was under turnips. In all four cases samples of the soil were taken for analysis, and in every case it was found that the soil was distinctly acid in its reaction to litmus paper. Analyses of the soils were made, and among other things the percentages of lime were determined which could be extracted from each by digestion with strong hydrochloric acid, and by treatment with cold 1 per cent. citric acid, according to Dyer's method, respectively. The results are shown in the table below.

TABLE III.

Amount of Lime (CaO) found in the Soils.

	Kinmundy.	Greenhowe.	Barra.	Blackhills.
Extraction with hydrochloric acid	0·70	0·61	1·72	0·62
Extraction with 1 per cent. citric acid	0·163	0·225	0·125	0·246

Although all these soils were found to contain an appreciable quantity of lime soluble even in weak citric acid, it does not follow that they contained any carbonate of lime. As they were all found to be acid in reaction the presumption is that they contained little, if any, carbonate of lime. They were therefore tested by a modification of the method of Amos and Marr.* In this modification the soil is not heated with acid, but air freed from carbon dioxide is drawn through it for several hours after addition of an excess of hydrochloric acid and the carbon dioxide estimated by Brown and Escombe's double titration method after absorption in a Reiset Tower. This method when used with suitable precautions is capable of estimating carbonate equal to less than 0·05 per cent. stated as carbonate of lime in 20 grams of soil. It does not of course follow that if carbonate is found it is necessarily present as carbonate of lime, but it is usual to estimate it as such.

In the case of all four soils no appreciable amount of carbonate could be detected. The titration never differed from the blank, which was always carried on alongside, by more than 0·1 c.c. of the $N/10$ HCl used. This is well within the probable error of experiment for the method.

The first experiment was carried out at Kinmundy where the soil is a good rich loam and carries heavy crops, but when previously in turnips the crop was almost completely destroyed by disease. Two varieties of turnips were grown on the plots; Challenger Green Top Yellow, and a Purple Top Yellow. The purple top variety was known to be very liable to disease.

Waste carbonate of lime from two different paper works, marked I. and II. in the table, was used. It was applied at the rate of 4 tons per acre. To another plot "shell lime" was applied at the rate of 2 tons per acre. All the lime was applied in January about 5 months before the turnips were sown. Four tons of paper works lime was taken as a standard dressing in these experiments, while 2 tons of shell lime of good quality, which contains about the same amount of available CaO as 4 tons of paper works lime, was taken as the standard dressing of this substance for purposes of comparison.

The weights of turnips per acre obtained on the different plots are shown in Table IV.

TABLE IV.

Finger and Toe Experiment: Kinmundy.

Variety (A) Challenger Green Top Yellow. Variety (B) Purple Top Yellow.

		No lime.		Waste carbonate of lime. 4 tons per acre.				Shell lime. 2 tons per acre.	
				I.		II.			
		tons	cwt.	tons	cwt.	tons	cwt.	tons	cwt.
Weight of turnips per acre	(A)	20	10	22	10	22	16	21	19
	(B)	10	11	13	1	13	1	13	1
Increase over no lime	(A)	—		2	0	2	6	1	9
	(B)	—		2	10	2	10	2	10

As the table shows considerable increases of crop were obtained from the use of each kind of lime and on each variety of turnips.

It was found that in spite of the liming the purple top turnips were very badly diseased on all the plots, while the green tops were affected to only a comparatively slight extent. This accounts for the great differences in weight between the two varieties. Up to a certain point they seemed to be equally vigorous. Had they been weighed early in the season instead of in December, it is probable that the purple tops would have given weights quite as great as the green tops, but after a certain point they went down rapidly with disease, and at the time of weighing there was hardly a turnip of this variety on any of the plots which was not more or less attacked. At the same time there was a great difference between the disease on the limed and on the unlimed plots. There were far more turnips which were only slightly diseased on the limec than on the unlimed plots.

An attempt was made to estimate the incidence of th disease, but the methods adopted were too crude to giv results of value except in so far as they taught us tha better but more laborious methods would have to b adopted in succeeding experiments. In the experiment which follow the incidence of disease was estimated by th extremely laborious method of lifting individually and a once examining on the field a large number of bulbs fror each plot, and dividing these into three classes:—

(A) *Badly diseased*, or those in which the bulb was cithe completely or badly rotted by the disease;

(B) *Slightly diseased*, where either the bulb was nc touched by the disease which was confined to the root or where the bulb, if attacked, was not rotted by tl disease;

(C) *Sound*, where no disease was noticed.

---

* Jour. of Agr. Science, 1905, I., 322, and 1909 III., 155.

It does not follow that bulbs classed as "sound" were quite free from disease. In pulling the bulbs many of the roots were left in the ground, and if the disease was confined to these it would not be noticed. The number of bulbs examined on each plot always amounted to several hundreds. These were taken up in lots of one hundred each along one drill, and the lots were systematically distributed over the plot so as to give as fair an average as possible.

In this method the disease is estimated not by weighing but by counting. Many of the bulbs in the badly diseased class were so far gone with disease that they were not fit to be weighed at all in estimating the crop by weight.

The result of this first experiment showed that the amount of lime applied was not sufficient on this soil to control the disease in the case of a susceptible variety like the purple tops, though in the case of both varieties it certainly diminished disease and increased the weight of crop.

The second experiment was carried out at Greenhowe on a poor, shallow, mossy loam, with pan beneath. The soil was distinctly acid, and infested with such weeds as are found on sour soils. The crop suffered considerably from drought as well as from the bad condition of the land. Gas lime at the rate of 2 tons per acre was used in this experiment as well as paper works carbonate of lime and shell lime. The lime was not applied directly to the turnip crop but early in the previous year before a crop of oats. Table V. shows the weight of crop per acre, and the incidence of disease on the different plots.

In every case the liming greatly increased the weight of crop, and in the case of paper works lime and shell lime, greatly diminished the amount of disease. The plot which was dressed with paper works lime was almost free from badly diseased roots, while that which received shell lime had the badly diseased reduced from over 20 per cent. to under 5 per cent. This plot was perhaps hardly fairly treated with regard to weight of crop per acre. The crop on it suffered most from drought and probably it was the thinnest soil. The dressing of gas lime, though it increased the weight of crop considerably, did not diminish the disease very much.

The third experiment was carried out on a good, fairly deep loam at Barra. This soil yields good crops, but was rotten with disease when previously in turnips. The lime was applied in February, only three months before the turnips were sown. Waste lime from two different paper works was used as well as shell lime and gas lime. The results, both as to weight per acre and incidence of disease, are shown in Table V.

As in the last experiment any form of lime increases he crop and diminishes the disease, but, just as at Greenowe, waste lime from paper works does better than either shell lime or gas lime, especially in diminishing disease. One sample of waste lime gave a better result both as to weight of crop and as to diminution of disease than the other. While the differences are not great enough to be treated as significant in the case of single plots, it is interesting to notice that the plot which gave the better result was treated with a waste lime containing a distinct amount of soda (Analysis III., Table II.). This indicates, at least, that the presence of soda was not injurious in the quantity here used. There was at first some hesitation in using this lime as it was feared that the soda might be injurious to the crop.

The fourth experiment was carried out on a somewhat peaty loam at Blackhills. The soil was considered a fairly good one, but was not in very good condition, and the previous turnip crop had been very badly diseased. The soil was quite acid in reaction and badly infested with such weeds as rejoice in a sour soil. Paper works waste lime, lime shells, and gas lime were all used as before. All these forms of lime were applied only two months before the turnip seed was sown. The results in this case were very curious, as none of the dressings of lime had any distinct effect in diminishing the disease or increasing the crop. The results tabulated in the usual form are shown in Table VI.

The differences in weight of crop and in amount of disease shown in this table from the use of lime, are of a quite different order from those shown in Tables V. and VI. In order to find the reason for this anomalous result, the soil from the limed plots was examined, and it was found that on this peaty soil the amount of lime used was not sufficient to neutralise the acidity. The limed soils were still acid to litmus paper. A representative sample taken from the plot which had been dressed with paper works lime was analysed. It yielded to extraction by strong hydrochloric acid 0·78 per cent. of CaO, and to extraction by 1 per cent. citric acid 0·34 per cent. of CaO. As might be expected, these figures are both somewhat greater than those given by the untreated soil (Table III.), but the lime was not present as carbonate of lime. When tested by the method described above no carbonate of lime was found: 20 grams of soil yielded the same result as the blank determination.

The soil sample was taken to a depth of 9 inches. There are roughly speaking about 1000 tons of soil on an acre to a depth of 9 inches. The paper works lime used contained 74·2 per cent. of calcium carbonate (V., Table II.), therefore about 0·3 per cent. of calcium carbonate had been added to the soil. As none was found the whole of this had been neutralised by the soil acids, and the soil still remained sour to litmus paper. It is evident that on this soil much more lime was needed to produce a result. It is proposed to make further investigations on this soil.

The foregoing results are, as already indicated, incomplete, but so far as they go they show that for, at any rate, certain soils paper works waste carbonate of lime is at least as effective as the other forms of lime in ordinary use. As great quantities of this by-product are at present being wasted, it seemed to be desirable to publish these early results, for it will be to the interests both of agriculture and of the paper makers if this waste lime is used for application to the soil.

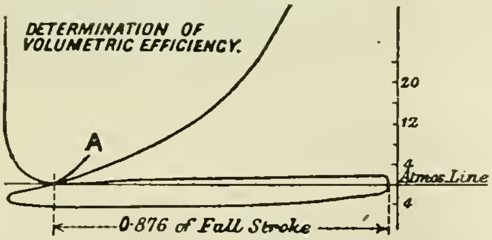
Journal and Patent Literature.

PATENT SPECIFICATIONS may be obtained by post by remitting as follows:—
English.—8*d.* each, to the Comptroller of the Patent Office, W. Temple Franks, Esq., Southampton Buildings, Chancery Lane, London, W.C.
United States.—1*s.* each, to the Secretary of the Society.
French.—1 fr. 05 c. each, as follows; Patents dated 1902 to 1907 inclusive, Belin et Cie., 56, Rue des Francs Bourgeois Paris 3e.); Patents from 1908 to date, L'Imprimerie Nationale, 87. Rue Vieille du Temple, Paris.
German.—1 mark each (with full particulars) to Kaiserlich Patentamt, Berlin, Germany.

I.—GENERAL PLANT; MACHINERY.

Internal-combustion engines; Commercial tests of ——. W. A. Tookey. Engineering, 1914, **97**, 129—132.

THE author has made 763 tests of gas engines of various makes and sizes as found in actual use by consumers. In 66 per cent. of the cases, the working was improved by adjusting the gas and air supplies, the ignition and the valve-setting. The average increase in the power obtained at each impulse was 27 per cent., and the average reduction in the consumption of gas per indicated horse-power per hour was 13·3 per cent. The method of testing recommended consists in taking indicator diagrams, including diagrams with light spring, and observing the number of impulses and the gas consumption per min. On the light-spring diagram (see Fig.), the point, A, where the compression line crosses the atmospheric line, gives the "volumetric efficiency," which is multiplied by the piston displacement in order to find the "effective piston displacement." It is assumed that the compression curve follows the law $\frac{P_1}{P_2}=\left(\frac{V_1}{V_2}\right)^{1\cdot3}$, and from the observed compression pressure P_2, the ratio of V_1 (the cylinder volume corresponding to point, A, in the figure) to V_2, the clearance volume, is at once obtained. The clearance volume, V_2, is then equal to the effective piston displacement divided by $\left(\frac{V_1}{V_2}-1\right)$, and the total cylinder volume at the point, A, is equal to the clearance volume added to the effective piston displacement. This volume, divided into the volume of gas used per impulse, as shown by the meter, and multiplied by the calorific value of the gas, gives the "mixture strength," *i.e.*, the number of British thermal units per cb. ft. of the actual mixture of gas, air, and exhaust gases which is present in the cylinder at the point, A. The factor $\frac{\text{mean pressure of diagram}}{\text{mixture strength}}$ affords a valuable test of the working of an engine. A factor of 2·4 is considered very satisfactory.—A. T. L.



PATENTS.

Mills for grinding, crushing, pulverising, separating, or mixing materials. E. Allen and Co., Ltd., Sheffield, H. Grey, Rotherham, and L. D Parker, Sheffield. Eng. Pat. 5069, Feb. 28, 1913.

A SERIES of large and small balls are arranged in a revolving circular track and are kept in position by an overhanging segmental stationary track which carries a series of scoops. The material is fed into the track and the finely-ground material is forced outwards and upwards by centrifugal force and directed upwards under the guidance of the scoops, to a fan driven by the same shaft as the track, but at a higher speed. The fan, the indraught to which is regulated by an adjustable circumferential damper, discharges the finely ground portion of the material through annular discharge openings and allows the coarser portions to return to the grinding channel. —W. H. C.

Evaporating apparatus for liquids. Farbenfabr. vorm. F Bayer und Co., Leverkusen, Germany. Eng. Pat 15,624, July 7, 1913. Under Int. Conv., Feb. 18, 1913

IN evaporating apparatus working under a high vacuum the boiling points of the upper and lower layers of liqui differ greatly if the depth of liquid is considerable. Thi defect is avoided in the apparatus claimed, in which number of slightly inclined boiling tubes pass across steam space and are provided at the ends with sma chambers or pockets having vapour-escape openings a the top and overflow pipes at the bottom leading to the tubes arranged next below, the depth of the overflow pipes being such that the depth of the liquid to be evaporated cannot exceed the diameter of the boiling tubes. —H. H.

Evaporating apparatus. D. Cozzolins, San Diego, Cal. U.S. Pat. 1,082,411, Dec. 23, 1913.

A steam-jacketed evaporating vessel has a number of frames or grids fixed within the upper part, from which weighted sheets of fabric hang down into the liquid and expose a large surface from which evaporation takes place.—W. H. C.

Desiccating ; Apparatus and process for——. L. C. Merrell, Assignor to Merrell-Soule Co., Syracuse, N.Y. U.S. Pats. 1,082,468 and 1,082,469, Dec. 23, 1913.

The liquid to be desiccated is introduced periodically in the form of spray into a chamber containing a gaseous moisture-absorbent which is also admitted and discharged periodically by valves operated by mechanism connected with that controlling the liquid-supply valve in such a manner that the spray and moisture-absorbent are confined within the chamber for an interval of time before being discharged. The desiccated product is separated from the moisture-laden absorbent in a separate chamber connected with the outlet pipe, while a fresh charge of liquid is being desiccated in the main chamber. The process is specially applicable for desiccating organic liquids containing solids, heated air being employed as the moisture absorbent.—H. H.

Distilling apparatus. J. A. Houser, Marion, Ind. U.S. Pat. 1,082,525, Dec. 30, 1913.

Air under pressure is forced by a piston-pump into the lower portion of the still, which is fitted with a stirrer, a relief valve, and a pressure-regulating valve on the pipe leading to the condenser.—A. T. L.

Gases ; Method of treating ——. C. A. Weeks and R. M. Hunter, Assignors to T. R. Patton and F. C. Mencke, Philadelphia, Pa. U.S. Pat. 1,083,233, Dec. 30, 1913.

Gases produced by chemical action, for example in coke ovens or in furnaces, are withdrawn under reduced pressure, and successive separate portions of the gases are cooled and scrubbed in the presence of a body of liquid over which they travel with decreasing speed and at increasing pressure until the pressure reaches that of the atmosphere.—A. T. L.

Solution of solid substances : Process for the continuous ——, especially for slaking lime with sugar juice or water. H. Eberhardt, Maschinen- und Armaturenfabrik. Ger. Pat. 268,442, April 10, 1912.

The solid material is conveyed downwards by means of a screw through a vertical perforated cylinder disposed centrally within the dissolving vessel, through which the solvent liquid passes also from the top to the bottom. The vertical cylinder is provided externally with curved blades which force the solvent to pass through the solid material resting on the blades of the screw. The dissolving vessel is connected at the bottom, below the outlet for the solution, with the lower end of a worm elevator, the upper end of which is enclosed in a perforated casing and is at such a height that the undissolved (or unslaked) solid material is discharged in a dry condition. The apparatus s specially suitable for the preparation of milk of lime. —A. S.

gitating and aerating liquids or pulps ; Apparatus for ——. A. C. Howard, Assignor to Minerals Separation, Ltd., London. U.S. Pat. 1,084,210, Jan. 13, 1914.

EF Eng. Pat. 22,743 of 1912 ; this J., 1913, 1055.—T. F. B.

ubricating grease which may be used for preventing and removing incrustations from steam boilers. Eng. Pat. 17,288. *See* XII.

IIa.—FUEL ; GAS ; MINERAL OILS AND WAXES.

Natural gas ; Condensation products of ——. L. Singer. Petroleum, 1914, 9, 453—469.

Fractional condensation is now the method used for the liquefaction of natural gases (this J., 1914. 15). The highest pressure reached in the compressors does not exceed 17 to 24 atmos., with temperatures not below 0° C. The first stage of compression (up to 3½ atmos.) yields gasoline of sp. gr. 0·6955 to 0·672, whilst in the second stage a product of sp. gr. 0·6365 to 0·616 is obtained. Between the first and second compressors is a system of cooling coils which effects further condensation, whilst in the second compressor the process is completed by sudden expansion of the compressed gas from about 24 atmos. to the ordinary pressure. The gasoline obtained by a process of fractional cooling in ammonia expansion coils without the use of compressors is stated to be of better quality than that produced by the compressor system. The latter gasoline is impregnated with the so-called "wild product," which causes a loss of up to 25 per cent. in storage. It is also of a yellow tint and requires further purification. A condensation product of sp. gr. 0·6855 to 0·651 obtained by fractional cooling alone, contained about 30 per cent. of pentane, 30 per cent. of hexane, and less than 7 per cent. of hydrocarbons of lower sp. gr. than 0·779, together with butane and higher hydrocarbons. The sp. gr. of the moist gas was 0·964 to 1·04, and that of the petroleum oil, 0·8705 to 0·8464. The gases leaving the second-stage compressors, may be subjected to further treatment to obtain condensation products known as "liquid gas" and "gas oil." For this purpose Snelling's process (U.S. Pat. 1,056,845 ; this J., 1913, 414) is employed. A mixture of ethane, propane and hexane is thus obtained, and this when liquefied in steel cylinders is sold as "gas oil." The residual natural gas is better suited than before for all ordinary purposes. "Gas oil" is a colourless transparent liquid at a pressure of 28 atmos. and volatilises without condensation at the normal temperature. One vol. of liquid gas oil yields 350 vols. of gas of 21,360 small cals. per litre (2400 B.T.U. per cb. ft.). It has a flame temperature of 2300° C., and thus gives more light with a mantle than air gas (flame temperature 2150° C.) or ethane (2205° C.). It can be used with every type of burner. The price per cb. m. is about 14 Pf. (3s. 10½d. per 1000 cb. ft.). The sp. gr. of gasoline from natural gas ranges from below 0·590 to 0·724. According to the method of production it is liable to contain more or less dissolved gas, and accidents caused thereby in transport have led the Official Classification Committee (U.S.A.) to publish the following specifications with which these products must comply :—"*Liquefied petroleum gas* is a condensation product of the gas issuing from the casing head of petroleum springs. If it has a lower vapour pressure than 10 lb. per sq. in. at 100° F. (37·7° C.), or at 90° F. (32° C.) from Nov. 1 to March 1, it must be described and transported as "gasoline." "Should the vapour pressure exceed 10 lb. but not exceed 25 lb., the product must be termed "liquefied gas," and be transported in metal drums or casks, or in tank wagons approved by the Master Car Builders' Association. Products having a vapour pressure above 15 lb. must be dealt with as "compressed liquefied gas." Difficulties in pumping caused by the dissolved gas are eliminated by expelling the gas by hot water coils or a current of air, or, more recently, *in vacuo* during the process of condensation. The "liquefied gas" has given good results in motor engines. A condensation plant costs on the average about $8000 (about £1670), and the expenses of dealing with 100,000 cb. ft. of gas per day are estimated at $5000 (about £1040) or $9275 (about £1930) for 500,000 cb. ft. A plant for 1,000,000 cb. ft. could be worked by six men. The market price of the condensation products ranges from about 10 cents (5d.) per gall. (American galls.) in the Gillcrease district to 14 to 18 cents (7d. to 9d.) in California. According to Hill the total production of gasoline from natural gas in the United States by 250 works in 1912 was 12,081,179 galls. (7,425,839 galls. in 1911), and for 1913 the total output is estimated at over 16,000,000 galls. (See also this J., 1913, 999, 1096).—C. A. M.

Petroleum oil fractions; Specific heat of heavy —— at high temperatures. N. Karawajeff. Neftjanoje Djelo, 1913, No. 16. Petroleum, 1914, **9**, 550.

Determinations of the specific heat of heavy fractions of petroleum oils by means of Bunsen's ice calorimeter have given the following results :—The mean specific heat of the fractions examined increased rapidly with the temperature. The specific heat of most of the fractions approximated 0·48 at 100° C., but rose to about 0·60 at 400° C. Between 100° and 400° C. the specific heat could be expressed with sufficient accuracy as a linear function of the temperature, in the case of the majority of petroleum oil products, viz., $C_m = 0{\cdot}4825 + 0{\cdot}000385\,(t-100)$. The specific heat of petroleum oil fractions of different sp. gr. differed but slightly at the same temperatures. The true specific heat could be calculated by means of the formula—

$$\frac{dQ}{dt} = 0{\cdot}4825 + 0{\cdot}00077(t-100),$$

according to which the true specific heat at 400° C. approximates 0·7110.—C. A. M.

Petroleum production in the United States. Eng. and Min. J., Jan. 17, 1914. [T.R.]

The production of petroleum in the United States experienced a noteworthy expansion in 1913, which was stimulated by the high prices prevailing for crude oil in every field. The accompanying table, which is based upon reliable estimates, gives the details of the production during the last three years in barrels of 42 galls.

Field.		1911.	1912.	1913.
		barrels.	barrels.	barrels.
California		77,224,359	84,823,992	96,881,967
Colorado		226,926	200,000	(*a*)220,000
Gulf	Texas	9,256,474	11,778,324	(*f*)14,280,000
	Louisiana	10,720,420	(*e*)9,791,896	(*e*)12,750,000
Illinois		31,317,038	28,400,000	21,600,000
Lima	Indiana	1,695,289	1,200,000	3,814,000
	Ohio	2,960,711	3,000,000	
Mid-continental (*b*)		57,911,525	52,771,603	64,556,000
Kentucky-Tennessee		472,458	500,000	(*a*)500,000
Appalachian (*c*)		26,117,960	26,000,000	22,224,000
Wyoming (*d*)		194,690	500,000	2,354,000
Others		5,000	5,000	(*a*)50,000
Total		218,372,850	218,970,815	239,229,967

(*a*) Estimated. (*b*) Kansas and Oklahoma. (*c*) Pennsylvania New York, West Virginia, and eastern Ohio. (*d*) Includes Utah, (*e*) Includes Marion County, Texas. (*f*) Includes Panhandle field of Texas.

Although there was a diminished production in the Eastern fields, there was nevertheless great activity in them and general prosperity.

Abel-Pensky apparatus; Extension of upper limit of applicability of the ——. K. Scheel. Petroleum, 1914, **9**, 545—546.

Experiments made in connection with the work of the International Petroleum Commission have shown that the upper limit of the Abel-Pensky flash-point apparatus may be extended to 150° C. Oil with flash points ranging from 100° to 149° C. were tested in two standard Abel's apparatus and two Pensky-Marten's apparatus, a special cylinder oil being used for the bath of copper or hard-soldered brass, whilst with the Pensky apparatus the determinations were also made over a gas-flame with the aid of a stirring device (cf. this J., 1913, 1096). The rise of temperature was at the rate of 2° C. and 3° C. per min. After applying the corrections for errors inherent in the copper or brass bath, the errors in the results with both forms of apparatus ranged from —0·8° to + 0·4° C. The correction to be applied for any individual apparatus varies directly with the temperature, and it is sufficient to determine it by comparison with a standard apparatus at two given temperatures and to interpolate it for other temperatures.—C. A. M.

Oils for steam turbines; Testing and valuation of ——. F. Schwarz and J. Marcusson. Mitt. K. Materialprüfungsamt; Papierfab., 1914, **12**, 73.

Those oils are most satisfactory which form no emulsion when shaken with water but which separate out easily. A number of samples of oils, the behaviour of which in practical use with steam turbines was known, were tested, and the following characters established as indicative of satisfactory quality: Degree of fluidity at 20° C., 9—14; sp. gr. at 15° C., 0·890—0·905; "tar value," not exceeding 0·2, determined after 50 hours' uninterrupted heating at 120° C. The oils must be pure mineral oils free from acidity and soaps; the ash-content must not exceed 0·01 per cent.—J. F. B.

Ozokerite; Origin of ——. J. Marcusson and H. Schlüter. Chem.-Zeit., 1914, **38**, 73—74.

Evidence is adduced in support of the view that ozokerite and petroleum have been produced together (from organic remains) and have become separated by a process of natural upward filtration, the relatively insoluble amorphous hydrocarbons of high molecular weight being retained by the porous rock, etc., through which the oil has penetrated, whilst crystalline paraffins of low molecular weight have passed on in solution.—F. Sodn.

Commercial tests of internal combustion engines. Tookey. *See* I.

Patents.

Peat; Process of and apparatus for treating ——. J. Berglund, Eskilstuna, Sweden. Eng. Pat. 11,971, May 22, 1913.

The peat is disintegrated and macerated in water by cutter-rollers or other convenient disintegrators, stones, twigs, portions of trunks or branches of trees, etc., being removed by an endless band conveyor-strainer which allows the pulp and water to pass through. The mixture of water and peat pulp is drawn off into settlers in which the peat dries into lumps which have a high fuel value and low content of ash.—W. H. C.

Peat, etc.; Treatment of [extraction of water from] ——. E. A. Buckle, Prestwich, Assignor to The International Nitrogen and Power Co., London. U.S. Pat. 1,083,317, Jan. 6, 1914.

The peat is pulped, and an electric current is passed through it while heated to 100° or 120° C. under a pressure of 10 atmospheres.—A. T. L.

Gas furnaces; Method and means for mixing gas with air for ——. W. Hoeller, Köln-Ehrenfeld, Germany. Eng. Pat. 29,654, Dec. 24, 1912. Under Int. Conv., Dec. 27, 1911.

A conical gas nozzle is arranged so as to cause air to be drawn in by the gas in a current surrounding the current of gas, and a conical deflector is arranged opposite the air and gas nozzles, so as to spread the currents outwardly and to diffuse them uniformly in layers. The dimensions of the mixing chamber near the nozzle and deflector are such that the velocity of the currents is not affected by the varying temperature of the gases. The object is to prevent preliminary ignition and the deposition of tar.
—A. T. L.

Gas retorts; Continuous ——. W. von Oswald, Coblenz, Germany. Eng. Pat. 24,234, Oct. 25, 1913.

A "feeder" projects into the top of the retort and is connected above with a tapered "filler" which has a doubly tapered cross-piece disposed centrally. The coal is fed into the filler from a hopper above; the latter carries a number of stampers which are actuated by cams and tap

the coal into the filler and cause it to be packed evenly and fall regularly through the feeder and retort.
—W. H. C.

Gas producer. N. F. Egler, Assignor to The Blair Engineering Co., Chicago, Ill. U.S. Pat. 1,083,067, Dec. 30, 1913.

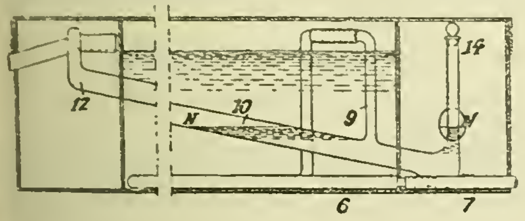
The body of the producer is cylindrical and rotates about an inclined axis. Fixed gas outlet and fuel feed devices are provided at the upper end of the producer and a fixed ash-discharge and an axial blast pipe at the lower end. The upper end of the blast pipe is screened by an inverted V-shaped hood having openings in its sides for distributing the blast. This hood projects horizontally from the blast pipe, and serves for stirring the fuel.—A. T. L.

Gas; Process of producing ——. J. H. Hirt, El Paso, Texas, Assignor to Allis-Chalmers Manufacturing Co. U.S. Pat. 1,083,683, Jan. 6, 1914.

Finely powdered carbonaceous material is blown, together with sufficient air to form carbon monoxide, tangentially into a chamber in which the mixture burns, moisture is mixed with the hot gases, and a portion of the resulting gas is withdrawn and passed with the material into the furnace chamber.—A. T. L.

Benzol in illuminating gas, Apparatus for determining the quantity of ——. Soc. Roubaisienne d'Eclairage par le Gaz et l'Electricité, and R. R. L. H. Forrières. Ger. Pat. 267,491, May 16, 1913.

A known volume of the gas is passed through benzene and the quantity absorbed measured; the difference between this quantity and the total quantity contained in the gas when saturated with benzene gives the quantity originally present in the gas. A sheet iron tank (see Fig.) is divided into three compartments, the middle one being filled with water. The copper tube, 6, is connected by rubber tubing, 7, with the gas-supply tube. The gas rapidly acquires the temperature of the water, and passes through the glass tube, 9, 10, which is filled with benzene up to the level, NN; the exit end, 12, of the tube, 10, is constricted to a diameter of 1 mm. After about 10 litres of gas have passed and become saturated with benzene, the gas supply is cut off, and the quantity of benzene taken up by the gas ascertained by running in mercury at 14 from a measuring vessel until the benzene again stands at its original level, NN.—A.S.



Gas-cleaning mechanism. N. F. Egler, Assignor to The Blair Engineering Co., Chicago, Ill. U.S. Pat. 1,083,068, Dec. 30, 1913.

The gas passes upwards through the scrubber in a ircuitous path between fixed annular baffles, alternating with circular baffles carried by a rotating shaft. The baffles are dished downwards, and the fixed baffles are hollow and perforated for discharging water into the crubber. The shaft is rotated by a water motor arranged n a chamber at the top of the scrubber, and the water which has passed through the motor is supplied to the crubber through valved connections —A. T. L.

'as washing and cooling apparatus. E. F. Lloyd, Detroit, Mich. U.S. Pat. 1,083,885, Jan. 6, 1914.

HE apparatus comprises a series of chambers communiating at their lower ends through openings sealed by the ashing liquor. The first of these chambers serves for cooling the liquor. The gas is passed in succession upwards through each of the other chambers, and meets a descending spray of liquor, the quantity of which can be varied independently in each chamber, separate pumps being provided for raising the liquor from the bottom of one chamber to the top of the next. The cooling chamber contains a coil over which the hot liquid is caused to flow in a descending stream.—A. T. L.

Benzine, petrol, etc.; Process of and apparatus for refining ——. H. Wade, London. From V. Beer, Vienna. Eng. Pat. 29,833, Dec. 27, 1912.

In the continuous process of purifying petrol by admitting it to the lower end of each of a series of closed vessels containing acid or lye, through which the petrol rises by gravity, the petrol is forced through the vessels under an adjustable pressure, as by a pump, in order that the rate of flow may be under control. The petrol passes through two vessels containing acid, a settling tank, two vessels containing lye, another settling tank and finally two vessels containing water. Each vessel contains a sieve beneath, through which the petrol passes.—A. T. L.

Briquettes; Process of making ——. [*Use of sulphite-cellulose lyes.*] M. Platsch, Frankfort, Germany. U.S. Pat. 1,084,479, Jan. 13, 1914.

See Fr. Pat. 455,099 of 1913; this J., 1913, 864.—T. F. B.

Oil-gas producers. F. H. Bates, Philadelphia. Eng. Pat. 29,275, Dec. 19, 1912.

See U.S. Pat. 1,046,540 of 1912; this J., 1913, 77.—T. F. B.

Gaseous fuel; Method of producing ——. A. W. Southey, Edgware. U.S. Pat. 1,083,468, Jan. 6, 1914.

See Eng. Pat. 27,612 of 1911; this J., 1913, 77.—T. F. B.

Gas-producer. E. Ragot, Bettaincourt, and P. Pierre-Hervotte, Joinville, France. U.S. Pat. 1,083,507, Jan. 6, 1914.

See Fr. Pat. 435,691 of 1911; this J., 1912, 377.—T. F. B.

IIb.—DESTRUCTIVE DISTILLATION; HEATING; LIGHTING.

Cellulose, starch, sugar and sulphite-cellulose lye; Decomposition of —— *by heat.* G. Bantlin. J. Gasbeleucht., 1914, 57, 32—41, 55—61.

The behaviour on dry distillation of cellulose, starch, and sugar, substances having the same percentage composition, was compared by heating them under the same conditions in an iron retort, 44 cm. long and 6·5 cm. diam., arranged in an electrically heated oven. A length of 21 cm. of the retort was charged with the material, and the temperature was raised gradually so as to reach 100° C. in 1½ hours and 500° C. in 7 or 8 hours. The products of distillation in percentage by weight of the dry substance, were as follows:—

	Cellulose.	Starch.	Sugar.
Coke	32·9	28·6	12·2
Water	31·7	29·7	6·29
Tar	3·25	2·69	55·04
Acetic acid	3·28	5·29	8·78
Aldehydes	5·82	5·66	6·15
Ketones	0·11	1·11	0·34
Total gases	17·33	22·70	5·96
Carbon dioxide	11·26	13·08	4·37
Ethylene	0·24	0·39	0·05
Hydrogen	0·02	0·03	0·01
Carbon monoxide	4·78	7·64	1·29
Ethane	0·35	0·74	0·11
Methane	0·68	0·82	0·13
Loss or not determined	5·23	4·20	5·38
Composition of tar:—			
Carbon	52·20	45·02	38·91
Hydrogen	6·86	6·31	6·19
Oxygen	40·94	48·67	54·90

The time-temperature curves showed that with cellulose an exothermic decomposition takes place between 250° and 300° C. and that this reaction is complete at 320° C. This phenomenon is not shown by starch and sugar. The stability towards heat increases in the order cellulose, starch, sugar, but the first two are more nearly alike in this respect than either is to sugar. Since cellulose does not yield methyl alcohol on dry distillation, it has been supposed that waste sulphite-cellulose lyes contain the constituents of wood which yield valuable distillation products. The lye was therefore partially separated from sulphur compounds by passing through it a current of air and steam, evaporated to dryness, and distilled. A very small yield of liquid products was obtained, and no methyl alcohol, whilst large quantities of hydrogen sulphide and of mercaptan were evolved.—A. T. L.

Hydrogen, The sorption [adsorption and absorption] of —— by wood charcoal at the temperature of liquid air. J. B. Firth. Z. physik. Chem., 1914, **86**, 294—308.

The "sorption," by which is meant either absorption (solid solution) or adsorption (surface condensation), of hydrogen by wood charcoal has a two-fold character: the adsorption occupies only a few minutes, while the equilibrium due to absorption is first attained after several hours. A particular specimen of cocoanut charcoal weighing 1·4645 grm. took up, at atmospheric pressure and the temperature of liquid air, 136 c.c. in 30 minutes and 139·8 c.c. in 12 hours (measurements at N.T.P.), and of this latter amount it is estimated that about 23 c.c. was absorbed. Wood charcoal invariably contains crystalline as well as amorphous carbon; the activity of the specimen depends chiefly upon the latter. The shell of the cocoanut yields material which, volume for volume, is far more active than that from the lining; but on a weight comparison the values are practically identical.—J. R.

Patents

Electric incandescent lamps. The British Thomson-Houston Co., Ltd., London. From General Electric Co., Schenectady, N.Y., U.S.A. Eng. Pat. 2901, Feb. 4, 1913.

Cryolite or other double halogen salt or compound of aluminium and an alkali or alkaline earth metal is introduce into the bulbs of electric incandescence lamps for the purpose of increasing the efficiency or life of the lamp. A paste of very finely divided cryolite with a small quantity of inorganic or organic binding material is preferably applied to the supports or hooks carrying the filament, without actually touching the latter, or it may be supported upon a wire secured to the glass rod of the lamp in such a position relatively to the filament that it attains a temperature of between 300° and 700°—800° C. when the lamp is in use.—H. H.

X-Ray tubes, etc.; Method of producing high vacua in ——. C. A. Friedrich, New York. U.S. Pat. 1,083,677, Jan. 6, 1914.

During the process of exhaustion both the anode and the cathode are heated to bright redness by means of low potential currents in a relatively low vacuum, in order to expel all gases from the metal, and these gases are removed as they are set free.—A. T. L.

Arc-light electrode. J. L. R. Hayden, Schenectady, Assignor to General Electric Co., New York. U.S. Pat. 1,082,950, Dec. 30, 1913.

See Eng. Pat. 2027 of 1909; this J., 1910, 264.—T. F. B.

Arc-lamp electrode. C. P. Steinmetz, Schenectady, Assignor to General Electric Co., New York. U.S. Pat. 1,082,978, Dec. 30, 1913.

See Eng. Pat. 26,916 of 1904; this J., 1905, 270.—T. F. B.

Tungsten and method of making the same for use as filaments of incandescence lamps and other purposes. U.S. Pat. 1,082,933. *See* X.

III.—TAR AND TAR PRODUCTS.

Pitch; Determination of the temperature of softening of ——. M. Klinger. Chem.-Zeit., 1914, **38**, 63.

Discrepancies often occur, owing to the present loose definition of Krämer and Sarnow's method (this J., 1903, 291). An exact internal diameter of 6 mm. is now proposed for the glass tube employed in the estimation. This is charged by dipping into a layer of molten pitch some 7 mm. deep, at about 150° C. After one minute the tube is removed as with a pipette, and is rested with the lower end upon a cold glass plate. This gives a solid layer of about 5 mm. in thickness. 5 grms. of mercury are poured in, and the tube is finally transferred to a double water-bath at 40° C., the temperature being then raised by 1° C. per minute until the mercury sinks through. —J. R.

Benzol; Determination of total sulphur in commercial ——. K. Schenk. Chem.-Zeit., 1914, **38**, 83—84.

Irwin's method for the determination of total sulphur (this J., 1901, 440) is stated to give low results. The author describes a method and apparatus for the determination, in which the benzol is volatilised by an air current in a specially constructed flask, the escaping gas being ignited and the products of combustion conducted through hydrogen peroxide. The sulphuric acid thus formed is determined acidimetrically. The results obtained by this method are stated to be accurate.—W. R. S.

Nitrobenzenesulphonic acids; The formation of isomeric ——. A contribution on the "self-orientation" of substituting groups. J. Obermiller. J. prakt. Chem., 1914, **89**, 70—86.

By direct sulphonation of nitrobenzene the *m*-sulphonic acid is obtained, only about 2 per cent. of the *p*- and *o*-acid being formed. By nitration of benzenesulphonic acid, on the other hand, the yield of *o*- and *p*- acids can be raised as high as 50 per cent., more of the *o*-acid than of the *p*-acid being formed. The conditions favourable to this are decreasing concentration or quantity of the sulphuric acid in which the nitration is performed, and increasing temperature, the same conditions which favour *o*- and *p*-orientation in the case of the amino-group when working in sulphuric acid solution. In explanation of these facts, the author puts forward a theory of "self-orientation," viz., that the nitro-group, independently of other influences, tends on its own account to enter the ring as near as possible to the substituent already present, this tendency exerting itself the more as the ordinary *meta*-directing influence of the substituent is weakened. This power of the nitro-group is illustrated in the formation of the 1.8-derivative in the nitration of naphthalene-α-sulphonic acid, whereas by the sulphonation of α-nitro naphthalene the 1.5-derivative is formed exclusively. Another example is the exclusive *ortho*-orientation of the nitro-group in the nitration of *m*-toluic acid, the 6- and the 2-nitro-toluic acids (COOH=1) being formed. The old problem presented in technology by the predomination of the less valuable o-nitrotoluene in the nitration of toluene, and the predominance of the less valuable 1.8-isomeride in the nitration of α-nitronaphthalene, is illustrated by this theory.—J. B.

Patents.

Bituminous or tarry materials; Process for increasing the heat-resisting properties of ——. K. L. V. Zimmer, Hamburg, Germany. U.S. Pat. 1,084,520, Jan. 13, 1914.

See Ger. Pat. 228,497 of 1909 this J., 1911, 15.—T. F. B.

Anthraquinone-carboxylic acids and anthraquinone-aldehyde carboxylic acids; Manufacture of ——. Act.-Ges. f. Anilinfabr., Treptow, Germany. Eng. Pat. 10,796, May 7, 1913. Under Int. Conv. Nov. 19, 1912. Addition to Eng. Pat. 10,791 of 1913.

See Fr. Pat 456,768 of 1913; this J., 1913, 1060.—T. F. B.

Anthraquinone compounds; Producing ——. J. Boner, Assignor to Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. U S. Pat. 1,083,051, Dec. 30, 1913.

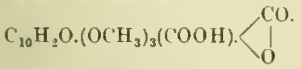
Halogenated 2·3-*naphthisatins.* W. Bauer, Vohwinkel, A. Herre and R. Mayer, Assignors to Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. U.S. Pat. 1,083,518, Jan. 6, 1914.

See Ger. Pat. 264,265 of 1912; this J., 1913, 972.—T. F. B.

IV.—COLOURING MATTERS AND DYES.

Galloflavin. J. Herzig and R. Wachsler. Monats. Chem., 1914, 35, 77—84.

Isogalloflavin can be readily obtained from galloflavin by allowing a solution of the latter to stand for some time and then acidifying and warming. Trimethylisogalloflavin, which is obtained, though in poor yields, from tetramethylgalloflavin by loss of a methyl group on hydrolysis, is shown to contain a carboxyl group and a lactone group, therefore it has the constitution:



$$C_{10}H_2O.(OCH_3)_3(COOH).\left\langle\begin{array}{l}CO.\\ \mid\\ O\end{array}\right.$$

The presence of the lactone ring is proved by its behaviour on treatment with caustic potash and methyl iodide or dimethyl sulphate, when a compound containing four methyl ether and two methyl ester groups is formed. This compound undergoes hydrolysis to yield a dibasic acid containing four methoxy groups.—J. B.

Colouring matters containing sulphur; Blue ——. A. Lüttringhaus, H. von Diesbach, and E. Schwarz, Mannheim, Assignors to Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. U.S. Pat. 1,083,110, Dec. 30, 1913.

See Fr. Pat. 431,981 of 1911; this J., 1912, 22.—T. F. B.

V.—FIBRES; TEXTILES; CELLULOSE; PAPER.

Acetylcellulose and its commercial uses. C. P. Schwabe. J. Soc. Dyers and Col., 1914, 30, 13—15.

Commercially, the triacetate of cellulose is the most important. It occurs in various modifications, according to the method of preparation, differing in physical and chemical properties, but especially in regard to solvents. Dehydrating agents, for example, sulphuric, phosphoric, phenol, sulphonic and chloroacetic acids play an important part in the preparation. The chief commercial process is that of Eng. Pat. 7346 of 1903 (see addition to Fr. Pat. 317,007 of 1901; this J., 1903, 1015), in which cellulose is treated with equal parts of acetic acid and acetic anhydride as well as sulphuric acid. As acetylation progresses the process passes successively through a water-soluble, a water-insoluble, an alcohol-soluble, and finally an alcohol-insoluble stage, and is stopped at the point where the product is soluble in hot alcohol. The product can be separated by precipitating with water, and is probably a hydrocellulose derivative. Another method is that of Merck in which the cellulose is first treated with glacial acetic and benzenesulphonic acid and subsequently with a solution of acetic anhydride in benzene. The product is soluble in methyl formate. Camphor is added to the ordinary "triacetate" with the same object as with celluloid, and addition of naphthol benzoate, thymol and salol increases this effect. Camphor can be replaced for some purposes by methylacetanilide, trichloroaniline, etc. "Cellit" or "Cellon" (Ger. Pat. 238,348) is made by mixing the alcohol-soluble acetylcellulose with camphor in the presence of a liquid medium and allowing the solvents to evaporate. It is soluble in alcohol and is used for making cinematograph films, insulating masses, etc. Non-inflammable cotton or silk threads made from it, are treated with soluble acetates together with metallic powders to produce imitations of gold and silver threads. The soluble acetates are also applied in lacquering. Another application is in the "solidification" of alcohol by adding 10 per cent. of acetylcellulose. A triacetate soluble in alcohol and acetic acid is on the market under the name "Sericose L." It is employed for fixing bronze powder, etc., on textiles, either alone or together with phenol and formaldehyde, or with resorcinol (see this J., 1913, 422 and 1105). "Cellon," which is used for balloon coverings, is not absolutely non-inflammable, but a product introduced recently, "Cellon Emmillit," is quite non-inflammable. In the discussion it was stated that acetylcellulose did not give such good results as albumin in printing zinc oxide and barium sulphate, but this might be due to insufficiently deep engraving of the rollers. Artificial silk from acetylcellulose would cost almost as much as real silk. —J. B.

Paper sizes; Report on commercial ——. von Possanner. Chem.-Zeit., 1914, 38, 100.

In connection with a series of comparative experiments with commercial paper sizes instituted by the *Verein der Zellstoff und Papier-Chemiker*, the author has analysed 29 samples submitted. The sizes are classified in three groups: rosin sizes, colloid sizes and sizes with loading. Of these samples, 28 had an alkaline reaction and 1 was acid; the solid contents ranged from 30 to 88 per cent.; 16 samples showed solid contents between

30 and 40 per cent. The percentage of rosin ranged from 25 to 82; that of organic colloids from 0·1 to 9·8; that of inorganic colloids from 0·2 to 3·4; the ash from 2·3 to 8·4 per cent. As organic colloids, glue, starch, casein and neutral plant-mucilages were encountered; the inorganic colloid generally found was water-glass.—J. F. B.

Gelatins; Examination of commercial —— with regard to their suitability for paper-making. R. W. Sindall and W. Bacon. Analyst, 1914, 39, 20—27.

The examination of gelatin for use in the sizing of paper comprises determinations of ash, chlorides, moisture, fat, tenacity or strength of jelly, viscosity of solution, sulphurous acid and "chondrinogen." When the ash exceeds 2 per cent. a complete analysis is desirable, chiefly with a view to the determination of aluminium salts, which impart a fictitious value to the stiffness of the jelly. For the determination of chlorides, which may make the gelatin hygroscopic, the solution is hydrolysed with nitric acid, filtered and precipitated with silver nitrate. The clear liquid is siphoned off and the silver chloride dissolved in ammonia and re-precipitated. For the moisture, 5 grms. of the finely rasped sample are dried, first over sulphuric acid, after which the particles will not adhere when heated in the oven. The moisture usually ranges from 11 to 14 per cent. The same sample is digested overnight with dry ether and then extracted in a Soxhlet apparatus for the determination of the fat; re-extraction of the extract is desirable, to eliminate small quantities of glue substance which may have been absorbed by the ether. The test for stiffness of jelly must be made at a standard temperature (15° C.) on a 5 per cent. solution which has set for 6 hours. The authors use a tube with a bulb of ½ in. diam. at the end, the tube being loaded with mercury from a burette until it sinks through the jelly. The viscosity is determined from a 50 c.c. pipette with a hot-water jacket; observations are made on a 25 per cent. solution of gelatin at a temperature of 60° C. Gelatins which show a maximum stiffness of jelly with low viscosity of solution are considered most suitable for paper-making. Sulphurous acid is determined by distillation with phosphoric acid, the mixture being heated first in a water-bath and then on wire gauze. The "chondrinogen" test consists in heating 10 grms. of the sample with 200 c.c. of 5 per cent. nitric acid at 60° C. until the liquid becomes bright, collecting and weighing the insoluble matter; this should not exceed 0·4 per cent.—J. F. B.

Decomposition of cellulose, starch, sugar and sulphite-cellulose lye by heat. Bantlin. *See* IIa.

Utilisation of pine-apple by-products in Hawaii. See XIXa.

Patents.

Flax; Process of retting ——. W. J. Fernie, Dromara, Ireland. U.S. Pat. 1,083,074, Dec. 30, 1913.

See Fr. Pat. 460,092 of 1913; this J., 1914, 19.—J. B.

Balloons; Fabrics for spherical and dirigible ——. B. D. Porritt and North British Rubber Co., Ltd., Edinburgh. Eng. Pat. 1972, January 24, 1913.

The impermeable layer of rubber spread between the outer and inner fabric of the balloon material is protected from the action of light by dyeing the fabric, or preferably the yarn before weaving, with a resistant red or yellow dyestuff developed from a reduction product (vat dyestuff) or else with a dyestuff of the alizarin type in conjunction with a mordant.—J. F. B.

Viscose; Manufacture of brilliant filaments, ribbons, films and the like from ——. W. P. Thompson, Liverpool. From Vereinigte Kunstseidefabriken A.-G., Kelsterbach, Germany. Eng. Pat. 330, Jan. 6, 1913.

For the coagulation of filaments, etc., from viscose a precipitating bath consisting of formic acid, alone or in conjunction with salts, is employed. A cold saturated solution of common salt, mixed with 200 grms. of formic acid per litre may be used. Formic acid acts not only upon the saline impurities of the viscose but also decomposes the xanthogenic ester in a manner similar to the mineral acids but more gradually, and the coagulated material contains very little free sulphur.—J. F. B.

Paper pulp; Apparatus for the preparation of ——. J. D. Rice, Oakland, Cal., U.S.A. Eng. Pat. 5595, March 6, 1913.

The apparatus comprises two or more cylindrical "cookers" mounted at an angle of 45° and provided with a central hollow shaft through which steam is introduced into pipes which serve both for heating and stirring the charge when the central shaft is rotated, the lower end of this shaft being connected with a steam-trap. The digested material discharged from the bottom of the "cooker" is conveyed by means of a screw to a series of squeezing rolls which remove the liquid and deliver the pulp to the beating engines. The liquid draining through the screw conveyor and squeezed out by the rolls is pumped to a steam-jacketed evaporator in which it is concentrated and through which it is forced by means of screw-conveyors until it emerges in a semi-solid form. —J. F. B.

Lignocellulose and the like; Apparatus for treating —— with steam and hydrolysing agents. G. H. Tomlinson, Fullerton, La., U.S.A. Eng. Pat. 30,073, Dec. 31, 1912. Under Int. Conv., Jan. 29, 1912.

See U.S. Pat. 1,032,449 of 1912; this J., 1912, 832.—T.F.B.

Wood or like material; Treatment of —— and the production of useful products therefrom. F. R. von Walther, Dresden, Saxony. Eng. Pat. 304, Jan. 4, 1913. Under Int. Conv., Jan. 6, 1912.

See Ger. Pat. 258,180 of 1912; this J., 1913, 597.—T.F.B.

Filaments and films from viscose; Production of ——. F. Steimmig, Hannover, Germany. Eng. Pat. 11,104, May 10, 1913. Under Int. Conv., Feb. 15, 1913.

See Fr. Pat. 458,979 of 1913; this J., 1913, 1153.—T.F.B.

Cellulose; Process for preparing solutions of —— and for the production of cellulose products from such solutions. E. Berl, Tubize, Belgium. U.S. Pat. 1,082,490, Dec. 30, 1913.

See Ger. Pat. 259,248 of 1912; this J., 1913, 653.—T.F.B.

Carbohydrate esters [nitrocellulose]; Dissolved —— and process of making the same. W. S. Weedon, Assignor to E. I. du Pont de Nemours Powder Co., Wilmington, Del. U.S. Pat. 1,082,573, Dec. 30, 1913.

VI.—BLEACHING ; DYEING ; PRINTING ; FINISHING.

Wool ; The absorption of acids by ——. M. Fort and L. L. Lloyd. J. Soc. Dyers and Col., 1914, **30**, 5—12.

Wool was treated with acid of different degrees of concentration at water-bath temperature under comparative conditions. After rinsing with cold water the acid baths were titrated and the amount absorbed by the wool estimated by difference. The wool was then repeatedly extracted with hot water until no more acid was removed and the amount of acid permanently retained by the wool after hot extraction found by titration and difference. These quantities —percentage of acid absorbed and percentage of acid permanently retained—were plotted on curves against the percentage concentration of the acid employed. The curves for five different acids—sulphuric, hydrochloric, oxalic, formic and acetic—all resembled one another: after a sharp rise the curve settled down to an approximately horizontal undulating line. The nodes and depressions in this undulating line appear to have chemical significance, for, taking a line through the nodes at the maximum point in the curve for acid permanently retained, the percentages of the different acids were found to be roughly in the ratio of their molecular weights, the formic : acetic acid ratio only being abnormal (*i.e.*, 51 : 47 instead of 46 : 60). This abnormality was, however, confirmed by experiments on another wool, merino sliver, a Botany flannel having been used in the first experiments. In these second experiments twice as much sulphuric acid was permanently retained as in the first experiments with concentrations up to 7 per cent., after which point, however, the quantities again become normal. These two points may be represented by the formation of the two additive salts, $W.(H_2SO_4)_2$ and $W.(H_2SO_4)$. Also in the curves for absorbed acid, when lines were taken through the corresponding nodes on the curves of the five acids, the ratios of percentage acid absorbed were very close to the molecular weight ratios of the acids. It is concluded that additive salt formation between the wool and the acid occurred.—J. B.

Indigo on woollen cloths ; The testing of ——. J. Soc. Dyers and Col., 1914, **30**, 15—21.

The report of a joint conference of the Soc. of Dyers and Colourists and of the Textile Institute on the report on the "Testing of Indigo on Woollen Cloth" (see this J., 1913, 823). According to J. Hübner difficulties in the use of the tintometer could be overcome by using artificial light, *e.g.*, the Gardner-Dufton lamp. In reply to other points, the authors emphasised the value of the older indigo tests as a preliminary to valuation by the new methods. Basic dyestuffs, for instance, would be discovered by preliminary treatment with alcohol or dilute acid. The dyestuff thus stripped would be estimated by difference in the tintometer, or by identification and re-dyeing on wool against a standard of the same dyestuff. Other vat dyestuffs occurring along with indigo would be estimated as indigo, but as those likely to be found on wool were of the indigo class their use would not constitute a fraud. Separation of indigo from the other vat dyes could be effected if necessary by extracting and sulphonating, when indigo alone was sulphonated and could be titrated. G. H. Frank doubted if indirubin was ever found on dyeings from natural indigo, and said both natural and synthetic indigo had been tested by the new methods.—J. B.

Diazo solutions for printing ; Improving the keeping qualities of ——. E. Justin-Mueller. Sealed note No. 653, dated Sept. 30, 1902, Soc. Ind. de Rouen. Rev. Gen. Mat. Col., 1914, **18**, 4.

Double salts of the diazo compounds are formed with zinc or stannic chloride, naphthalene-sulphone-sulphonic acids and picric acid. For neutralisation aluminium acetate is preferred to sodium acetate.—J. B.

Acetylcellulose and its commercial uses. Schwabe. *See* V.

Patents.

Dyeing and otherwise treating textile materials and fibres ; Beam or cylinder for ——. J., T., and E. Brandwood, Bury. Eng. Pat. 436, Jan. 7, 1913.

A hollow warp beam constructed from a thin, perforated, sheet of indifferent metal (*e.g.*, a nickel alloy), supported by rings and having flanges at the ends which will make a liquid-tight joint in the dyeing machine. One end of the beam may be closed.—J. B.

Dyeing, bleaching or like treatment of textiles on beams. J., T., and E. Brandwood, Bury. Eng. Pat. 551, Jan. 8, 1913.

An apparatus of the kier type for treating warps on the beam at a pressure higher than atmospheric pressure. The warp beams are perforated, have the top end closed and are pressed down vertically on a plate containing holes with which the open ends of the beams make liquor-tight joints. The machine has the usual circulation pump and is also fitted with means for circulating air through the beams.—J. B.

Textile materials [*cops*] *; Gaseous and like treatment of* ——. J., T., and E. Brandwood, Bury. Eng. Pat. 1762, Jan. 22, 1913.

The plate containing the spindles is held in a suitable frame over which descends a bell-shaped cover actuated by a compressed air piston, the cover making a tight joint with the plate. The piston is hollow and through it compressed air is admitted at high pressure and in large volume so that the material is very thoroughly penetrated and regular oxidation ensured.—J. B.

[*Dyeing*] *Treating textile fibres with liquids and gases ; Apparatus for* ——. J., T., and E. Brandwood, Bury. Eng. Pat. 5280, March 3, 1913.

A cop-dyeing machine allowing of the treatment of the material subsequent to dyeing, with air or gases under pressure, consists of a closed kier across which is fixed the plate holding the spindles with sufficient space below it in the interior of the kier to hold all the dye-liquor. The cops being impregnated and the liquor being all at the bottom of the kier, air is admitted under pressure above the plate containing the cops and makes its exit below the plate and above the level of the liquor in the kier. The kier has the usual circulating apparatus.—J. B.

Impregnating and coating fabrics, cords, cables, etc. ; Apparatus for ——. L. P. Destribats, Trenton, N.J., U.S.A. Eng. Pat. 20,103, Sept. 5, 1913.

A roll of the material is placed inside a vacuum drum from which it passes into the trough containing the impregnating liquid through a slot in open communication with the interior of the drum, and thence to a suitable dryer. The interior of the drum is fitted with heating pipes.—J. B.

Dyeing [*furs*] *; Process of* ——. C. Goldstein, New York. U.S. Pat. 1,082,627, Dec. 30, 1913.

After immersion for 24 hours in ferrous sulphate solution at 102° F. (39° C.) the furs are drained for 24 hours and then immersed for 12 hours at the same temperature in the dye-liquor, after which the temperature of the latter is lowered to 100° F. (38° C.) and the dyeing continued for 12 hours longer, the furs being finally dried. The dye-liquor is made by boiling ground and roasted nut-galls in water for ½ hour, subsequently boiling with sumac and afterwards cooling and adding a little lime water.—J. B.

Dyeing or impregnation of materials or substances. F. R. von Walther, Dresden, Saxony. Eng. Pat. 305, Jan. 4, 1913. Under Int. Conv., Jan. 6, 1912.

See Fr. Pat. 452,583 of 1912; this J., 1913, 653.—T. F. B.

Dyeing and otherwise treating hanks of woollen and other yarns; Machines for ——. J. Decock, Tourcoing, France. Eng. Pat. 8336, April 9, 1913.

See Addition of March 15, 1913, to Fr. Pat. 442,713 of 1912; this J., 1913, 1007.—T. F. B.

Colouring fabrics; Method of —— and apparatus for carrying out the said method. J. Rousseau, Sedan, France. Eng. Pat. 9200, April 19, 1913. Under Int. Conv., April 26, 1912.

Textile materials; Apparatus for treating —— with liquids. C. W. Fulton, Paisley. U.S. Pat. 1,083,360, Jan 6, 1914.

See Eng. Pats. 26,893 and 26,894 of 1911; this J., 1912, 1121.—T. F. B.

VII.—ACIDS; ALKALIS; SALTS; NON-METALLIC ELEMENTS.

Ammonia production in the United Kingdom in 1913. Bradbury and Hirsch, Liverpool. January, 1914. [T.R.]

Production of ammonia, calculated into sulphate (including that used in the manufacture of ammonia soda and for other chemical purposes), from all sources in the United Kingdom during 1913, is estimated at 420,000 tons, viz.:—

	1912.	1913.
	tons.	tons.
Gas works	172,000	182,000
Iron works	17,000	19,000
Shale works	62,000	62,000
Coke and carbonising works and producer gas	137,000	157,000
	388,000	420,000

Of this quantity it is estimated that England contributed 292,000 tons, Scotland 125,000 tons, and Ireland 3,000 tons. The exports during 1913 amounted to 325,000 tons and the home consumption to 97,000 tons, leaving a stock of 20,000 tons to carry forward to 1914.

Pyrites; Norwegian and Spanish ——, as raw material in the sulphuric acid manufacture. P. W. Uhlmann. Chem.-Zeit., 1914, **38**, 59—60.

The author controverts the views of Keppeler (Chem.-Zeit., 1913, **37**, 1219) upon the respective merits of the two kinds of pyrites and states that the Norwegian product is generally preferable: under similar conditions it has an effective sulphur content of about 7 per cent. more than the Spanish product. For the manufacture of an acid containing little arsenic it certainly has the advantage in the chamber-process and probably also in the contact-process.—J. R.

Pyrites; Determination of carbon in bituminous ——. R. Lepsöe. Tids. for Kemi, Farmaci og Terapi, 1913, No. 24. Apoth.-Zeit., 1914, **29**, 69.

A mixture of 0·5 grm. of the finely powdered pyrites and 10 grms. of sodium peroxide is melted over a small flame in a Ledebur porcelain crucible for 15 minutes. When cold, the melt is covered with water, transferred to a small flask and treated with hydrochloric acid. The flask is heated and the carbon dioxide evolved absorbed by a solution of barium hydroxide, the precipitated barium carbonate being filtered off and weighed.—F. Sodn.

Potassium chloride manufacture by the continuous method. E. Krüger. Chem.-Zeit., 1914, **38**, 60—61, 74—76.

Descriptions are given of lixiviating and crystallising plant of a continuous type now available for the treatment of salt deposits containing potassium chloride (carnallite, etc.).—F. Sodn.

Kelps [of Alaskan coast]; Composition of giant ——. A. R. Merz. J. Ind. Eng. Chem., 1914, 6, 19—20.

Analyses of samples collected from the Alaskan coast showed that the *Nereocystis* of Alaskan waters was, in regard to potash-content (12·74—30·12 per cent. K_2O), as important an economic source of potassium salts as that of the more southern waters (this J., 1912, 227). The *Macrocystis* contained a somewhat lower (6·92—22·48 per cent.) and the *Alaria* a decidedly lower percentage of potash (2·27—13·07 per cent.) than the *Nereocystis*, and the sea-weeds *Fucus* and *Porphyra* (about 3·5 and 7·3 per cent. K_2O respectively) were valueless as sources of potash. The potash content and the proportion of total soluble salts were invariably larger in the stems than in the leaves of the same plant, whilst the reverse was the case in regard to the content of ash and of nitrogen as is shown in the following table:—

No.	Name of plant.	Part of plant.	K_2O.	Total soluble salts.	Ash.	N.
			per cent.	per cent.	per cent.	per cent
1.	Macrocystis	Stem	18·28	36·78	2·36	0·51
		Leaves	9·90	25·94	3·88	0·84
2.	Nereocystis	Stem	28·26	52·88	3·60	1·06
		Leaves	15·44	39·40	4·34	2·27
3.	Nereocystis	Stem	24·69	56·40	3·10	1·15
		Leaves	14·78	38·44	4·30	2·02
4.	Nereocystis	Stem	23·88	49·44	10·66	1·53
		Leaves	12·74	34·38	5·12	2·87
5.	Nereocystis	Stem	30·12	63·74	2·76	1·07
		Leaves	15·12	40·10	4·34	3·06
6.	Nereocystis	Stem	27·02	58·86	3·22	0·81
		Leaves	19·63	47·26	3·46	1·04
7.	Nereocystis	Stem	28·76	64·44	2·90	0·59
		Leaves	16·74	42·74	5·66	1·52
8.	Nereocystis	Stem	24·80	53·54	3·68	0·98
		Leaves	17·67	44·40	4·98	2·01

—A. S.

Pure substances; Utilisation of diffusion processes in the preparation of ——. J. Johnston. J. Amer. Chem. Soc., 1914, **36**, 16—19.

Sparingly soluble substances can be precipitated in a state of great purity by allowing the reacting materials to come slowly into contact with each other as the result of diffusion. For example a large vessel is filled with water, or a saturated solution of the substance to be prepared, or a solution containing some foreign substance which increases the solubility of the substance to be prepared, but does not separate with it as a double salt. Two small dishes containing the reacting substances are placed at opposite sides of the large vessel. Or a vessel containing the main bulk of liquid, covered with a layer of paraffin to prevent evaporation, may be placed inside a steam bath, and the reacting solutions allowed to flow slowly in through siphons from flasks disposed above: the air-inlet tubes of the flasks are drawn out to very fine capillaries to ensure a very slow flow of the solutions through the siphons. Hexagonal prisms of calcium hydroxide, 2—3 mm. long by 1 mm. thick, were prepared in this way from calcium chloride and sodium hydroxide at the ordinary temperature and crystals of barium sulphate, 1—2 mm. long, and free from retained material, were prepared at 100° C. (Compare Dreaper, this J., 1913, 678.)—A. S.

Colloidal ferric hydroxide ; New method for the preparation of ——. T. Cohen. J. Amer. Chem. Soc., 1914, **36**, 19—23.

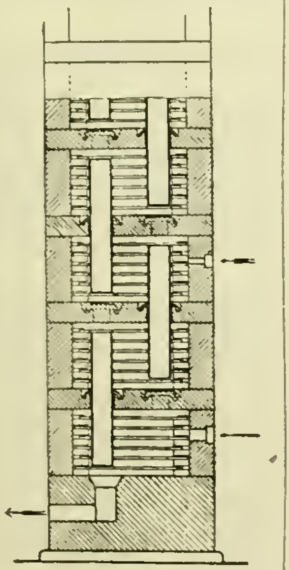
A red colloidal solution of ferric hydroxide is produced if a concentrated solution of ferric nitrate be boiled for a considerable time, but on cooling, the red colour disappears, probably owing to the action on the hydroxide of the nitric acid produced by hydrolysis of the ferric nitrate. If a metal (copper, iron, zinc), preferably finely divided, be added, this combines with the liberated nitric acid, and the colloidal solution persists even on cooling. —A. S.

Mercury-copper compounds ; Basic ——. B. Finzi. Gaz. chim. ital., 1913, **43**, II., 708—712.

Yellow mercuric oxide was added in small portions to a boiling, nearly saturated solution of copper nitrate. On filtering and allowing to cool, blue crystals separated containing water of crystallisation which was evolved at 100° C. The crystals were insoluble in, but rapidly decomposed by, water, with separation of mercuric oxide. When treated with caustic potash they became green, but neither cupric hydroxide nor mercuric oxide separated. Ammonia decomposed the blue substance with formation of a cuprammonium compound and white mercuriammonium nitrate. The blue compound had the composition, $Cu(NO_3)_2,HgO,3H_2O$. Compounds containing mercury were also prepared in a similar manner from cupric chloride and copper-potassium sulphate but not in sufficient quantity for analysis. (See also this J., 1912, 26.)—A. S.

Bromine ; Apparatus for the production of ——. K. Kubierschky. Chem. Apparatur, 1914, **1**, 2—5.

At the present time two-thirds of the world's total consumption of bromine (about 1,500,000 kilos.) are produced in Germany, mainly from the final liquors from the manufacture of potash salts, the bromine being liberated by means of chlorine, distilled over with steam, and the crude product thus obtained, containing about 3 per cent. Cl, purified by treatment with iron bromide or calcium bromide followed by a second distillation. The author describes, with illustrations, an installation whereby the bromine may be obtained continuously by a system of distillation and fractionation in column apparatus, 90—95 per cent. of the bromine being recovered with a minimum consumption of steam, chlorine and labour. The preheated liquor flows down through a tower of sand stone, granite, or volvic lava, at the bottom of which steam is supplied, and at a short distance higher, chlorine. To prevent the heavy bromine vapours from descending the tower, the latter is divided into eight compartments (Ger. Pat. 194,567), provided with Lunge-Rohrmann plates and connecting tubes as shown in the figure. The vapours from the upper end of the tower pass to a condenser; the condensed liquid consists of crude bromine surmounted by a layer of an aqueous solution of chlorine and bromine, which latter is returned to the tower. The crude bromine flows to a rectifying column (Ger. Pat. 174,848; this J., 1907, 824), in which it flows downwards in contact with an ascending current of bromine vapour, and is thus freed from chlorine. The vapours from the rectifying column pass through a condenser, the condensed portion, mainly bromine, flowing back to the column, whilst the uncondensed portion, mainly chlorine, is led to the upper part of the main tower, where it comes in contact with the fresh liquor. It is stated that with a tower of 700×700 mm. cross-section, up to 5 cb. metres of the liquor per hour can be treated.—A. S.



Hydrogen peroxide ; Displacement of acids [from salts] by ——. J. Sperber. Schweiz. Woch. Chem. Pharm., 1914, 5. Apoth.-Zeit., 1914, **29**, 69. (See also this J., 1913, 486.)

When a concentrated solution of hydrogen peroxide (perhydrol) is allowed to act upon calcium bromide, oxygen and hydrobromic acid are evolved but no bromine. Calcium chloride behaves in a similar manner. Calcium fluoride gives rise to hydrofluoric acid at the ordinary temperature, and at higher temperatures oxygen is evolved as well. The reaction with iodides is practically explosive at the ordinary temperatures, and free iodine is evolved even when the reaction is moderated by cooling with a freezing mixture.—F. Shdn.

Zirconium chloride ; Compounds of —— *with pyridine.* E. Chauvenet. Comptes rend., 1914, **158**, 128—130.

Besides the compound $ZrCl_4,2C_5H_5N$, described by Matthews (J. Amer. Chem. Soc., 1898, **20**, 815), another exists, $ZrCl_4,4C_5H_5N$, in prismatic, strongly polarising crystals, obtained by evaporation of a solution of zirconium chloride in pyridine, saturated at 19° C. It is very unstable, and is quickly decomposed by water. The molecular heats of formation of the two compounds were determined as 54 cals. and 70 cals. respectively.—J. T. D.

Arsenic ; Melting-point of ——. R. Goubau. Comptes rend., 1914, **158**, 121—122. (See also Jolibois, this J., 1911, 893.)

A 25 c.c. capacity bulb tube of quartz was filled to the neck with metallic arsenic, and a tube containing the wires of a thermo-couple inserted into it. On heating the bulb slowly in a large crucible filled with sand, the arsenic which volatilised formed an air-tight plug in the neck. The curve of rising temperature showed that fusion occurred at 817° C. At 900° C. the pressure burst the flask. After solidification the ingot of arsenic consisted of a series of crystalline plates.—J. T. D.

Patents.

Fuming sulphuric acid or oleum ; Apparatus for the manufacture of ——. T. L. Briggs, Flushing, N.Y., and H. F. Merriam, Summit, N.J., Assignors to General Chemical Co., New York. U.S. Pat. 1,082,301, Dec. 23, 1913.

An apparatus for converting sulphuric acid and sulphuric anhydride into oleum consists of a tower, through which the materials are passed, fitted with a gas inlet and an oleum outlet at the bottom, and an air outlet at the top. The tower is filled with a packing material to about the height of the air outlet, the acid is supplied by means of a distributor, and means are provided for cooling the tower from the outside, the proportions of the apparatus being such that there is one square inch of lateral cooling surface for every three cubic inches of effective tower space.—O. R.

Sulphur from metallic sulphides [other than iron pyrites] ; Process for the extraction of ——. W. A. Hall, New York. Eng. Pat. 26,595, Sept. 11, 1912.

Sulphides of zinc, copper, or lead, are agitated in a suitable furnace and subjected to the action of a reducing flame and a small quantity of steam; the latter, whilst insufficient to decompose the sulphide appreciably, prevents the formation of sulphur dioxide and carbon oxysulphide. Sulphur distils off, metallic oxide and hydrogen sulphide are formed, and the latter combines with the sulphur dioxide which is present, to form a further quantity of sulphur, so that the issuing gases are practically free from sulphur dioxide.—O. R.

Sulphides of the alkalis or alkaline earths [from polysulphides]; Regeneration of——. L. P. Wilson, Coventry. Eng. Pat. 29,711, Dec. 24, 1912.

Soluble polysulphides are converted into sulphides by treatment with an alkali or alkaline-earth hydroxide and a reducing agent, such as glucose, starch, or dextrin. The process is particularly suitable for the treatment of polysulphides obtained in desulphurising viscose artificial silk, or in the denitration of nitrocellulose.—O. R.

Alkali chromate solutions; Process of making——. J. H. Payne, Yorktown, Va., Assignor to F. E. Gigneux, Cape Elizabeth, Me. U.S. Pat. 1,081,625, Dec. 16, 1913.

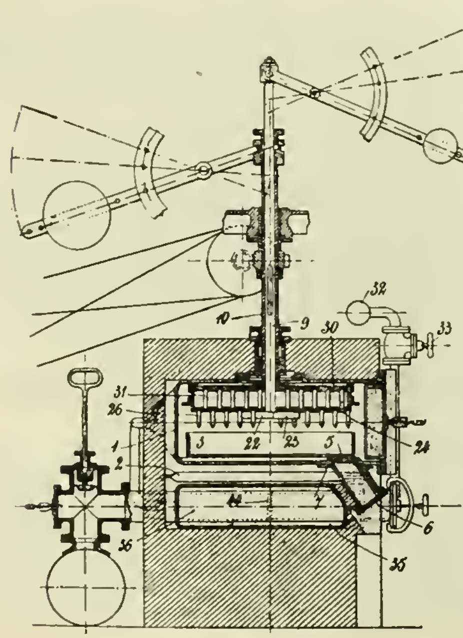
A wet mixture of chrome iron ore, lime, and sodium carbonate, is passed down an inclined, rotary cylinder, against a counter-current of oxidising gases, heated to a temperature which causes incipient fusion, and the resulting porous nodules are leached with water.—O. R.

Citrate of lime; Manufacture of——. L. Rose and Co., Ltd., and H. G. Rose, London. Eng. Pat. 4060, Feb. 17, 1913.

Lime or lemon juice is neutralised by chalk or whiting, sufficient of the mother liquor is withdrawn to leave the deposited calcium citrate in the form of a thick cream, and a thin, uniform layer of the latter is passed, whilst still hot, between the adjacent peripheries of a pair of heated cylinders, which are rotating in opposite directions. The cylinders may be suitably heated to about 260° F. (127° C.) by means of steam at a pressure of 30—40 lb., and the dried citrate is removed from the cylinders in the form of a fine powder by means of two stripping knives, and deposited in a settling cone by means of an exhaust fan. A small quantity of a binding material, such as gelatin, may be added to the liquid before evaporation, and the citrate is then obtained in the form of thin, moist sheets, which become quite dry on cooling.—O. R.

Alkali peroxides; Process and apparatus for the manufacture of——. E. Marguet, Valence, France. Eng. Pat. 11,174. May 13, 1913. Under Int. Conv., April 22, 1913.

A horizontal iron furnace, 1, disposed inside a brick chamber, is heated by means of an electric resistance, 2, and contains a circular, aluminium "boat," 3, which carries the alkali metal and is separated from the lower wall of the furnace by a space as shown. A discharging trap, 5, is fixed to a plug, 6, which slides inside a discharging tube, 7, and is held in place by a suitable tightening device. The roof of the furnace is traversed by a solid aluminium shaft, 9, which is free to move up and down inside, but can only rotate in conjunction with the hollow shaft, 10. The vertical movement is produced by means of levers and the rotation by means of pulleys and worm drives. The shaft, 9, carries at its lower end a double aluminium scraper, 22 and 23, two arms of 22 being straight, and two arms of 23 being curved. Two aluminium plates, 24 and 30, provided with a large number of teeth, 26 and 31 respectively, are bolted on to the lower part of the hollow shaft, 10, and the combination of the two shafts, the two toothed plates, and the double scraper, constitutes a device for subdividing the peroxide in the course of formation, stirring the contents of the boat, scraping and trimming the boat, and discharging the finished product, all with the exclusion of air. The air necessary for oxidation is supplied from a collector, 32, controlled by a valve, 33, traverses a metal chamber, 35, which is furnished with baffle plates, 44, and is strongly heated by circulating around pipes, 36, which serve for the discharge of the exhaust gases.—O. R.



Caustic alkali solutions; Treatment of —— containing sulphates, from the decomposition of natural rocks. Chem. Fabr. Rhenania and A. Messerschmitt. Ger. Pat. 268,282. March 7, 1912.

The sulphates are separated partly as potassium sulphate and partly as a double potassium sodium sulphate by concentration and suitable cooling.—A. S.

Calcium-magnesium carbonate; Production of a voluminous form of——. Lipsia, Chemische Fabrik. Ger. Pat. 267,543, May 19, 1912.

Burnt dolomitic lime is suspended in water, treated, under pressure, with carbon dioxide or gases containing the same, and the whole again decomposed by heating.—A. S.

Calcium hydrosulphide; Manufacture of——. E. Bindschedler. Ger. Pat. 267,870, March 11, 1913.

Spent solutions containing calcium hydrosulphide and nitrate are treated with sulphuric acid and the resulting mixture of calcium sulphate, sulphur, and organic matter, to which a porous substance such as powdered wood charcoal may be added, is heated to dark redness and treated with carbon monoxide or gases containing the same, the gaseous reaction products being led into contact with calcium sulphide and milk of lime.—A. S.

Dialkalicyanamide; Manufacture of——. Chem. Fabr. von Heyden A.-G. Ger. Pat. 267,595, Feb. 2, 1913.

Cyanamide or a polymeride thereof, especially dicyandiamide, is heated with caustic alkali :—

$$4NaOH + C_2N_4H_4 = 2Na_2CN_2 + 4H_2O.$$

The water partly escapes as steam, but in part reacts with the melt, with the formation of ammonia :—

$$Na_2CN_2 + 3H_2O = Na_2CO_3 + 2NH_3.$$

To avoid loss from this cause, as far as possible, substances capable of combining with water, *e.g.*, alkali or alkaline-earth metals or their oxides, amides, nitrides, carbides, or alloys may be added.—A. S.

Hydrogen; Production of —— by the alternate oxidation and reduction of iron. A. Messerschmitt. Ger. Pat. 263,390, July 24, 1912.

Instead of iron turnings or spongy iron, compact iron is used in the form of a framework, preferably consisting of removable pieces, or of tubes of relatively small cross-section, heated either directly or indirectly. When tubes are used, these may be exposed both inside and outside to the reacting gases, or the latter may be led alternately over the inner and outer surfaces respectively of the tubes.—A. S.

Hydrogen; Production of —— by the alternate oxidation and reduction of iron. A. Messerschmitt. Ger. Pat. 268,062, Nov. 3, 1912.

The vertical reaction-column is disposed within a heating chamber and is provided below with an extension, open at its lower end, which projects into a separate heating chamber. In the latter is a grate which serves to support the column of reaction-material (iron). Heating gases are supplied to both heating chambers in such a way that they flow in one direction through the interior of the reaction chamber and in the opposite direction around the outside of the latter, whereby uniform heating is ensured. The lower heating chamber is provided with discharge openings for the reaction material and with tangential air inlets.—A. S.

Hydrogen; Apparatus for the production of —— by the alternate oxidation and reduction of iron. A. Messerschmitt. Ger. Pat. 268,339, Oct. 18, 1912. Addition to Ger. Pat. 267,594.

A modification of the apparatus described in the chief patent (see Fr. Pat. 441,105 of 1912; this J., 1912, 1126), the annular reaction chamber being bounded externally by the brickwork of the column or shaft and communicating directly with the inner heating chamber.—A. S.

Carbon dioxide; Preparation, by compression and cooling, of liquid —— or other constituents of gaseous mixtures. H. Hirschlaff. Ger. Pat. 267,379, Sept. 17, 1912.

In order to attain the necessary degree of cooling at first, an auxiliary medium, such as compressed air, is passed, along with the compressed gaseous mixture, through the apparatus, flowing first through an expansion-device and then through a heat-exchanger surrounding the separating vessel. The supply of compressed air is continued until liquid carbon dioxide begins to deposit in the separating vessel.—A. S.

Aluminium hydrate; Method of precipitating ——. E. S. Fickes, Pittsburgh. Reissue No. 13,668, Jan. 6, 1914, of U.S. Pat. 1,070,438, Aug. 19, 1913.

See Fr. Pat. 451,593 of 1912; this J., 1913, 602.—T. F. B.

Oxides of nitrogen; Apparatus for forming ——. J. S. Island, Toronto. U.S. Pat. 1,082,529, Dec. 30, 1913.

See Eng. Pat. 11,363 of 1912; this J., 1913, 909.—T. F. B.

Mercury bichloride; Apparatus for manufacturing ——. F. Kaufler, Brückl, Austria-Hungary, and A. Klages, Salbke, Germany. U.S. Pat. 1,082,530, Dec. 30, 1913.

See Eng. Pat. 19,601 of 1912; this J., 1912, 1125.—T.F.B.

Mercuric chloride and process of producing same. F. Kaufler, Vienna, and A. Klages, Salbke, Germany. U.S. Pat. 1,084,346, Jan. 13, 1914.

See Eng. Pat. 19,601 of 1912; this J., 1912, 1125.—T.F.B.

Nitrates; Process for the dehalogenisation of halogeniferous ——. C. Uebel, Heidelberg, Germany. U.S. Pat. 1,082,781, Dec. 30, 1913.

See Fr. Pat. 451,069 of 1912; this J., 1913, 602.—T. F. B.

Cyanogen compounds and the like; Synthetic production of ——. J. E. Bucher, Coventry, R.I. U.S. Pat. 1,082,845, Dec. 30, 1913.

See Fr. Pat. 455,799 of 1912; this J., 1913, 943.—T. F. B.

Ammonia; Process for the production of ——. R. W. Wallace and E. Wassmer, London. U.S. Pat. 1,083,232, Dec. 30, 1913.

See Eng. Pat. 18,450 of 1912; this J., 1914, 22.—T. F. B.

Ammonia; Catalytic production of ——. C. Bosch and A. Mittasch, Assignors to Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. U.S. Pat. 1,083,585, Jan. 6, 1914.

See Fr. Pat. 436,472 of 1911; this J., 1912, 432.—T. F. B.

Ammonia and compounds of ammonia; Method of producing ——. F. Rothe, Dessau, Germany. U.S. Pat. 1,083,703, Jan. 6, 1914.

See Fr. Pat. 426,307 of 1911; this J., 1911, 1012.—T. F. B.

Sulphuretted hydrogen; Process for the production of ——. W. A. Hall, New York. U.S. Pat. 1,083,247, Dec. 30, 1913.

See Fr. Pat. 455,905 of 1912; this J., 1913, 943.—T. F. B.

Sulphur from metallic sulphides; Process for the extraction of ——. W. A. Hall, New York. U.S. Pat. 1,083,248, Dec. 30, 1913.

See Fr. Pat. 458,028 of 1912; this J., 1913, 1156.—T.F.B.

Sulphur; Process for the production of ——. W. A. Hall, New York. U.S. Pat. 1,083,249, Dec. 30, 1913.

See Eng. Pat. 20,760 of 1912; this J., 1913, 1009.—T.F.B.

Separation of the constituents of gaseous mixtures [air]; Process of ——. G. Claude, Assignor to Soc. L'Air Liquide (Soc. Anon. pour l'Etude et l'Exploit. des Proc. G. Claude), Paris. U.S. Pat. 1,083,988, Jan. 13, 1914.

See Fr. Pat. 410,967 of 1909; this J., 1910, 949.—T. F. B.

VIII.—GLASS; CERAMICS.

Presence of traces of zinc in glass. Cause of error in studying the biological action of chemical reagents. Javillier. *See* XXIV.

Patents.

Drying apparatus for clay; Air ——. A. W. and E. Borlase, St. Austell, Cornwall. Eng. Pat. 104, Jan. 2, 1913.

The apparatus comprises a series of shallow trays supported and pivoted to a framing, a pair of levers holding the trays in an almost horizontal position, but readily allowing the same to fall into an inclined position for emptying.—B. N.

Translucency of thin plates of marble, alabaster and similar substances; Process for increasing the ——. H. W. Engel. Ger. Pat. 267,065, Feb. 17, 1912. Addition to Ger. Pat. 265,027 (see Eng. Pat. 28,361 of 1911; this J., 1913, 87).

The plates are soaked in liquid, non-volatile hydrocarbons, whereby, it is stated, their translucency is so augmented that they can be used in the manufacture of lamp globes and the like.—A. S.

Glazes; Production of white and coloured —— for pottery. O. Völkel. Ger. Pat. 267,191, Nov. 5, 1912.

A mixture containing an antimony compound and an alkaline-earth compound is added to an ordinary lead glaze mixture or to the fused glaze.—A. S.

Enamel, glass, and the like; Manufacture of white ——. Verein. Chem. Fabriken, Landau, Kreidl, Heller und Co., Vienna. Eng. Pat. 29,382, Dec. 20, 1912. Under Int. Conv., May 4, 1912. Addition to Eng. Pat. 1136 of 1912, dated Sept. 30, 1911.

See Addition of Jan. 18, 1913, to Fr. Pat. 438,908 of 1912; this J., 1913, 753.—T. F. B.

IX.—BUILDING MATERIALS.

Zinc chloride in treated wood; Determining the amount of ——. E. Bateman. J. Ind. Eng. Chem., 1914, **6**, 16—18.

Extraction of the zinc chloride from the wood by leaching is unsuitable, as organic substances are also dissolved and would have to be subsequently removed or destroyed. Incineration leads to inaccurate results owing to loss of zinc by volatilisation. The most satisfactory method of destroying the zinc is as follows:—Five grms. of finely ground wood or sawdust are treated with 50 c.c. of a saturated solution of potassium chlorate in concentrated nitric acid; after the violent reaction has subsided, 10 c.c. of concentrated sulphuric acid (sp. gr. 1·8) are added and after some time the solution is boiled, and when the colour darkens, a further quantity of the chlorate solution is added, and the boiling and treatment with chlorate continued until no further charring takes place on evaporating till fumes of sulphuric acid appear. The zinc is subsequently determined by titration with ferrocyanide in hydrochloric acid solution, using uranium acetate as outside indicator, or by the following method. 100 c.c. of the zinc solution are treated with 10 c.c. of a 2 per cent. solution of ferric chloride, 10 c.c. of dilute nitric acid, and 1 grm. of citric acid, then made slightly ammoniacal, and titrated with ferrocyanide until a drop of the solution when placed in the centre of a small quantity of a mixture of equal volumes of glycerin and glacial acetic acid, gives a blue or greenish blue colour. The solution should have a volume of 200 c.c. and be at 80° C. at the beginning of the titration. The two methods give equally accurate results, but the second is not affected by the presence of iron, nitrates, or phosphates, and is quicker. In both cases control determinations should be made with a sample of untreated wood.—A. S.

Patents.

Wood; Process of preserving ——. E. E. Somermeier, Columbus, Ohio. U.S. Pat. 1,082,658, Dec. 30, 1913.

Fibrous, organic materials are preserved by treating them with a solution of one or more compounds of copper, together with arsenious oxide dissolved in a dilute alkaline solvent.—W. C. H.

Cement and process for making the same. E. Duryee, Los Angeles, Cal. U.S. Pat. 1,082,684, Dec. 30, 1913.

Hydraulic cement is finely ground with natural colloidal silica, *e.g.*, diatomaceous earth (with or without the admixture of hydrated lime), in order to reduce the cement and diatomaceous earth to a finer state of division and to bring the finely divided particles into intimate contact with one another. By grinding a sufficient quantity of an active form of silica with ordinary basic hydraulic cement, the latter is converted into an acidic cement.
—W. C. H.

Blocks or the like suitable for road or other purposes; Formation of ——. J. S. Kruse, London. U.S. Pat. 1,082,752, Dec. 30, 1913.

About 19½ parts of asphaltum are heated with 78½ parts of a filling material, *e.g.* clinker, to 400° F. (204° C.) and after thorough mixing, 1½ parts of sulphur and ½ part of mineral oil are added, and the whole subjected to a pressure of at least 4 tons per sq. in. The resulting blocks are claimed to be capable of resisting a crushing stress of about 2 tons per sq. in.—W. C. H.

Mortar, artificial stone mixtures, and cements, especially Sorel cements; Process for gauging —— *by means of a solution of water-glass containing bases soluble in alkalis.* R. Eberhard. Ger. Pat. 267,031, Feb. 11, 1912.

The water-glass solution used for gauging contains such a quantity of alkali-soluble bases, especially aluminium hydroxide and lead hydroxide, that the material after setting has a composition and properties similar to those of the zeolites. For example a mixture of magnesia and magnesium chloride mixed with a solution of water-glass containing alkali aluminate and plumbite, yields a magnesia cement of great strength and hardness and showing complete constancy of volume.—A. S.

Sand; Treatment of —— *for the preparation of mortar.* J. Joachim. Ger. Pat. 267,681, Oct. 23, 1912.

The moist sand, as excavated, is covered with hydrofluosilicic acid, heated, the evolved gas led into water, and the latter together with the separated gelatinous silicic acid and the regenerated hydrofluosilicic acid used for treating a further quantity of sand. The presence of the gelatinous silicic acid renders the sand capable of reacting more readily with lime—A. S.

Roofing paper and the like; Manufacture of non-inflammable ——. A. Maschke. Ger. Pat. 267,407, Jan. 21, 1913.

A simple or mixed phosphoric acid ester of phenol or its substitution products or a mixture of these substances, *e.g.*, triphenyl phosphate, tricresyl phosphate or a mixed phenylcresyl phosphate, is added to the impregnating composition for the roofing paper.—A. S.

X.—METALS; METALLURGY, INCLUDING ELECTRO-METALLURGY.

Iron ores; Report of Committee (Verein Deutscher Chemiker upon methods of analysing —— E. Hintz. Z. angew. Chem., 1914, 27, 9—11.

Sampling:—The sample, which should be fairly finely ground and not exceed about 50 grms., is emptied in a heap upon paper, and divided into two parts with a spatula. One part is pressed out with a broad spatula, the other part is sprinkled on to the layer thus obtained, and the whole mass then pressed out in the same way. This treatment is repeated 20 times, the final heap being pressed flat with a glass plate and divided into sections with a quadrant. The two parts opposite each other are united to form one sample, the original thus giving two representative samples. *Iron*:—Five grms. of each of the samples are moistened with 1 to 2 c.c. of water in a 400 or 500 c.c. Erlenmeyer flask, 100 c.c. of hydrochloric acid (sp. gr. 1·19) added, and the flask covered with a watch glass and heated for 3 hours at 60° C. The liquid is then boiled to expel chlorine, diluted with 150 c.c. of water and filtered into a 500 c.c. flask. The residue is ignited, and fused with sodium bicarbonate, the melt dissolved in dilute hydrochloric acid, the iron oxidised and precipitated with sodium hydroxide, the precipitate washed and dissolved in hydrochloric acid, and the solution added to the main solution. Or the residue may be treated with hydrofluoric acid and sulphuric acid, and dissolved in hydrochloric acid before the precipitation of the iron. Residues from ores containing chromium are fused in a nickel crucible with sodium peroxide and sodium carbonate, the melt dissolved in hot water and filtered, and the residue of iron oxide dissolved in hydrochloric acid (1 : 3) and added to the main solution. The united solutions are made up to 500 c.c., and 100 c.c. of the liquid concentrated to 50 c.c., reduced with hot concentrated stannous chloride solution (an excess of 1 or 2 drops being given), then thoroughly cooled and treated with 25 c.c. of a 5 per cent. solution of mercuric chloride. After 2 minutes the liquid is poured into 2 litres of water containing 60 c.c. of manganese sulphate-phosphoric acid solution (200 grms. of manganese sulphate per litre treated with a mixture of 1000 c.c. of phosphoric acid of sp. gr. 1·3, 600 c.c. of water, and 400 c.c. of sulphuric acid of sp. gr. 1·84) with sufficient permanganate solution to give a pink colouration. The iron is then titrated with potassium permanganate solution (about 6 grms. per litre), which has been standardised upon pure iron oxide. In the case of ores containing copper the results for iron are not so accurate, but separation of the copper effects no improvement.—C. A. M

Iron and manganese ores: Analysed ——. Methods of analysis. U.S. Bureau of Standards, Washington, D.C. Circular No. 26, 3rd Ed., May, 1913.

The following methods were used, iron ores being dried at 100°—105° C. and manganese ores at 120° C. before analysis:—*Silica:* The "silica and insoluble" was fused with sodium carbonate, as usual, the silica obtained being evaporated with hydrofluoric and sulphuric acids. *Phosphorus:* (See Blair: "Chemical Analysis of Iron," 7th ed.). When titanium was present the procedure included a double fusion of the ore with sodium carbonate and precipitation of the phosphorus by a small quantity of ferric salt, the precipitate being subsequently dissolved and treated by the molybdate process. *Sulphur:* Fusion with alkali carbonate (alone or with nitre) followed by precipitation with barium chloride in a boiling, feebly acid solution, and filtration after standing for 36 hours. *Aluminium:* (1) The phosphate method was used, but is not recommended for ores containing much titanium, owing to the uncertain composition of the co-precipitated titanium phosphate. (2) Iron, separated by means of ether and the solution treated by the basic acetate process, the latter precipitate being dissolved in hydrochloric acid and re-precipitated by ammonia; as finally ignited and weighed the precipitate consisted of Al_2O_3,TiO_2, about 70 per cent. of the P_2O_5 (Wysor, this J., 1910, 355) and a little Fe_2O_3. (3) By the phenylhydrazine method (this J., 1899, 1053) the sum of $Al_2O_3+TiO_2+P_2O_5$ was obtained; reprecipitation was necessary to eliminate iron. (4) Electrolytic method of Drown and McKenna (this J., 1892, 268) the separation of iron was very satisfactory; the alumina, etc. was precipitated twice by ammonia and subsequently weighed as $Al_2O_3+TiO_2+P_2O_5$. (5) When vanadium was present in the ore the greater part of this element was found in the precipitates from methods (3) and (4) and was determined. *Titanium:* The usual gravimetric and colourimetric methods were employed for which latter the alumina precipitates from the preceding processes were used. *Vanadium:* One of the ores (magnetite) contained 0·08 per cent. V_2O_3, for the determination of which a combination of existing methods was employed, the vanadium solution being finally titrated with $N/100$ permanganate, reduced with sulphur dioxide and titrated again. *Total iron* was determined gravimetrically and by titration with permanganate in sulphuric and hydrochloric acid solutions. For the former titration reduction was effected by means of a Jones reducer (containing a column of zinc dust; see Chem. News, **60**, 93); the permanganate was standardised against pure sodium oxalate (Sörensen), corrections being made for the reducing substances derived from the reducer, for the volume of permanganate required to produce the tint in a solution of ferric sulphate of the concentration employed, and, in the case of the magnetite ore referred to above, for the reduced titanium and vanadium also. For the titration in hydrochloric acid solution the procedure outlined by Jones and Jeffrey (this J., 1909, 818) was followed, and similar corrections to the preceding applied; the results obtained were slightly high when the sodium oxalate titre of the permanganate was used, but accurate when the latter was standardised against an iron ore of known composition. The hydrochloric acid solution of the magnetite ore was reduced by sulphur dioxide before titration with permanganate by the preceding process. *Ferrous iron* was determined by the Pratt method (Bull. 422, U.S. Geol. Survey, p. 127): 0·5 grm. of ore was treated with 10 c.c. of sulphuric acid (1 : 3) and 40 c.c. of boiled water in a large platinum crucible, the air expelled from the covered crucible by a current of carbon dioxide, and after boiling the contents for some time, 7 c.c. of hydrofluoric acid added, and boiling continued for 10 mins. The mixture was poured into a large platinum dish containing 100 c.c. of 5 per cent. sulphuric acid, 200 c.c. of water (both freshly boiled and cooled) and a quantity of permanganate slightly less than required (as determined by a preliminary test), and quickly titrated with permanganate to the first pink. Allowance was made for the vanadium content of the ore. *Available oxygen* (in the manganese ore) was determined by effecting solution of the ore in the presence of a known amount of ferrous sulphate, or oxalic and sulphuric acids, and titrating the excess of ferrous sulphate or oxalic acid with permanganate; by treating the ore with sodium oxalate and sulphuric acid in an apparatus through which dry air was finally aspirated, the loss in weight being due to the evolution of 2 mols. CO_2 for each mol. MnO_2 present; and by distillation with hydrochloric acid, absorption of the chlorine in potassium iodide and subsequent titration of the liberated iodine with sodium thiosulphate, the latter being standardised against potassium permanganate, metallic copper and resublimed iodine. *Manganese:* For the gravimetric determination, the usual methods (see also this J., 1898, 796), or (this J., 1912, 1055); in each case the manganese remaining in the filtrate was determined colourimetrically. For the volumetric determination the methods of Volhard, Ford and Williams (Blair: "Chemical Analysis of Iron," 7th ed.), von Knorre (this J., 1902, 72), the persulphate colourimetric process, and the bismuthate method were employed. It is stated, as the result of an exhaustive investigation (this J., 1912, 1055) that the bismuthate method yields results of high accuracy. *Lime and magnesia* were determined by the usual methods, but in platinum vessels, iron, etc. being removed as basic acetate and manganese by means of bromine and ammonia. The calcium was precipitated twice as oxalate and the weighed oxide corrected for traces of occluded iron and silica; two precipitations of the magnesia were also made and the weighed pyrophosphate corrected for the presence of calcium. *Alkalis:* The method of J. Lawrence Smith (heating with calcium carbonate in the presence of ammonium chloride) was used, a blank test being made with the reagents employed. *Combined water:* The already dry ore was heated to redness for 15 mins. in a current of dry air and the water absorbed by calcium chloride and weighed. *Carbon dioxide* determined as usual.—W.E.F.P.

Irons and steels; Analysed ——. Methods of analysis. U.S. Bureau of Standards, Washington, D.C. Circular No. 14, 4th Ed., July 1913.

Methods for irons and ordinary steels:—*Total carbon:* Direct combustion with oxygen in porcelain tube, heated to 1000°—1100° C., iron being mixed with twice its weight of pure ferric oxide and steel heated alone. Combustion was conducted so as to produce a well-fused oxide, subsequently ground and re-burned. Lead peroxide (at 300° C.) or zinc (at room temperature) was employed for eliminating oxides of sulphur from the gases leaving the tube; and a blank test was made upon the oxygen employed. *Graphitic carbon and silicon,* determined as usual. *Titanium:* Metal dissolved in hydrochloric acid of sp. gr. 1·05, and the insoluble residue, containing practically all the titanium, treated as usual for the determination of the latter by the hydrogen peroxide colourimetric method. *Phosphorus:* Molybdate precipitation employed. (See this J., 1912. 927—928.) *Sulphur:* 5 grms. of the metal dissolved in nitric acid, a little sodium carbonate added, the solution evaporated to dryness, the residue baked, then re-dissolved in hydrochloric acid, and evaporation and baking repeated. Residue dissolved in hydrochloric acid, and solution evaporated to a syrup, diluted to 40—50 c.c and filtered, the insoluble portion being treated separately for recovery of sulphur, by fusion with alkali carbonate and nitrate. To the cold filtrate (about 100 c.c.), 10 c.c. of a 10 per cent. solution of barium chloride added, liquid filtered after standing for 48 hours, and precipitate washed, first with a hot dilute solution of hydrochloric acid and a little barium chloride and then with hot water, the washings being collected separately and evaporated for recovery of dissolved barium sulphate. In the evolution method the gaseous products from the dissolution of the sample were passed through a mixture of 25 c.c. of ammonia (sp. gr. 0·90) and 5 c.c. of a 3 per cent. solution of hydrogen peroxide, this liquid being subsequently acidified and precipitated with barium chloride as usual. *Manganese:* The bismuthate method (Blair, Chemical Analysis of Iron, 7th ed., p. 121) was used. In the case of steels containing small amounts of chromium as impurity, titration against arsenite solution was employed; or the chromium was removed by zinc oxide before the application of the bismuthate process.

Methods for special alloy-steels:—*Copper:* The metal was dissolved in 10 per cent. sulphuric acid, the hot solution saturated with hydrogen sulphide (to prevent possible solution of copper during filtration) and filtered, the residue being digested with nitric acid and evaporated (ultimately to dryness) with hydrofluoric and sulphuric acids. From the solution obtained by dissolving the residue in sulphuric acid (or fusing it with alkali bisulphate) the copper was deposited electrolytically or determined colourimetrically with ammonia. *Molybdenum (in small amounts) with and without copper :* The steel was dissolved as for copper, the residue digested with *aqua regia* without previous ignition, the solution evaporated nearly to dryness with sulphuric acid, the residue dissolved in water and the solution saturated with hydrogen sulphide. In absence of copper, the precipitated molybdenum sulphide was collected on a Gooch crucible, converted into trioxide by ignition, and weighed; when copper present, the sulphides were dissolved in nitric acid and the copper removed by boiling the solution with potassium hydroxide and filtering, the filtrate being acidified with sulphuric acid and saturated with hydrogen sulphide to precipitate the molybdenum. *Nickel :* The dimethylglyoxime method used, the nickel being precipitated direct from an ammoniacal tartrate solution of the alloy-steel; with iron or ordinary steel a larger quantity of the sample was used and the bulk of the iron removed by an ether separation before the addition of the precipitant. In either case the nickel precipitate was allowed to stand for 1 hour before filtering. *Chromium :* For small amounts Blair's method (*loc. cit.*, p. 209) was used, the final determination being made colourimetrically (Hillebrand, Bull. 422, U.S. Geol. Survey, p. 147.) For larger amounts the methods of Blair (*loc. cit.*) and Cain (this J., 1912, 132) were employed. *Phosphorus :* The acetate separation, followed by double precipitation as magnesium phosphate was used for steels containing vanadium. *Manganese :* Steels free from vanadium, dissolved in *aqua regia*, the bulk of the iron removed by means of ether, the solution treated with magnesia or zinc oxide and filtered, the filtrate evaporated to a small volume, the salts converted into nitrates, and the manganese determined by the bismuthate method. Cain's method (Bureau of Standards, Tech. Paper, No. 24) was also used, either as described by the author, or with substitution of zinc oxide for cadmium carbonate. *Vanadium :* 5—10 grms. of the steel were dissolved in hydrochloric acid (1 : 1) with the addition of a few drops of hydrofluoric acid, and filtered, the insoluble residue being ignited, fused with sodium carbonate, extracted with water and added to the main filtrate. After oxidation with nitric acid the bulk of the iron was removed from the solution by means of ether, the acid layer concentrated and finally evaporated to dryness with strong nitric acid. The solution obtained by dissolving the residue in strong nitric acid was diluted, nearly neutralised with sodium hydroxide and poured slowly, with vigorous stirring, into 150—200 c.c. of a 10 per cent. solution of the latter; after which the solution was filtered and the precipitate re-dissolved and re-precipitated until shown to be free from vanadium by solution in nitric acid and addition of hydrogen peroxide. The combined filtrates were nearly neutralised with nitric acid and the vanadium precipitated by the addition of mercurous nitrate, the precipitate filtered off, washed with dilute mercurous nitrate solution, dried and ignited, the impure vanadium pentoxide thus obtained being purified by two or more fusions with sodium carbonate, each followed by precipitation with mercurous nitrate and ignition of the product. The pure vanadium pentoxide finally obtained was fused with sodium carbonate, the melt dissolved in dilute sulphuric acid, the vanadium reduced by sulphur dioxide, the latter expelled by boiling, and the liquid titrated against $N/50$ permanganate. The methods of Cain and Cain and Hostetter (this J., 1911, 958; 1912, 333) were also employed. *Tungsten :* The *aqua regia* method was used.—W. E. F. P.

Iron ore ; Concentration and briquetting of —— in Scandinavia. A. Beielstein. Stahl u. Eisen, 1914, **34**, 41—46, 100—105.

The methods of concentrating (mechanically and magnetically) and briquetting iron ore at various Scandinavian works are described. The briquettes as first shaped in a press, contain 8 to 10 per cent. of water. They are then passed through a long tunnel furnace, in which they first receive a preliminary heating, and are then suddenly exposed to a temperature of 1200° to 1300° C. The author considers that the magnetic iron oxide thereby becomes oxidised to ferric oxide with evolution of heat, so that locally much higher temperatures are reached, which cause the particles to fuse together. This view is confirmed by the fact that hæmatite briquettes require higher temperatures and are not so strong as magnetite briquettes. The size of grain, as affecting the drying, and the relative amounts of lime and silica, as affecting desulphurisation and the final structure of the briquette, are discussed with special reference to the ores treated at the various works. —T. St.

Gray cast-iron ; The influence of manganese on the mechanical properties of ——. F. Wüst and H. Meissner. Ferrum, 1914, **11**, 97—112.

Four series, each of 10 samples, were prepared with Mn from about 0·2 to about 2 per cent. in each series; C (total) about 2·79 per cent. in the first series, 3·08 per cent. in the second, 3·32 per cent. in the third, and 3·89 per cent. in the fourth; Si about 1·5 per cent. in the first three series, and 1·7 per cent. in the fourth. Mechanical and microscopic tests were made on all the samples. The members of the fourth series, with the highest carbon content, gave markedly the lowest "strength" results. Of the other three series, the second, in which the combined carbon most nearly approached 0·9 per cent., gave the best results. In the fourth series the strength increased with increasing manganese due to the graphite lamellæ becoming smaller. In the first three series, tensile and transverse strength attained a maximum with about 1 per cent. Mn. Flexibility and impact strength fell with increasing manganese, the effect being greater, the lower the carbon content. Hardness rose with increasing manganese, but for the low manganese values it remained practically constant in consequence of the increasing separation of graphite. The formation of graphite increased as the manganese content rose to 0·3 per cent., but higher amounts up to 2·5 per cent. had no further effect.—T. St.

Steel ingots : The making of sound ——. B. Stoughton. J. Franklin Inst., 1914, **177**, 65—73.

The addition of titanium alloy to molten steel has been found most effective for preventing or remedying the occlusion of oxides by the metal. In steel containing normal amounts of phosphorus and sulphur, segregation does not occur to a dangerous extent provided the metal is properly deoxidised before teeming, is not "wild" in the moulds and is cast in ingots not exceeding 5 to 10 tons each: the larger the ingot required, the smaller shoul be the phosphorus and sulphur contents of the metal ingots of great thickness should not be used unless th central core is to be drilled out and discarded as in th manufacture of large guns. For the prevention or elimination of shrinkage cavities in steel ingots, suitable "cro ping" of the latter, in conjunction with careful inspectio is regarded as being in most cases an adequate safeguar against the occurrence of unwelded pipe in finished stee (See also this J., 1912, 987; 1913, 536.)—W. E. F. P.

Damascene steel ; The problem of the old ——. W. Guertle Int. Zeits. Metallog., 1914, **5**, 129—141.

Damascene steel contains 1·0 to 1·6 per cent. C, a consists structurally of extremely small grains of cementi in a ground mass of ferrite. The characteristic appeara and properties of the steel are due to alternations cementite-poor and cementite-rich zones. Prolong heating at elevated temperatures, as recommended in earlier literature, cannot possibly give the desired res The most promising method seems to be to heat suita steel, in which an extremely fine-grained structure has b induced, to a temperature below 700° C. for a sufficie lengthy period. The necessary preliminary structure r be produced by very rapid cooling, or by severe work above the eutectoid temperature.—T. St.

Ferrosilicon. M. v. Schwarz. Ferrum, 1913, **11**, 80—90, 1914, **11**, 112—117.

The specific gravities of ferrosilicons containing up to 95 per cent. Si are given, and the determination of the specific gravity is recommended as a quick control test when the silicon exceeds 25 per cent. The specific resistance of ferrosilicon with up to 40 per cent Si increased discontinuously with increasing silicon content, the curve changing direction at points corresponding approximately with the iron silicides. The hardness, determined by Shore's scleroscope, attained a maximum at 7·5 per cent. Si. The analysis of ferrosilicon is described in detail. With up to 15 per cent. Si, *aqua regia* is used to dissolve the alloys, which are first reduced to a very fine state of division in a glass-hard steel mortar; with higher percentages, distillation in a current of chlorine, or fusion with potassium hydroxide must be resorted to. Both methods give good results. The fusion is best carried out in a deep, narrow, nickel crucible, and the addition of an oxidising agent, such as potassium nitrate, or small quantities of sodium peroxide, is sometimes necessary. —T. St.

[*Silver.*] *Ore flotation; A study of* ——. D. G. Campbell. School of Mines Quart., 1913, **35**, 28—34.

An investigation to determine the best conditions for concentrating—by agitation and froth flotation—a silicious silver ore containing 5—6 per cent. of finely disseminated sulphide minerals (pyrites, stibnite, silver sulphide and antimonide) including about 150 oz. Ag per ton. In the tests, for each of which 100 or 200 grms. of ore were employed, mineral (cylinder and machine), sperm, fish, whale, corn (maize), cotton-seed, rape-seed, China-wood, resin, pine and pine-tar oils were used; and variations were made in the proportion of sulphuric acid used, the period and rate of agitation, and the temperature of the ore mixture. A peripheral speed of 1100—1200 ft. per min. of the agitator-blades was necessary for efficient concentration of the material; and pine-tar oil was found to be the best frothing-agent, the most satisfactory proportion being about 0·1 per cent. of the weight of ore. The froth was non-selective in the absence of acid; and the amount of the latter necessary to give the best results was about 0·4 per cent. of the weight of ore. The concentrate obtained at 150° F. (65·6° C.) contained much less gangue than that produced at 65° F. (18·3° C.); the percentage extraction was also greater, and the time of agitation and consumption of oil less, at the higher than at the lower temperature.—W. E. F. P.

Cupellation losses. J. Loevy. Chem.-Zeit., 1914, **38**, 82—83.

In the assay of gold bullion the loss of metal due to bsorption by the cupel must be determined at frequent ntervals even for the same make of cupel. The following igures represent averages from six determinations made under exactly the same conditions in cupels of different nanufacture. (The paper gives no information as to the omposition of the cupels.)

pper; Resistivity of ——, *in temperature range* 20° *C. to* 1450° *C.* E. F. Northrup. J. Franklin Inst., 1914, **177**, 1—21.

IREE series of measurements were made, viz., in the nges 20° to 1143° C., 1394° to 20·5° C. and 1443° to ° C., and resistivity curves plotted from the data tained. The following values for copper of 99·39 per cent. conductivity are mentioned as having the highest probability of being correct:—

Temperature (° C.).	Resistivity (microhms per c.c.).
20	1·7347
1000	9·42
1082·6	10·20 (metal solid)
1082·6	21·30 (metal molten)
1100	21·43
1340	23·39
1450	24·22

—W. E. F. P.

Arsenic and antimony [*in copper*]; *Determination of* ——. E. E. Brownson. Min. and Eng. World, Dec. 27, 1913, 1155—1157.

The following methods, employed for converter and refined copper at the works of the Anaconda Copper Mining Co., Great Falls, Mont., U.S.A., and requiring about 24 hours for a single sample, are stated to give very accurate results.

Converter copper. 10 grms. are dissolved in a mixture of 30 c.c. of sulphuric acid, 20 of nitric acid and 50 of water, the solution boiled, diluted and electrolysed (current 4 amp.) until only about 0·25 grm. of copper remains unprecipitated: the liquid is made ammoniacal, acidified with hydrochloric acid, saturated with hydrogen sulphide, and after 30 mins. is filtered. The precipitate is dissolved in 25—30 c.c. of *aqua regia*, the solution evaporated to dryness, the residue boiled for 10—15 mins. with a solution of 4—5 grms. of potassium hydroxide in 30 c.c. of water, 25 c.c. of sodium sulphide solution (1 lb. of crystallised monosulphide in 2 litres of water) are added, the boiling continued for 5—10 mins. and the solution cooled and decanted through a small filter, the black residue being re-treated with a further 25 c.c. of sodium sulphide and finally washed, on the paper, with dilute sulphide solution. The filtrate (volume preferably 150—175 c.c.) is heated with 5 c.c. of hydrogen peroxide until the strong yellow colour fades, cooled, and electrolysed (0·10—0·15 amp.) to precipitate the antimony, re-solution of the latter being prevented by removing the cathode from the liquid as soon as the current is discontinued; the cathode is subsequently washed with water and alcohol, dried over an alcohol flame and weighed. The solution is acidified with sulphuric acid, saturated with hydrogen sulphide, and after 30 mins. filtered; the precipitate is dissolved in dilute ammonia (1 : 4), the solution acidified with sulphuric acid, in excess (7 or 8 c.c.), and the liquid evaporated until fumes of sulphur trioxide appear; the vessel is then covered and the solution heated strongly for 60—90 mins., after which it is successively cooled, diluted, neutralised with ammonia, acidified with hydrochloric acid, filtered, made alkaline with an excess of sodium bicarbonate, and titrated with iodine solution (5·105 grms. per litre) which has been previously standardised against arsenic trioxide. When the copper contains less than 0·04—0·05 per cent. As, the determination is best made on 20 grms.

Refined copper. The percentages of arsenic and antimony being usually very small, no attempt is made to separate the two elements. 25 grms. of the sample and 0·05 grm. of pure iron are dissolved in 85—90 c.c. of nitric acid and 75 c.c. of water, the solution boiled and diluted to 600—700 c.c. with very hot water: after which ammonia is added until the copper hydroxide first precipitated is redissolved, the liquid thoroughly stirred to coagulate the ferric hydroxide (boiling is not permissible), allowed to stand for 10—15 mins. and filtered. The iron precipitate, containing the arsenic and antimony, is washed with hot water and/or ammonia solution until most of the copper is removed, and dissolved, on the paper, in a boiling mixture of 3 c.c. of nitric acid, 5 of sulphuric acid and 50 of water, the solution being subsequently heated to boiling and electrolysed for 2 hrs. (current 0·5 amp.) to remove the last traces of copper. The liquid is then boiled, made ammoniacal, boiled again, allowed to stand, and filtered; the iron precipitate is dissolved in dilute hydrochloric acid, the solution neutralised with ammonia and reduced with ammonium bisulphite, or preferably with sodium hypophosphite, after which the liquid (freed from sulphur dioxide by boiling, if bisulphite has been used) is saturated with hydrogen sulphide and allowed to stand overnight. The precipitated sulphides are subsequently filtered on an asbestos felt in a platinum Gooch crucible, washed with water, alcohol, carbon bisulphide and alcohol, dried for 1 hour at 105° C. and weighed. When the assay is made on 25 grms. the percentage of arsenic and antimony combined is obtained by multiplying the weight of the mixed sulphides by the empirical factor 2·4.—W. E. F. P.

Copper-nickel matte ; The roasting of ——. E. F. Kern and M. H. Merris. School of Mines Quart., 1913—1914, 35, 1—21.

The paper is divided into sections dealing with the separation and determination of the sulphates, oxides and sulphides of copper and nickel in mixtures of these compounds: the determination of the reaction between copper oxide and nickel sulphide; and the roasting of a commercial copper-nickel matte. On heating a mixture of copper oxide and nickel sulphide, a small amount of the sulphate of each metal was produced between 525° and 600° C.: above 650° C. no sulphates were formed, but a mixture of the subsulphides of copper and nickel with cuprous sulphide, the formation of the latter being more rapid at higher temperatures; no reaction was observed on heating nickel subsulphide with copper oxide. In the roasting of copper-nickel matte, oxidation proceeded slowly below 600° C., while above 730° C. the particles became pasty and caking occurred. The best results were obtained by first roasting the powdered matte for about an hour at 450°—500° C., with free access of air, to cause a coating of oxide to form on the particles, and then raising the temperature to between 675° and 725° C., vigorous rabbling of the charge being maintained throughout the whole operation. —W. E. F. P.

Bronze, brass, and German silver ; Analysis of ——. L. Bertiaux. Ann. Chim. Analyt., 1914, **19**, 6—14.

Copper: 5 grms. are dissolved in a mixture of 10 c.c. of sulphuric acid (sp. gr. 1·84) and 20 c.c. of nitric acid (sp. gr. 1·33), diluted to 300 c.c. and electrolysed with a current of 2—3 amp. If much tin be present, the deposit of copper must be redissolved, and the solution again electrolysed, using 1 amp. At the end, the solution is removed and replaced (without breaking the electrical connections) by a beaker containing 2·5 c.c. of each acid and 300 c.c. of water; after 5 minutes, this is replaced by water: after another five minutes the electrodes are detached, the cathode washed with water, twice with alcohol, and dried for 10 minutes at 90° C. *Iron, nickel and cobalt, manganese, and aluminium:* The combined mother-liquors from the electrolysis are boiled down till they fume strongly, cooled, water added, the solution warmed till all salts dissolve, transferred to a beaker, saturated with hydrogen sulphide, and 1 or 2 c.c. of 50 per cent. ammonium sulphate added. The solution is filtered, heated to expel hydrogen sulphide, treated with 1 c.c. of perhydrol (hydrogen peroxide solution), and excess of ammonia, boiled, filtered, the precipitate redissolved in sulphuric acid, re-precipitated, filtered off, washed, dried, ignited in a silica crucible, and weighed. A few drops of sulphuric acid (1 : 1) and a few c.c. of hydrochloric acid are added, the oxides dissolved, and the solution evaporated to fuming; it is cooled, diluted to known bulk, and aliquot portions taken to determine iron and manganese. Aluminium is obtained by difference. The united filtrates from the ammonia precipitation are treated with 5 c.c. of sulphurous acid, 20 c.c. of 25 per cent. solution of magnesium sulphate and 25 c.c. of ammonia, heated to boiling, and electrolysed with a current of 0·1 amp., keeping very hot during the whole day during which the electrolysis goes on. This gives the nickel and cobalt together. *Zinc:* The mother liquor from the last electrolysis is boiled to concentrate it and remove sulphur dioxide, 50 c.c. of an 18 per cent. alcoholic solution of sodium hydroxide are added, and the solution concentrated to 200 c.c. A few c.c. of perhydrol and 20 c.c. of citric acid (10 per cent.) are added, and dilute sulphuric acid to neutrality, then a few drops of the sodium hydroxide and 20 c.c. of citric acid; the zinc is now deposited on a coppered cathode by a current of 0·4 amp. *Lead:* If manganese be absent, 5 grms. of the alloy are dissolved by means of so much copper solution (100 grms. of copper dissolved in 500 c.c. of nitric acid and made up to a litre) that there shall be 10 grms. of copper in all, and nitric acid so as to make 37 c.c. in excess. The solution is electrolysed with 0·3 amp. all night, and the anode weighed. If manganese be present, 5 grms. are dissolved as for the determination of copper, the solution evaporated to fuming, cooled, treated with water, warmed, and filtered through a close filter, washing with dilute sulphuric acid. The filter and precipitate are treated, in the original beaker, with 100 c.c. of the copper nitrate solution, 40 c.c. of ammonia (sp. gr. 0·92) and 80 c.c. of nitric acid (sp. gr. 1·33), kept just boiling for half an hour, filtered, diluted to 300 c.c., and electrolysed. *Tin:* From 2·5 to 10 grms. are treated with nitric acid (3·8 c.c. per grm., and 6 c.c. excess); after solution, the liquid is diluted to 450—500 c.c. with boiling water, a few c.c. of 50 per cent. ammonium nitrate added, the liquid boiled for a few minutes, filtered, and the insoluble residue washed, dried and weighed. In accurate work, it must then be fused with sodium carbonate and sulphur, and the impurities determined as usual.—J. T. D.

Aluminium ; Electro-plating —— *with nickel.* J. Canac and E. Tassilly. Comptes rend., 1914, **158**, 119—121.

The metal is passed through a bath of boiling potassium carbonate, washed, brushed with milk of lime, washed, dipped in 2 per 1000 solution of potassium cyanide, washed, dipped in a bath of 500 c.c. of hydrochloric acid and 500 c.c. of water in which 1 grm. of iron has been dissolved, till it acquires a "moiré" appearance, washed again, then placed in the depositing bath (in which nickel chloride gives better results than the sulphate). The nickel adheres so strongly as to be practically inseparable by any treatment which does not break the aluminium itself. Microscopic examination of the surface of the metal after the iron bath favours the view that the iron accentuates and localises the attack by the acid so as to produce a sort of cellular etching; by deposition in thes cellules the nickel is interlocked with the aluminium and thus firmly attached. Nickel-plated aluminium i permanent in moist air, and resists dilute sodium car bonate, glacial acetic acid, and saturated common sal solution. Its expansion-coefficient by heat is lowered and wires of it show no Thomson effect.—J. T. D.

Zinc-cadmium alloys ; Hardness and electrical conductivit of ——. A. Glasunow and M. Matweew. Int. Zeit Metallog., 1913, **5**, 113—122.

The alloys were prepared from the pure metals ar formed into rods by drawing up the molten metals in Jena-glass tubes. The rods were annealed for 84 hou at 225° C., and their conductivity then determine The curve obtained was a straight line, indicating t absence of solid solutions. The conductivity valu found for the pure metals were $\lambda_0 = 14·5$ for cadmiu and $\lambda_0 = 18·1$ for zinc. Tests made by Brinell's hardn curve, using a ball of 9·52 mm. diam. and a load of 2 kilos. with samples annealed at 225° C. for 72 hours, show a single maximum at the eutectic concentration, v 26·6 atomic per cent. Zn, but with alloys which had b first hammered and then annealed at 225° C. for 900 hou it was a straight line. The values for the pure metals we Zn 38·1 and Cd 22·0.—T. St.

Metals and alloys ; Experimental determinations of viscosity and density of some molten ——. R. A Int. Zeits. Metallog., 1914, **5**, 142—168.

The molten metal or alloy was drawn up from a grap crucible into a quartz vessel shaped like a pipette, and time measured for the outflow through a capillary t as the level passed two constrictions. The viscosity ve was surrounded by a glass tube on which a spira resistance wire was wound, whereby the determina could be made at a desired temperature. The experimental difficulty was to prevent oxidation of metal, and to cope with it an atmosphere of hydrogen containing methyl alcohol was provided inside the glass tube. In each case the coefficient of viscosity was calculated by Poiseuille's formula, the vessel being calibrated with mercury as the normal liquid. Determinations were made upon the pure metals Cd, Sn, Pb, and Bi, and upon Pb-Sn and Pb-Bi alloys, at temperatures ranging from the melting point to 550° C. The viscosity of all the metals investigated was of the same order of magnitude. The sequence of the viscosities was the same as that of the melting points. With cadmium, mercury, tin and lead, the fall in viscosity with rising temperature was larger in proportion as η was larger, but in the case of bismuth the fall was relatively less. The viscosity of the Pb-Sn alloys was somewhat smaller than would be the case if the law of mixtures held rigorously, and with the Pb-Bi alloys at low temperatures this discrepancy was even more marked. The viscosity temperature-coefficient of the Pb-Bi alloys was surprisingly small, and at higher Bi-concentrations appeared to be even lower than that of pure bismuth. The specific gravities of the same metals and alloys at different temperatures were determined using the same apparatus. The observed specific gravities of the alloys were very slightly lower than those calculated by the law of mixtures.—T. St.

Mineral and metal production in the United States. Eng. and Min. J., Jan. 10, 1914. [T.R.]

The following tables show the approximate production of the principal metals and minerals in the United States in 1913, figures for 1912 being added for comparison :—

Production of metals in the United States.

Metal.	Unit.	1912.	1913.
luminium	pounds ...	(*g*)40,000,000	(*h*)50,000,000
opper (*a*)	pounds ...	1,241.762,508	1,228,811,581
erromanganese .	long tons .	227,725	353,100
old (*b*)	dollars ...	93,451,500	88,301,023
ron	long tons .	29,525,412	30,808,300
ead (*c*)	short tons	410,006	433,476
ickel (*e*)	pounds ...	42.168.769	(*e*)38,614.745
uicksilver	flasks	(*f*)25,147	(*h*)21,000
ilver (*b*)	troy ounces	63,766,800	67,601 111
inc (*d*)	short tons	348,638	356,146

(*a*) Production from ore originating in the United States. *b*) The statistics for 1912 are the final and those for 1913 are he preliminary statistics reported jointly by the director of the int and the U.S. Geological Survey. (*c*) Production of refined ead from ore and scrap originating in the United States; antimonial lead is included. (*d*) Total production of smelters, except hose treating dross and junk exclusively; includes spelter derived rom imported ore. (*e*) Imports; for 1913, first 10 months only. his nickel is refined in the United States for the production of etal, oxide and salts. (*f*) As reported by U.S. Geological Survey.) As reported by the Metallgesellschaft, Frankfort am Main.) Estimated.

Production of mineral and chemical substances.

Patents.

on.] *Magnetic body; Process for improving the magnetic qualities of a ——.* R. A. Hadfield, Sheffield. U.S. Pats. 1,082,947 and 1,082,948, Dec. 30, 1913.

e material, an alloy of iron with other elements (*e.g.*, con), is heated to 700°—800° C., or to 900°—1000° C., cooled slowly; then reheated to 900°—1000° C., to 700°—800° C., respectively, and cooled rapidly. —W. E. F. P.

Sintered product rich in metallic iron; Production of —— from fine iron ores, pyrites cinder, or the like. Metallbank und Metallurgische Ges. A.-G. Ger. Pat. 268,159, Nov. 13, 1910.

The fine ore or the like, mixed with a certain quantity of carbon, is subjected to a blast which is passed first through a layer of incandescent carbon below or above the charge and of such thickness that the gases which come in contact with the charge before sintering are as far as possible rich in carbon monoxide and free from oxygen. Several alternating layers of the charge and of carbon may be employed.—A. S.

[*Gold and silver.*] *Ores; Treating metal-carrying ——.* I. Kitsee, Philadelphia, Pa. U.S. Pat. 1,082,596, Dec. 30, 1913.

A cyanide process in which the solution is periodically subjected to the action of an electric current while in contact with the ore.—W. E. F. P.

Zinc; Condensation of ——. A. L. J. Queneau, Philadelphia, Pa. U.S. Pat. 1,082,765, Dec. 30, 1913.

The interior of the condenser is provided with carbon baffle-plates arranged transversely and longitudinally, or radially.—W. E. F. P.

Zinc; Process for precipitation of ——. F. L. Wilson and S. E. Bretherton, Berkeley, Cal. U.S. Pat. 1,083,785, Jan. 6, 1914.

In the electrolysis of zinc sulphate solution, the strength of the solution is maintained substantially constant by the addition of zinc carbonate. Acid ammonium carbonate is also added so that ammonium sulphate is formed, which acts as a catalytic agent and causes a more uniform deposition of the zinc. The ammonia and carbon dioxide liberated from the bath are recovered.—T. St.

Zinc; Separation of —— by the action of a blast of air on a mixture of the zinciferous material with fuel and, if necessary, with other substances. F. C. W. Timm. Ger. Pat. 268,427, Oct. 9, 1912.

The "blowing" is effected in stages, and between successive blowings the charge is moved from one part of the permeable hearth or grate, and then replaced thereon or on another part or moved from one grate to another one: during this operation portions of the charge at different temperatures may be mixed with one another. A rotating or tilting grate may be used, the blast being delivered only through that part covered by a sufficient depth of charge. The apparatus shown consists of a rotary converter with a grate let into the wall at one part. The blast is delivered below the grate with the converter in such a position that the grate is at the lowest part. After a period of blowing, the blast is cut off, the converter rotated several times to mix the charge, then restored to its original position, and the blast again delivered, and so on.—A. S.

Tungsten and method of making the same for use as filaments of incandescence electric lamps and for other purposes. W. D. Coolidge, Assignor to General Electric Co., Schenectady, N.Y. U.S. Pat. 1,082,933, Dec. 30, 1913.

A mass of pure tungsten, formed by agglomerating and sintering the powdered metal, is subjected to repeated hot swaging, until it becomes fibrous in structure, and then further reduced by hot drawing.—W. E. F. P.

(1) *Desulphurising ores;* (2) *recovering sulphur;* (3) *obtaining sulphur from sulphides;* (4) *desulphurising and briquetting ores;* (5) *extracting sulphur: Processes of ——.* W. A. Hall, New York. U.S. Pats. 1,083,246, 1,083,250, 1,083,251, 1,083,252 and 1,083,253, Dec. 30, 1913.

(1) For recovery of the "fixed sulphur atom," sulphide ores are exposed, in the presence of steam, to a non-oxidising flame, at a temperature sufficiently high to distil

the sulphur, without fusing the ore. (2) A layer of sulphide ore, especially pyrrhotite ore, in which no considerable amount of sulphide having both "fixed and feeble sulphur atoms" exists, is treated with a reducing flame obtained by burning gas containing much methane and ethylene, the temperature in the reaction zone being maintained at 700°—900° C.; steam may be added to the gases leaving the furnace. (3) Sulphide ores are exposed to the simultaneous action of a flame and steam, preferably with agitation, in a series of successive steps in each of which the quality of the flame and the relative amount of steam is different: at first a highly reducing flame and much steam may be employed, then a flame of less reducing power with less steam, and finally an oxidising flame almost in the absence of steam. (4) A moving body of ore is subjected to a non-oxidising flame (*e.g.*, of oil fuel) projected downwards upon it, and the vaporous products, from which the sulphur (expelled as such) may be recovered, are withdrawn from below the body of ore which may be heated to sintering temperature. (5) A moving mass of pyrites (whilst being agitated) is heated, in the substantial absence of materials capable of combining with it, to a temperature at which the loosely combined sulphur atom is expelled, fresh pyrites being continuously introduced into the heating chamber and the desulphurised ore withdrawn.—F. Sodn.

Aluminium; Process for obtaining ——. P. C. McIlhiney, Great Neck, N.Y. U.S. Pat. 1,083,691, Jan. 6, 1914.

Felspar is treated with aqueous hydrofluoric acid, and the solid aluminium fluoride obtained is added to a fused bath of aluminium fluorides and a fluxing ingredient. Water or steam is added at the same time in sufficient quantity and in such a manner as to react with the aluminium fluoride to produce hydrofluoric acid and alumina. The fused mixture is subjected to electrolysis to obtain metallic aluminium, fresh quantities of aluminium fluoride being continuously added, and the hydrofluoric acid recovered and used again. The potassium silicofluoride formed from the felspar is treated to yield potassium hydroxide.—T. St.

Aluminium alloy; Hard ——. W. de l'Or, geb. Feyjean. Ger. Pat. 268,515, March 8, 1913. Addition to Ger. Pat. 265,924 (this J., 1913, 1160).

The alloy described in the chief patent consisting of Al 84, Pb 11, and "glass" 5 per cent., is stated to be considerably improved by the addition of about 2 per cent. Sn.—A. S.

Nickel alloy of high chemical resistance and which can be worked mechanically. W. and R. Borchers. Ger. Pat. 268,516, June 12, 1913. Addition to Ger. Pat. 265,328.

The nickel in the alloy described in the chief patent (this J., 1913, 1160) may be partly (up to 90 per cent.) replaced by iron.—A. S.

Furnace; Metallurgical ——. L. Addicks, Perth Amboy, and C. L. Brower, Chrome, N.J. U.S. Pat. 1,083,719, Jan. 6, 1914.

The furnace has a lining of magnesite bricks laid with a mortar of magnesite dust and a solution of sodium silicate, the walls and roof being of chrome brick.—T. St.

Molten metal; Process of mixing minerals and metals with ——. S. L. Boggs, Pittsburgh, Pa. U.S. Pat. 1,083,724, Jan. 6, 1914.

Flue dust, or other fines, is added to molten metal as this runs from the furnace spout into a receiving vessel. The metal is then further agitated and its temperature maintained by the introduction of a blast.—T. St.

Alkali metals; Electrolytic production of —— from fused caustic alkalis. Oesterreichischer Verein für Chem. und Metall. Produktion. Ger. Pat. 267,897, Jan. 23, 1912.

Concentric electrodes are used, separated by an annular partition of the solidified electrolyte produced by artificial cooling. In order to prevent the aqueous alkali gradually formed at the anode, as the result of the production of water by the discharge of hydroxyl ions, from reaching the cathode compartment and so diminishing the current yield, the partition is made to dip into the fused electrolyte to a lower level than the electrodes.—A. S.

Soaking pits. [" *Tiefōfen.*"] O. Uehlendahl. Ger. Pat. 266,974, Jan. 19, 1913.

One or more of the pits are connected with fore-hearths. The waste gases from the pits are utilised in part for preheating the air used for combustion of the heating gases for the pits and for the fore-hearths and in part for directly heating the fore-hearths.—A. S.

Soaking pit. F. Siemens. Ger. Pat. 268,379, Jan. 25, 1913.

Partitions or pillars of refractory chequerwork, acting as heat-accumulators, are interposed between the ingots in the pit.—A. S.

Heating or annealing easily oxidisable articles in regenerative furnaces. F. Siemens. Ger. Pat. 268,278, June 5, 1912.

The heating or annealing is effected by non-oxidising gases which have been heated in the regenerators, and after leaving the annealing chamber, these gases are burnt in order to heat the cooled regenerators.—A. S.

Steel ingots and castings; Process and apparatus for the thermal treatment of ——. E. C. R. Marks, London. From Soc. Anon. Italiana Gio. Ansaldo & Co., Genoa, Italy. Eng. Pat. 2484, Jan. 30, 1913.

See Fr. Pat. 453,712 of 1913; this J., 1913, 794.—T. F. B.

Metals; Process for rendering non-ductile —— ductile. C. Trenzen, Cologne, Germany. Eng. Pat. 26,800, Nov. 21, 1912. Under Int. Conv., Aug. 14, 1912.

See U.S. Pat. 1,074,993 of 1913; this J., 1913, 1017. —T. F. B.

Metals and alloys; Preparation of ——. A. P. Strohmenger, Westminster. Eng. Pat. 27,643, Nov. 30, 1912.

See U.S. Pat. 1,073,543 of 1913; this J., 1913, 981.—T.F.B.

Metallic surfaces; Cleaning ——. C. H. Thompson, Amblecote, Stafford. Eng. Pat. 9, Jan. 1, 1913.

See Fr. Pat. 458,524 of 1913; this J., 1913, 1074.—T. F. B.

Condensation of vapours of volatile metals, especially o zinc vapour; Process and apparatus for the ——. F. C. W. Timm, Hamburg, Germany. Eng. Pat. 1616 Jan. 20, 1913. Under Int. Conv., Feb. 17, 1912.

See Fr. Pat. 454,399 of 1913; this J., 1913, 871.—T. F. B

Ores; Process of chloridizing ——. A. D. Ledou Summit, N.J. U.S. Pat. 1,082,509, Dec. 30, 1913.

See Fr. Pat. 460,579 of 1913; this J., 1914, 88.—T. F.

Metallurgical furnace. L. A. Smallwood, Birmingha U.S. Pat. 1,082,828, Dec. 30, 1913.

See Eng. Pat. 14,812 of 1909; this J., 1910, 958.—T. F.

Alloys; Process of improving ——. A. Wilm, Schlach ensee, Germany. U.S. Pat. 1,083,903, Jan. 6, 1914.

See Eng. Pat. 6485 of 1910; this J., 1910, 1210.—T. F.

Metals from their ores; Apparatus for extracting — H. S. MacKay, Assignor to MacKay Copper Proc Co., Riverside, Cal. U.S. Pat. 1,084,351, Jan. 13, 19

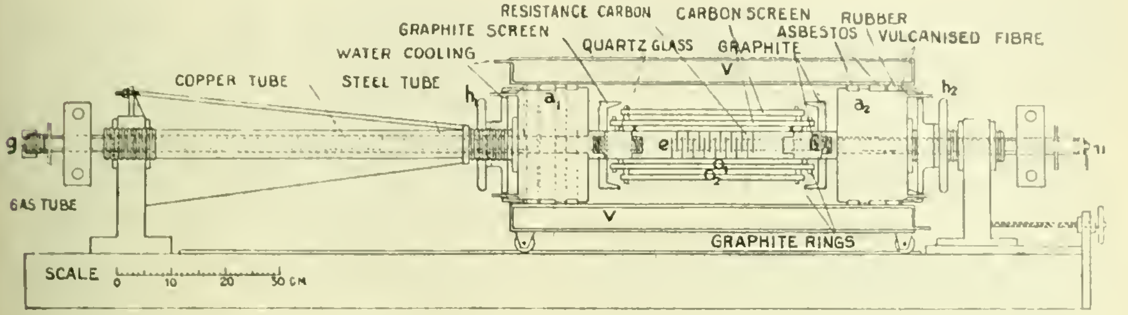
See Fr. Pat. 428,521 of 1911; this J., 1911, 1167.—T. F

XI.—ELECTRO-CHEMISTRY.

Electric vacuum furnace for high temperatures. J. Wolf and E. Müller. Z. Elektrochem., 1914, 20, 1—4.

The furnace which is represented diagrammatically in the figure has a heating unit consisting of a carbon or graphite tube, e, provided with slits about 1—2 mm. wide, 10 mm. apart, extending two thirds of the diameter alternately from opposite sides. This gives a certain elasticity and avoids fracture. The outer cooling jacket, v, which is mounted on wheels, can be readily removed to expose the interior, and can be made gas-tight by turning the wheels (h_1 h_2) which compress the rubber rings between the outer jacket and the end jackets (water-cooled pistons) a_1, a_2. The rubber is protected from the hot gases by rings of asbestos. The carbon tube screens, o_1, o_2, are each divided by horizontal slits so that the heating element can be easily exposed; they are spaced apart and insulated by quartz blocks, x. The substance to be heated is contained in a carbon boat, 1 cm. wide and 10 cm. long, to which is attached a long graphite rod which facilitates introduction into and removal from the furnace at a. If the object is to be suddenly cooled, a steel tube carrying an iron receiver is attached at g. When the boat is passed into the steel tube and inverted, the object falls into the receiver which may then be removed. Temperatures are measured optically through g, the copper tube being blackened inside. Very high and constant temperatures can be reached very rapidly, while the cost of the furnace and of the energy consumed at a given temperature is very low.

—W. H. P.



Tentative specifications and analytical procedure for 30 per cent. Hevea rubber insulating compound. See XIV.

Patents.

Furnaces; Electric ——. F. C. Wardall and J. Marchant, Huddersfield, Yorks. Eng. Pat. 2718, Feb. 3, 1913.

The furnace, provided with a vacuum casing, has a tapping tube constructed of alumina, extending through the lining and the metal wall to the base of the hearth. A carbon or like tube surrounds the portion of the tapping tube which extends through the lining and wall, with means for temporarily putting the carbon tube into an electric circuit, thus preventing the congealing of material in the vent hole during tapping. A wad, adapted to fuse at a given temperature, or a special valve, is used to close the vent hole. The outer end of the tapping tube is surrounded by a cylinder, the interior of this and of the tapping tube being in communication with the vacuous space in the casing. The upper part of the furnace casing forms a dome, and is provided with a controlled outlet for the gases. When the wad begins to soften, the valve in the dome is closed, and the gas pressure rises in the interior of the furnace; on the outlet side of the wad there is a diminished pressure, and the wad is thus forced towards the outlet end of the tapping tube.—B. N.

Furnace: Electric ——. P. Eyermann, Witkowitz, Austria. Eng. Pat. 9381, April 21, 1913.

The furnace, of the tilting variety, is so constructed that the hearth may be rotated in relation to the stationary cover, or the latter may be rotated whilst the hearth is stationary, or both may be rotated continually or periodically in the same, or in opposite directions, at the same or at different angular velocities, the tilting frame of the furnace remaining stationary in all cases. The central line between the electrodes is disposed eccentrically to the central line of the hearth. Both electrodes may pass through the cover of the furnace, or through the base and lateral walls.—B. N.

Furnace; Electric ——. J. Burke, Erie, Pa., Assignor to Burke Electric Co. U.S. Pat. 1,082,459, Dec. 23, 1913.

The furnace is supplied with polyphase currents through a transformer, which converts an alternating current into several secondary alternating currents of different phases by means of secondary coils unconnected with each other. Each secondary current is conveyed to a separate pair of electrodes disposed in the furnace in arcing relation to the charge.—B. N.

Ozone generators; Electric ——. C. W. Denny, London. Eng. Pats. 4355 and 17,969, Feb. 20 and Aug. 7, 1913.

The generator comprises a number of elements, each consisting of an outer and inner tubular or cylindrical electrode, arranged concentrically and separated by an annular space. The inner electrode consists of a metallic stationary tube provided on its periphery with a great number of integral points, produced from the metal of the tube by a "knurling" process, the surface being cut up by longitudinal and circumferential grooves. Each element is mounted by means of a clip upon a radial arm carried by a central boss or spindle, so as to be situated in the current of air created by a fan. In an alternative form, the outer electrode consists of a chain wound upon an insulating tube.—B. N.

Diaphragm for electrolytic apparatus. H. D. Rul m, Buffalo, N.Y., Assignor to Niagara Alkali Co., Niagara Falls, N.Y. U.S. Pat. 1,082,286, Dec. 23, 1913.

The diaphragm comprises a wire gauze cathode, and a number of superposed permeable layers, one or more of the inner layers being supported by and secured to the cathode, and one or more of the outer layers only loosely retained in position. The thickness of the diaphragm may thus be readily varied by adding or removing layers, a removable arrangement being provided for holding the loose layer or layers in position.—B. N.

Insulating compound. T. A. Edison, Llewellyn Park, West Orange, N.J. U.S. Pat. 1,083,354, Jan. 6, 1914.

The compound contains six parts by weight of tetrachloronaphthalene in tough flexible crystals, the interstices

being filled with one part by weight of a fusible substance, such as asphaltum, to render the compound non-porous.
—B. N.

Insulating material [from paper pulp] and process of making the same. J. C. Peabody, Assignor to The Republic Manufacturing Co., Boston, Mass. U.S. Pat. 1,083,755, Jan. 6, 1914.

A MIXTURE of sizing and free or uncombined resin is added to paper pulp in suspension in a liquid, in the proportion of at least 3 oz. of resin to 1 lb. of the dry fibre. The resin is distributed uniformly over the surface of the fibres by beating the mixture, the liquid being then extracted, and the residue subjected to heat and pressure to render it dense and homogeneous.—B. N.

Chemical compounds [nickel hydroxide for use in alkaline storage batteries]; Art of forming ——. T. A. Edison, Llewellyn Park, West Orange, N.J. U.S. Pat. 1,083,355, Jan. 6, 1914.

NICKEL hydroxide is formed by rubbing together in an undissolved condition, a dry pulverised salt of nickel containing water of crystallisation and an excess of a dry soluble hydroxide. The resulting mass is dried, washed to remove the soluble salt, and the nickel hydroxide finally dried.—B. N.

Battery; Storage ——. T. A. Edison, Assignor to Edison Storage Battery Co., West Orange, N.J. U.S. Pat 1,083,356, Jan. 6, 1914.

THE active material for the positive electrodes of alkaline storage batteries is obtained by adding to a solution of a nickel salt, containing a small percentage of a cobalt salt, from 2 to 12 per cent. of alkali in excess of the amount necessary to effect complete precipitation. The precipitated nickel hydroxide, containing not more than 5 per cent. of cobalt hydroxide, is dried, together with the excess of alkali and the soluble reaction products, the latter and free alkali being afterwards washed out and the residue dried.—B. N.

Chemical reactions [production of nitrogen oxides, etc.] in gases by means of electric arcs. J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. Eng. Pat. 974, Jan. 13, 1913.

SEE Ger. Pat. 265,413 of 1912; this J., 1913, 1068.—T. F. B.

Electrode for preventing cathodic reduction. A. Pietzsch and G. Adolph, Munich, Germany. U.S. Pat. 1,083,132, Dec. 30, 1913.

SEE Eng. Pat. 22,028 of 1912: this J., 1913, 31.—T. F. B.

Fireproof electrically-conducting bodies and process of manufacturing the same. G. Egly, Treptow, Assignor to Gebr. Siemens und Co., Lichtenberg, Germany. U.S. Pat. 1,084,199, Jan. 13, 1914.

SEE Fr. Pat. 420,183 of 1910; this J., 1911, 372.—T. F. B.

Furnace; Electric ——. G. Méttler, Berlin. U.S. Pat. 1,084,466, Jan. 13, 1914.

SEE Fr. Pat. 436,947 of 1911; this J., 1912, 499—T. F. B.

Manufacture [sterilisation and purification] of sugar. Eng. Pat. 29,524. *See* XVII.

XII.—FATS; OILS; WAXES.

Palm oil; Mechanical separation of ——. W. Kemner. Verhandl. Ölrohstoff-Kommission der Kolon.-Wirtsch. Komitees, 1913, 1, 17—22.

BY the native method of separating the oil from the palm fruit in the Cameroons (viz., heating over free fire and hand expression) it is estimated that 10 men can produce about 400 kilos. of palm oil in a month, so that about 22,000 natives would be required for the year's production of about 13,000 tons of palm kernels and 3500 tons of palm oil. In Haake's process, introduced in 1907, the fruit is broken up, repeatedly heated with hot water, and expressed, and the fragmentary residue of shells separated from the kernel pulp by centrifugal force. On the average 15 kilos. of oil and 14 kilos. of kernels are thus obtained from 100 kilos. of fruit, and 15 to 20 men can deal with 4 to 5 tons of fruit a day. The quality of the oil is similar to that produced by the native process, but the high proportion of free fatty acids (sometimes over 30 per cent.) renders the product only suitable for soap or candles. The oil is inferior to the best native soft Lagos oil. The process recently introduced into the Agu plantation in Togo gives much better results, the proportion of free fatty acids being usually below 8 per cent. In this process the entire fruit, after removal of the central core, is heated for some time at 100° C., within two hours of gathering, and is then mechanically pounded and expressed once only. From 16 to 17 per cent. of palm oil and 10 to 11 per cent. of kernels are thus obtained. The preliminary heating checks the formation of free fatty acids during the expression, though it probably causes a loss of aroma
—C. A. M.

Palm oil as an edible fat. F. Hupfeld. Verhandl. Ölrohstoff-Kommission der Kolon.-Wirtsch. Komitees, 1913 1, 23—30.

PALM oil containing only 7 per cent. of free fatty acids fetches M.25 per metric ton (24s. 10½d. per ton) more than oil containing 12 per cent. of free acids, and a premium of M.2.50 per metric ton (2s. 6d. per ton) is offered by one German firm for each reduction of 0·5 per cent. below 12 per cent. of free fatty acids. Now that it is possible to produce palm oil with a smaller proportion of acidity, it is suggested that a distinction should be made between ordinary palm oil and "edible palm oil," and that the latter should contain not more than 8 per cent. of free acids, 0·5 per cent. of dirt and 0·5 per cent. of water. There would be no difficulty with regard to the German Customs, since such palm oil would not be suitable as such for food, but only for the manufacture of edible fats.
—C. A. M.

Para rubber seed [oil]; Utilisation of ——. Bull. Imp. Inst., 1913, 11, 551—559.

THE results of examination of further samples of Para rubber seed, oil and oil-cake are given (see also this J., 1905, 1117; 1907, 764; 1910, 35; 1911, 755, 1265). Samples of oil were submitted to several paint and varnish manufacturers who stated generally that the oil was suitable for use in paints and varnishes, although it dried more slowly than linseed oil. A sample of the oil which caused "feeding up" of the paint, was found to have high acidity (acid value about 41); the "feeding up" of the paint appeared to be due to the free acid, as the oil when ground with white lead gave a stiff pasty paint, while the oil from which free acids had been removed gave a fluid paint. The oil appeared to be unsuitable for linoleum manufacture (cf. this J., 1914, 33), but could be used for the production of soft soap. The general conclusion was that the oil is less valuable than linseed oil for paint manufacture but that it should fetch from 25s.—30s. per cwt. (July, 1912). Small experimental consignments of oil, seed, and cake have been sold already in the United Kingdom. A sample of Para rubber seed cake contained: moisture, 8·75; crude protein, 30·19; true protein, 24·85; fat, 8·71; starch (by diff.), 41·74; fibre, 5·01; and ash, 5·60 per cent., corresponding to a nutrient ratio of 1 : 2·0, with 139 food units. The cake was free from alkaloids or saponin, but cyanogenetic glucosides were present in the above sample in quantity equivalent to about 0·02 per cent. HCN. Feeding trials on a fairly extensive scale were carried out at the South-Eastern Agricultural College, Wye. Sheep refused to eat the cake even when admixed with other foods. The cake produced a laxative effect when fed to young cattle at the rate of 5 lb. per diem, but dairy cows consumed

14 lb. per diem without any injurious effect upon the milk or butter produced, while satisfactory increases in weight were obtained. Trials on a larger scale are considered necessary to determine more exactly the value of Para rubber-seed cake as a food for cattle.—R. G. P.

Oil seeds and oils; Some new or little known ——. Bull. Imp. Inst., 1913, **11**, 559—574.

Safflower (*Carthamus tinctorius* L.) from Nyasaland. The seeds contained 29·6 per cent. of oil and 5·7 per cent. of moisture. Oil seed crushers reported that the seeds contained rather more moisture than is usual in average quality Indian seed, and would be worth about £7 10s. per ton in London (Feb., 1913). "*Raina*" *seed* (*Amoora Rohituka* W. and L.) from Bengal. The tree yielding these seeds is an evergreen growing in Northern and Eastern Bengal and Assam where the oil is used locally for burning, and medicinally. The seeds were nearly spherical, brownish-black with a pale brown hilum, and consisted of a thin brittle husk which adhered to the kernel; weight of 1 seed about 0·7 grm. Two samples of seed contained 42·5 and 43·5 per cent. of oil respectively. The oil was viscous, clear, and yellow brown; it had an unpleasant smell and bitter taste. Sp. gr. at 15° C. 0·929—0·931; saponification value, 193·0—192·3; iodine value, 131·7—132·5; Hehner value, 92·4; unsaponifiable matter, 1·2 per cent.; Reichert-Meissl value, 1·2; solidif. pt. of fatty acids (titer test), 32·4° C. The oil would be suitable for soap-making. The residual cake could be used only as manure on account of its bitter taste. Nominal value of seed £9 per ton in the United Kingdom (April, 1913). "*Toramani*" *seed* (*Eruca sativa* Mill.) from India. This Cruciferous plant is extensively grown as a green fodder in India, where the seed oil is used as an illuminant and as an edible oil, the cake being used as cattle food. The seed is occasionally imported to the United Kingdom as a substitute for rape seed. The very small seeds (100 weigh only 0·25 grm.) were dark brown or dark grey and yielded 30·8 per cent. of clear yellow oil with a slight mustard-like odour and taste. Sp. gr. at 15° C., 0·915; saponification value, 175·7; iodine value, 101·6. The oil could probably be used as a substitute for rape or colza oil. The seeds contain rather less oil than rape seed and were valued at 40s. per quarter (416 lb.) in London when rape seed was at 49s. 3d. per quarter. "*Panang*" *seed* (*Calophyllum Inophyllum*) from Bengal. The seeds were brownish black, almost spherical, ¾—1 inch in diameter and consisted of an easily-broken shell surrounding a round, soft, whitish kernel which weighed about 4 grms. The kernels contained 13 per cent. of moisture and 55 per cent. of viscous, green, bitter oil. A large sample of kernels from Bengal contained 3·3 per cent. of moisture and 71·4 per cent. of oil having the sp. gr. at 15° C., 0·950; acid value, 45·9; saponification value, 193—203; iodine value, 97·7. Oilseed crushers stated that the oil was excellent for soap-making and that the kernels would be worth £16 per ton. The residual cake is bitter and therefore would only be suitable for use as manure. A sample of the oil prepared in Fiji ("Ndilo" oil) was of deep blue colour, probably owing to contact with an iron vessel during preparation, as the oil contained iron and it is known that iron compounds give a blue colour with oils of *Calophyllum* species. "*Nahar*" *seed* (*Mesua ferrea* L.) from Assam. The seeds were brown and generally pear-shaped; they consisted of a shiny, brittle, woody shell containing a single buff-coloured kernel. Shell, 34 per cent., kernel 56 per cent. The kernels contained 76 per cent. of reddish-brown oil with a sweetish smell and slight bitter taste. The oil became semi-solid on standing at 15° C. Sp. gr. at 15° C., 0·935; saponification value, 204; iodine value, 90. The oil should be worth about £25—£27 per ton in the United Kingdom (July, 1913) for use in soap-making. The esidual cake is bitter and probably poisonous (cf. Bull. nst. Botan. Buitenzorg., 1904, **21**, 4): it would only e of value as manure. The whole seeds would be worth 10—£11 per ton, the kernels £17—£18 per ton. *Telfoiria edata* (Hook) seeds from Uganda. The kernels contain early 63 per cent. of viscous reddish-brown oil. The hells contain a bitter principle, which contaminates the oil when the whole seeds are crushed and no machine has yet been devised for removing the shells (see this J., 1912, 692, 731). "*Illipé*" *oil* (*Bassia latifolia*) from Mauritius. This was a pasty yellow fat with a slightly rancid taste of somewhat softer consistence than that of samples of *B. latifolia* fat previously examined. Sp. gr. at 100°/15° C., 0·861; acid value, 20·3; saponification value, 196·2; iodine value, 52·6. The fat would be suitable for soap-making but probably not for edible use. It would probably be better to export the kernels as there is a large market for such material at about £11 per ton. *Pentadesma butyracea* (Don) fruits and kernels from West Africa. The fruits were lemon-shaped, about 5 to 6 in. in length, 2½ to 3½ in. in diameter, and of dark brown colour. Each fruit contained about 8 kernels imbedded in dark coloured pulp. The fruits yielded 37 to 41 per cent. of moist kernels of irregular shape, about 1½ in. long and 1 in. in diameter. On drying in air the kernels lost up to 74 per cent. by weight. The fat content of the air-dried kernels was very variable, probably owing to imperfect drying and differences in degree of ripeness, results varying from 7·0 to 40 per cent. being recorded. The fat was of pale yellow colour and had a pleasant taste and smell. Sp. gr. at 100°/15° C., 0·857; acid value, 3·1; saponification value, 186; iodine value, 46·5. The residual cake is of no value for cattle feeding. Kernels in good dry condition should be worth £8—£10 per ton. "*Gru-gru*" *nuts* (*Acrocomia sclerocarpa*) and kernels from the West Indies. The gru-gru palm is a native of the West Indies and South America and is widely distributed in Trinidad but does not usually occur in such abundance as to enable kernels to be exported commercially, while there is a local demand for kernels for edible use (cf. this J., 1914, 9). This palm also occurs in Grenada, St. Vincent, St. Lucia and the Leeward Islands. The nuts had a hard brittle, woody shell about ⅛ in. in thickness; the kernels resembled oil palm kernels (*Elaeis guineensis*). Trials showed that the nuts could be shelled fairly well by a palm nut cracking machine. The kernels contained about 7 per cent. of moisture and 56—57 per cent. of fat resembling cocoanut and palm kernel oils. Sp. gr. at 100°/15° C., 0·868; acid value, 1·5; saponification value, 255; iodine value, 16—21; Reichert-Meissl value, 5·7—6·8; Polenske value, 10·0—12·6; solidif. pt. of fatty acids (titer test), 20·5° C. The kernels should fetch about the same price as palm kernels if exported in fair quantities.—R. G. P.

Drying oils; Note on the insoluble bromide test for ——. J. A. L. Sutcliffe. Analyst, 1914, **39**, 28—30.

The method for the determination of the amount of insoluble brominated glycerides resulting from the bromination of linseed oil has led to such variable results, according to the conditions of experiment, that the value of the test has been called in question. The author recommends the following procedure as giving standard results: One grm. of the oil in a tared flask is dissolved in 40 c.c. of redistilled ether, 5 c.c. of glacial acetic acid are added and the contents of the flask cooled to about 11° C. Bromine is added, drop by drop, with constant shaking, until an excess is indicated by a red colour. The closed flask is allowed to stand in water over-night. The liquid is filtered through a Gooch crucible having a disc of filter-paper over the asbestos. The precipitate is retained in the flask as far as possible during the first three washings, each with 10 c.c. of cooled ether, and is transferred to the crucible with the two last washings. The crucible and the flask are dried for 3 hours in the water-oven and weighed. Finally the melting point of the insoluble bromides is determined; in the case of linseed oil this should be 141°—144° C. The percentage of bromide obtained is related to the iodine value of the oil graphically as a straight line, which may be expressed by the formula: per cent. of bromide = (0·63 iodine value)—78·0.

—J. F. B.

Fat from the seeds of Trichilia subcordata. J. Östling. Ber. deuts. Pharm. Ges., 1913, **23**, 667—671.

The seeds of the German E. African tree, *Trichilia subcordata*, yielded 55·7 per cent. of a fat consisting in the main of palmitin and stearin with a little olein, and glycerides of butyric and other volatile fatty acids. The fat had the following characters :—M. pt. 45° C. ; solidif. pt. (not sharp), 30°—24° C. ; acid value, 39·6 ; saponif. value, 201·5 ; iodine value, 39·94 ; Reichert-Meissl value, 3·3 ; m. pt. of fatty acids, 54°—55° C. ; solidif. pt. of fatty acids, 51·5 ; and iodine value of fatty acids, 42·45. The fat is suitable for the manufacture of soap and candles. —C. A. M.

Iodine in oils ; Detection and determination of small quantities of ——. G. Fendler and W. Stüber. Z. physiol. Chem., 1914, **89**, 122—132.

Twenty-five grams of the oil are saponified in a platinum dish, with 50 c.c. of alcoholic potassium hydroxide solution (14 grms. KOH and 70 c.c. alcohol per 100 c.c.). After evaporation of the alcohol, the soap is carefully charred over a rose burner and the char ground and carefully heated again until the greater part has been burnt. The residue is treated with hot water, cooled, filtered and washed with cold water so long as the washings are alkaline. The filtrate (about 150 c.c.) is treated with 50 c.c. of dilute sulphuric acid (about 24 per cent.) and 20 c.c. of a 10 per cent. solution of potassium bichromate, and shaken with successive small quantities of carbon tetrachloride (altogether about 10—15 c.c. in the case of cod-liver oil). The united extracts are washed with water and the washings shaken with a few c.c. of carbon tetrachloride which is afterwards mixed with the main extract and titrated with $N/100$ sodium thiosulphate solution until colourless ; no indicator is required. Minute traces of iodine (*e.g.*, 0·0005 per cent. of the oil) are best determined by colorimetric comparison of the carbon tetrachloride extracts. All reagents should be tested by a blank experiment.—J. H. L.

Soaps ; Determination of free caustic alkali in ——. E. Bosshard and W. Huggenberg. Z. angew. Chem., 1914, **27**, 11—20.

The following modification of the method of Davidsohn and Weber (Seifensiederzeit., 1907) is rapid and gives accurate results :—Five grms. of the soap are dissolved in 100 c.c. of 50 per cent. alcohol on the water-bath, the solution rapidly cooled in water, the soap precipitated with 15 to 20 c.c. of 10 per cent. barium chloride solution, and the free alkali titrated with $N/40$ stearic acid solution, after the addition of 2 to 5 c.c. of α-naphtholphthalein solution as indicator. The stearic acid solution is prepared by dissolving 7·1 grms. of stearic acid in 1000 c.c. of absolute alcohol, filtering and standardising against alkali, whilst the indicator consists of 0·1 grm. of α-naphtholphthalein in 150 c.c. of alcohol and 100 c.c. of water. For the determination of alkali carbonate a second portion (5 grms.) of the soap is dissolved in 100 c.c. of 50 per cent. alcohol, and titrated in the cold (without precipitation of the soap) with the stearic acid solution with phenolphthalein or α-naphtholphthalein as indicator. If the liquid remain colourless even on boiling, free fatty acids are present, and may be titrated with $N/10$ alcoholic alkali. The amount of free caustic alkali that escapes determination by this method does not exceed 0·01 per cent. when the total free caustic alkali is less than 0·1 per cent. or 0·025 per cent. for amounts below 0·2 per cent.—C. A. M.

Patents.

Molten fats and such-like substances ; Cooling ——. G. J. Lemmens, London. Eng. Pat. 1924, Jan. 23, 1913.

The melted fat, etc., is exposed to a blast of compressed cold air, the sudden expansion of which abstracts heat from the fat and causes rapid solidification.—C. A. M.

Fat-melting apparatus. L. Wright, London. Eng. Pat. 5797, March 8, 1913.

The fat is melted in a horizontal steam- or water-jacketed tank, provided with a shaft carrying beaters, and with steaming devices and chambers at each end to receive the melted fat.—C. A. M.

Lubricating grease which may be used for preventing and removing incrustations from steam boilers. J. Oliveras, Barcelona. Eng. Pat. 17,288, July 28, 1913. Under Int. Conv., July 26, 1912.

The grease consists of a mixture of animal fat (*e.g.*, 100 parts of pig or horse tallow), lampblack (3 to 10 parts), and benzene (1 to 5 parts).—C. A. M.

Soap ; New —— *and process of making same.* C. Billing, Leytonstone. Eng. Pat. 27,572, Nov. 30, 1912.

Potassium or ammonium monoborate (prepared *e.g.*, by adding a slight excess of potassium hydroxide solution to a solution of boric acid) or a mixture thereof, is added to the soap, with or without further addition of alkali. —C. A. M.

Soap, soap powders, cocoa, chocolate ; Apparatus applicable for use in the manufacture of —— *and analogous processes.* K. B. Edwards, Berkhamsted, and H. Rance, Watford. Eng. Pat. 4654, Feb. 24, 1913.

The substances are heated, mixed, dried and powdered in a vessel provided with a heating and cooling jacket, and with blades rotating on shafts in such a way as to propel the mixture from the ends to the middle of the vessel.—C. A. M.

Soap. A. Kreutzinger and E. Juenger, London. Eng. Pat. 6691, March 18, 1913.

A soap, preferably in powdered form, is made from a mixture of sawdust (say 200 or 400 parts), powdered soap (200), calcined soda (150), pumice stone (150 or 350), potato meal (50), and chalk (50).—C. A. M.

Cleansing purposes ; Preparation for ——. H. F. Slack, West Bridgford, Notts. Eng. Pat. 8934, April 16, 1913.

A paste miscible with water is obtained by incorporating an organic solvent such as benzene, toluene or other hydrocarbon or mixture thereof (with or without carbon tetrachloride or other substituted hydrocarbon) with a neutral potash soap in the proportion of about 20 to 50 per cent. or more. The composition may be prepared by dissolving melted stearic acid in the organic solvent, adding sufficient potash solution at 60° C. to form a soap, and stirring the mixture with a strong solution of ammonia until a homogeneous cream is obtained.—C. A. M.

Shaving compositions ; Manufacture of ——. J. Jellinek, Vienna. Eng. Pat. 10,222, April 30, 1913.

Vaseline oil (say 20 to 30 grms.), ether (10 grms.), and shaving soap (2 to 5 grms.) are emulsified with a solution of borax (say 20 grms. per litre), with or without addition of scent.—C. A. M.

Fatty acids and glycerin ; Process of manufacturing ——. E. Twitchell, Wyoming, Ohio. U.S. Pat. 1,082,662, Dec. 30, 1913.

See Fr. Pat. 456,956 of 1913 ; this J., 1913, 1119.—T. F. B.

Fatty substances from oil ; Manufacture of solid ——. J. Schlinck, Hamburg, Germany. U.S. Pat. 1,082,707, Dec. 30, 1913.

XIII.—PAINTS ; PIGMENTS ; VARNISHES ; RESINS.

Prussian blue ; The constitution of ——. P. Woringer J. prakt. Chem., 1914, **89**, 51—68.

The author advances the view that Prussian blue is ferrous ferricyanide, contrary to the opinions of K. A Hofmann (this J., 1904, 1209 ; 1907, 199), and E. Mülle (J. prakt. Chem., 1909, **79**, 81, **80**, 153 ; 1911, **84**, 353 who state that it is a ferrocyanide, the latter holding th the same product must result whether by reacting on a ferric salt with a ferrocyanide or on a ferrous salt with a ferricyanide. The first step in the reaction between ferric chloride and potassium (or sodium) ferrocyanide appeared to be the formation of the soluble product, $KFe(FeCy_6)$, which in the presence of an excess of ferric salt suffered further change:—

$$3KFe(FeCy_6)+FeCl_3 = Fe_7Cy_{18}+3KCl,$$

the tendency of the reaction in a right-handed direction being influenced by the excess of iron salt. For the formation of the soluble potassium blue compound an excess of ferrocyanide was required. In attempting to form it by the use of exactly equimolecular quantities of ferric chloride and potassium ferrocyanide, the ratio of extra-radical to intra-radical Fe in the product was not exactly 1 : 1 but 1·06 : 1, and the filtrate contained potassium ferricyanide, and not ferrocyanide. With an excess of ferrocyanide, also, ferricyanide was found in the filtrate, but the ratio of extra- to intra-radical Fe in the blue compound was exactly 1 : 1. More ferricyanide was found in the filtrate the greater the excess of ferrocyanide used. These facts indicate that simultaneous oxidation and reduction of the ferrocyanide and the ferric salt take place thus:—

$$\left(\overset{\mathrm{II}}{\mathrm{Fe}}\,\mathrm{Cy}_6\right)^{''''} + \overset{\mathrm{III}}{\mathrm{Fe}}{}^{\cdots} = \left(\overset{\mathrm{III}}{\mathrm{Fe}}\,\mathrm{Cy}_6\right)^{''} + \overset{\mathrm{II}}{\mathrm{Fe}}{}^{\cdot\cdot}$$

the resulting ferro-ions attaching themselves to the ferricyan-ions to form

$$\mathrm{K}\overset{\mathrm{II}}{\mathrm{Fe}}\left(\overset{\mathrm{III}}{\mathrm{Fe}}\,\mathrm{Cy}_6\right),$$

which reacts with further free ferro-ions to form either

$$\overset{\mathrm{II}}{\mathrm{Fe}}_3\left(\overset{\mathrm{III}}{\mathrm{Fe}}\,\mathrm{Cy}_6\right)_2 \quad \text{or} \quad \mathrm{K}\overset{\mathrm{II}}{\mathrm{Fe}}_4\left(\overset{\mathrm{III}}{\mathrm{Fe}}\,\mathrm{Cy}_6\right)_3$$

Very careful decomposition of Prussion blue with alkali showed that alkali ferricyanide was formed, which, however, is readily reduced to alkali ferrocyanide by the ferrous hydroxide also formed, unless special precautions be taken. Almost quantitative separation of ferricyanide was obtained and the relationship was not disturbed by using a blue previously treated with hydrogen peroxide.—J. B.

Copal from the Congo. Lamont. Roy. Bot. Gard. Kew. Bulletin, 1913, [5], 194.

This resin is derived in the Congo from *Copaifera demeusei*, and other trees of the leguminous family. It is found chiefly in marshy forests bordering rivers. Two kinds of resin are found: fresh copal, collected from the trees, and fossil copal, dug up from trees in decay, sunk under the soil. Before exporting, it is divided into parcels, hard and soft. The former is treated with a solution of caustic soda of one per cent. strength for half an hour and then washed in water and dried in the sun. The softer copals of whitish or yellow texture and of recent formation, are simply scraped, before packing. Exposed to the air for a certain time they become clearer and harder. The Congo copal is classified in the Antwerp market under five heads:—(1) Sorted, white, best quality. (2) Sorted, clear, transparent. (3) Assorted, less transparent. (4) Somewhat opaque. (5) Not sorted. The exports during the last eight years are as follows.—1904, 938·6 metric tons; 1905, 754·0; 1906, 912·3; 1907, 1060·3; 1908, 1608·9; 1909, 826·5; 1910, 975·5; and 1911, 2138·8 metric tons.

The price at Antwerp varies from 6d. to 1s. 3d. per lb. The kind most valued is that which is hard, transparent, and with a fracture like glass.

Resins; Synthetic ——. L. V. Redman, A. J. Weith, and F. P. Brock. J. Ind. Eng. Chem., 1914, **6**, 3—16.

In all of the methods hitherto described for the preparation of artificial resins by the condensation of phenolic compounds with compounds containing active methylene groups (formaldehyde, etc.), the reaction appears to have been carried out in aqueous solution. The authors have found that by working with anhydrous substances (phenol or the like and hexamethylenetetramine) the process is considerably simplified, more uniform products of higher dielectric strength are obtained, and the sole by-product of the reaction is ammonia. If 12 mols. or more of phenol be used for 1 mol. of hexamethylenetetramine, the reaction is very rapid on heating, the nitrogen of the hexamethylenetetramine is evolved quantitatively as ammonia, and the reaction-product consists of a soluble rosin consisting of 13 phenol residues connected by 12 methylene groups (phenylendeka-saligenosaligenin, $C_6H_5OCH_2(C_6H_4OCH_2)_{11}.C_6H_4OH$), dissolved in excess of phenol. The reaction appears to proceed in stages and aminosaligenosaligenin, $NH_2.CH_2.C_6H_4.CH_2.O.C_6H_4OH$, has been isolated as an intermediate product. The soluble resin has properties practically identical with those of Baekeland's "Novolak" (see Lebach, this J., 1913, 559). When less than 12 mols. of phenol per mol. of hexamethylenetetramine are used, the reaction product changes in character, becoming harder and more brittle as the proportion of phenol is diminished, until with 6 mols. of phenol, a hard, dense, transparent resin, with a tensile strength of 4000—5200 lb. per sq. inch is obtained, which softens very little even at high temperatures. By so working that the evolution of ammonia proceeds slowly, a homogeneous solid product can be obtained, whilst by heating rapidly, *e.g.* to 180° C., a spongy mass is produced, which can be more readily pulverised; the fine powder yields a transparent homogeneous solid of maximum mechanical strength, highest dielectric properties, and chemical inertness when pressed in hot moulds under a pressure of 4—6 tons per sq. in.—A. S.

Patents.

Paints; [Damp-proof and fire-proof] ——. A. McKechnie, London. Eng. Pat. 228, Jan. 3, 1913.

A resin (*e.g.* colophony) and a basic substance, such as lime, are ground separately, and then mixed and incorporated with paraffin oil (with or without boiled or raw linseed oil or other medium) and a pigment. Or the rosin and paraffin oil may be separately heated, mixed with the pigment, and added to the lime, which has been made into a paste, before grinding.—C. A. M.

White lead; Method of making ——. A. S. Ramage, Buffalo, N.Y., U.S.A. Eng. Pat. 17,857, Aug. 5, 1913.

A basic carbonate of lead is prepared by the interaction of lead sulphate and an alkali carbonate in insufficient quantity to convert the whole of the sulphate into carbonate, and the resulting product is treated with an alkali hydroxide.—C. A. M.

Lead pigments; Manufacture of ——. C. D. Holley. Assignor to Acme White Lead and Color Works, Detroit, Mich. U.S. Pat. 1,082,953, Dec. 30, 1913.

"Basic lead oxide" is boiled with a dilute aqueous solution of an alkali nitrate (containing a small proportion of nitric acid if metallic lead is present), the mixture evaporated to dryness and the residue heated in a furnace to produce massicot.—W. E. F. P.

Crayons; Process for producing a substance for manufacturing water- and temperature-proof coloured marking chalk or pencils, artists' —— *and the like.* A. Herda, Iserthal, Austria. Eng. Pat. 12,109, May 24, 1913.

A wax, such as candle wax (46 per cent.) is melted, mixed with a pigment (54 per cent.), and cast in suitable moulds such as paper tubes. (Reference is directed to Eng. Pats. 2493 of 1877, 2430 of 1878, 3762 of 1881 and 11,182 of 1902.)—E. W. L.

Rosin and turpentine from wood; Process of obtaining ——. C. Howard, New York. U.S. Pat. 1,082,526, Dec. 30, 1913.

Comminuted coniferous wood is subjected to the action of a vacuum and then treated under pressure with a solvent of rosin, *e.g.* turpentine. During the treatment the charge is agitated by means of currents of heated air under pressure, introduced in a downward direction, and the pressure is alternately increased and diminished. —A. S.

Turpentine and resin extractor. J. H. Castona, Moss Point, Assignor to Castona Improved Process Co., Gulfport, Miss. U.S. Pat. 1,083,802, Jan. 6, 1914.

THE apparatus comprises a vertical cylinder containing a cage for the material to be extracted, with a space outside the cage for the discharge of volatile products, a heating chamber at the bottom of the cylinder a central vertical steam pipe within the cage, and a space above the heating chamber to receive the extracted resin. —C. A. M.

Resinous compound; Process of producing a ——. Resinous compounds. D. Whipple, New York, Assignor to Standard Chemical Co., Bayonne, N.J. U.S. Pats. 1,083,168, 1,083,169 and 1,083,170, Dec. 30, 1913.

(1) RESIN is heated in the presence of moisture to about 135° C. so as to break up the complex turpentine products and volatilise the same together with the volatile organic acids, then the temperature is raised to 140° C. and the residue treated with an oxidising agent, *e.g.* a current of dry air. (2) Claim is made for resin derivatives in the form of a soft non-drying, plastic, gummy mass, of sp. gr. about 0·98, and having a high electrical resistance. (3) An insulating composition consisting of a soft, non-drying, plastic resin derivative and a non-drying, non-oxidising, unsaponifiable oily resin derivative.—A. S.

XIV.—INDIA-RUBBER; GUTTA-PERCHA.

Caoutchouc; Addition reactions of ——. F. Kirchhof. Kolloid-Zeits., 1914, 14, 35—43.

IT was shown previously (see this J., 1913, 799) that vulcanised rubber behaved differently to raw rubber when oxidised by air or oxygen; besides differences in the velocity of oxidation, the vulcanised rubber behaved as though only one double linkage was present in the $C_{10}H_{16}$-molecule. Experiments with different kinds of raw rubber have now shown that these when treated with air carrying sulphur chloride or bromine vapour also behaved as though the $C_{10}H_{16}$-mol. contained only one double linkage, products approximating to the composition $C_{10}H_{16}S_2Cl_2$ and $C_{10}H_{16}Br_2$ respectively being formed. On warming the dibromide or on carrying out the treatment at 80° C., a monobromide was formed, with elimination of hydrobromic acid. When solutions of rubber were treated with sulphur chloride, there was first a diminution of the viscosity of the solution, followed by a continuous increase. In explanation of these facts the author develops a hypothesis based on the assumption that in raw rubber the $C_{10}H_{16}$ mols. are held loosely together by partial valencies, and that in addition reactions these are converted into full valencies with simultaneous addition of two atoms of halogen or the like. The greater reactivity of rubber in solution and the decrease of viscosity observed at first when the solution is treated with sulphur chloride is considered to be due to depolymerisation of the caoutchouc which follows quantitatively in solution, but only partially with solid caoutchouc, in which case a condition of equilibrium of opposing tendencies to depolymerisation and repolymerisation results. In vulcanisation the chief action of the sulphur is held to be that of a catalytic (or condensing) agent causing the breakdown of the loosely-bound caoutchouc complex into stable condensed systems, probably with the formation of tetramethylene rings; in the subsequent chemical combination of sulphur, the isocyclic tetramethylene-ring is converted into a heterocyclic six- or seven-membered ring by introduction of atoms of sulphur.—A. S.

Rubber insulating compound; Tentative specifications and analytical procedure for 30 per cent. Hevea ——. J. Ind. Eng. Chem., 1914, **6**, 75—82.

THE preliminary report of a joint committee appointed in Dec., 1911 by a group of manufacturers and users of rubber insulating compounds, including representatives of the American Chemical Society and the U.S. Bureau of Standards. The specification is as follows: A 30 per cent. fine Para or smoked first latex Hevea rubber compound with mineral base shall be furnished, containing only rubber, sulphur, inorganic mineral matter, and refined solid paraffin or ceresin, and free from red lead or carbon. The vulcanised compound shall conform to the following requirements, the figures representing percentage by weight of the whole sample: rubber, 30—33 per cent.; waxy hydrocarbons, not more than 4 per cent.; free sulphur, not more than 0·7 per cent. The permissible limits for other constituents and for specific gravity for compounds containing respectively 30 per cent. and 33 per cent. of rubber are as follows: for intermediate rubber contents the permissible limits are varied in proportion.

	Permissible limits:			
	30 per cent. compound.		33 per cent. compound.	
	Max.	Min.	Max.	Min.
Saponifiable acetone extract	1·35	0·55	1·50	0·60
Unsaponifiable resins	0·45	—	0·50	—
Chloroform extract	0·90	—	1·00	—
Alcoholic potash extract	0·55	—	0·60	—
Total sulphur*	2·10	—	2·30	—
Specific gravity	—	1·75	—	1·67

* The limit of total sulphur may be omitted at the option of the purchaser.

The acetone solution shall not fluoresce and the acetone extract (60 c.c.) shall not be darker than a light straw colour. The hydrocarbons present shall be solid, waxy, and not darker than a light brown colour. The chloroform extract (60 c.c.) shall not be darker than a straw colour. Failure to meet any requirement of the specification shall be sufficient cause for rejection. The specification should be supplemented by clauses relating to tensile strength, elasticity, insulation resistance and dielectric strength. The method of analysis is described in minute detail, with illustrations of the grinding machine for the preparation of the sample and of the extraction apparatus. In outline it consists in extracting 2 grm.-samples (20 mesh-size) with acetone for 8 hours, and the residue with chloroform for 4 hours. The final residue is saponified with alcoholic potash and the solution acidified and extracted with ether. The acetone extract is saponified with alcoholic potash and in the aqueous portion the free sulphur is determined, whilst the unsaponifiable material is used for determining the waxy hydrocarbons and the unsaponifiable resins. The filling materials and total sulphur are determined in separate samples, the former by using first a mixture of terebene and xylene and then terebene alone to dissolve and remove the rubber, and the latter by fusion with a mixture of sodium peroxide and potassium carbonate, followed by precipitation as barium sulphate. Duplicate determinations should agree within 0·01 for specific gravity, 0·05 per cent. for free sulphur, 0·5 per cent. for tillers, free from sulphur, and 0·1 per cent. for the other constituents determined. The rubber is ascertained by difference. The committee desires to obtain the results of experience with the methods during the ensuing year and then issue a final report with any improvements found desirable.—A. S.

Rubber; Formic acid in the regeneration of ——. A. Dubosc. Caoutchouc et Guttapercha, 1914, **11**, 7944—7948.

In separating textile material from vulcanised rubber, although a partial separation may be effected mechanically, it is necessary to destroy the cellulose chemically. This may be effected either by strong acids, or by dilute acids at a high temperature and pressure. The author describes the use of acetic and formic acids; certain solvents can be found for cellulose triacetate and triformate, which do not dissolve rubber. If the esterification is continued however, products soluble in water are obtained, esters of cellobiose. Acetic anhydride is expensive and it is necessary to apply heat, hence formic acid is preferable. The acid (90 per cent. strength) may be saturated with dry hydrochloric acid gas to aid the reaction. The amount of acid used should be twice the weight of the waste material. At ordinary temperatures, aided by a little petroleum benzine, the reaction is over in about 12 hours. The liquid first becomes viscous and opalescent, and then mobile again. At 60°—70° C., the reaction is over in 4 hrs. The rubber is then filtered off, washed and dried; the properties of the product are stated to be excellent.—H. E. P.

Utilisation of Para rubber seed. See XII.

Patents.

Rubber milk or latex; Apparatus for treating —— and sheeting the coagulated product. L. Norzagaray, London. Eng. Pat. 29,369, Dec. 20, 1912.

Over a smoke-producing fireplace is built a chimney consisting of rectangular metal sections, each with the exception of the top one containing a rotating flanged drum, a scraper and baffle-plates. Latex is supplied to feed-rollers in the top section, and passes down through the chimney from drum to drum, being removed from each by a scraper. From the bottom roller the rubber is removed either by a fixed scraper, from which it passes between pressing-rollers, or by means of one of a pair of corrugated rollers acting as a scraper. Baffle-plates are provided to give the smoke the desired direction up the chimney.—E. W. L.

Caoutchouc; Process for manufacturing synthetic ——. C. K. F. L. Gross, Bevön, Norway. Eng. Pat. 13,826, June 14, 1913. Under Int. Conv., June 15, 1912.

See Fr. Pat. 459,987 of 1913; this J., 1913, 1164.—T. F. B.

Caoutchouc substance and process of making same. F. Hofmann and C. Coutelle, Assignors to Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. U.S. Pat. 1,084,333, Jan. 13, 1914.

See Fr. Pat. 422,955 of 1910; this J., 1911, 637.—T. F. B.

Caoutchouc-like substances; Vulcanised ——. F. Hofmann, C. Coutelle, K. Delbrück, and K. Meisenburg, Assignors to Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. U.S. Pats. 1,084,334, 1,084,335, 1,084,336, 1,084,337, and 1,084,338, Jan. 13, 1914.

XV.—LEATHER; BONE; HORN; GLUE.

Tannin; Comparison of the extraction of vegetable materials containing —— in copper and glass. C. R. Oberfell and L. M. Richeson. J. Amer. Leather Chem. Assoc., 1914, **9**, 28—32.

The differences obtained in the tannin content on both new and spent material were well within the limits of accuracy of the method and indicated that the copper flask and extractor had no appreciable effect. In the case of new materials the average difference per determination was 0·0125 per cent. higher with glass than with copper and with spent materials 0·046 per cent. higher with copper than with glass.—D. J. L.

Vegetable tannins; Qualitative differentiation of ——. E. Stiasny. J. Amer. Leather Chem. Assoc., 1914, **9**, 19—25.

Lauffmann (this J., 1913, 53) from his test of precipitating tannin solutions with ammonium molybdate and ammonium chloride concluded that quebracho extracts containing no pyrogallol tans (formaldehyde test) and no wood-pulp (aniline test) could be regarded as adulterated with mangrove if the molybdenum figure (weight of precipitate from 100 grms. of tannin) was higher than 30—40. The author in conjunction with C. D. Wilkinson has confirmed Laufmann's results. Mangrove can also be detected when mixed with sulphited quebracho, but the variations of the figure obtained for quebracho and sulphited quebracho lessen the value of the test. Sulphited quebracho extracts yield figures from 5 to 37 according to the extent of the sulphiting. A strongly sulphited quebracho extract (Mo figure 5) can be adulterated with 20 per cent. of mangrove (Mo figure 125) without reaching the limit of 30. A scheme is given for the qualitative determination of vegetable tannins in which three main groups are formed according as precipitation is complete, partial, or absent on boiling with formaldehyde and hydrochloric acid.—D. J. L.

Tanning materials; Determination of pentoses in —— with special reference to quebracho and mangrove extracts. J. L. van Gijn and H. van der Waerden. Collegium, 1913, 639—645.

Quebracho extract was found to be almost free from pentosans and pentoses and contained no methylpentoses, while mangrove extract contained a considerable quantity of methylpentoses. With mixtures of quebracho and mangrove extract it was possible to detect 10 per cent. of mangrove extract when mixed with untreated quebracho, but with sulphited quebracho extract not less than 25 per cent. of mangrove extract could be detected. The inhibiting effect of the sulphite could be prevented by means of iodine. The following method (see this J., 1901, 396; 1902, 875; 1905, 212; 1911, 242, 1181) therefore provides a reliable test for mangrove in quebracho extract. 10 grms. of the sample are placed in a distillation flask with some glass beads and a little paraffin wax to prevent foaming. If the extract is sulphited, sufficient iodine to oxidise the sulphite and 100 c.c. of 12 per cent. hydrochloric acid are added, and after boiling gently for 16 mins. under a reflux condenser, the solution is distilled. For every 30 c.c. of distillate obtained in 10 mins., 30 c.c. of 12 per cent. hydrochloric acid are added to the distillation flask from a dropping-funnel. Distillation is continued until the distillate gives only a pink colour with aniline acetate. Usually 420 c.c. of distillate are sufficient; this is made up to a known volume, filtered, and to an aliquot part, an excess (200 mgrms.) of phloroglucinol dissolved in 12 per cent. hydrochloric acid is added. After standing 15—24 hours the precipitate is collected in a Gooch crucible, washed free from acid and weighed after drying for 3 hours at 98°—99° C. The precipitate is then treated with 30 c.c. of 96 per cent. alcohol at 60° C., washed with 50 c.c. of alcohol and weighed again after drying. The loss of weight represents methylfurfural-phloroglucide. The change of colour on adding the phloroglucinol is very characteristic and shows of itself whether a quebracho extract is pure. In that case the liquid becomes yellow, then green, and finally a black precipitate forms, leaving the supernatant liquid colourless. With a mangrove extract the colour is first yellow, then red and finally a red precipitate is produced, turning brown on standing. —D. J. L.

Mangrove; The determination of —— in admixture with other tanning materials. G. A. Kerr. J. Amer. Leather Chem. Assoc., 1914, **9**, 23—28.

The test proposed is based on the production of furfural by distillation with hydrochloric acid and precipitation in the distillate with phloroglucinol. (See van Gijn and van der Waerden: preceding abstract.)—D. J. L.

Tans; Rendering powdered —— (phlobaphenes) soluble by hydrolysis with sulphurous acid and the action of dextrin glucose on tannin-glucosides. E. O. Sommerhoff. Collegium, 1914, 3—5.

Pure hot solutions of quebracho extract probably contain compounds of a starchy and cellulosic character, which, on cooling, separate partly as the so-called phlobaphenes, but under the prolonged action of sulphurous acid are hydrolysed to dextrin-glucose. The dextrin-glucose formed thus and also the glucose originally present act in a similar manner to cane sugar (this J., 1913, 952) in that, on gentle warming, they rapidly render soluble sparingly soluble tannins. The action of sodium bisulphite in rendering soluble sparingly soluble tanning extracts becomes apparent only after 2—3 hours, hence secondary products must also influence the solubility of the extract. The mechanism of the action may be as follows. The insoluble tannins (phlobaphenes) are transformed into dextrin-glucose and hence are partly lost as far as tanning effect is concerned, as dextrin is only absorbed by hide to a small extent. The action of cane sugar or glucose on tanning extracts becomes of more importance since recent investigations have shown that tannins are taken up as glucosides or other compounds containing sugar, the hydrolysis of which would be retarded by addition of glucose. An objection to the addition of excess of glucose to a tanning extract is that it chokes up the pores of the hide in the earlier stages; dextrin-glucose renders hide slimy. This corresponds with the effect of sugar in preventing the setting of gelatin solutions. Since glucose is a strong anti-coagulant, a large quantity of a coagulating electrolyte, having a salting-out action, such as sodium sulphite, must be added to the extract to compensate for this effect. Easily soluble extracts only produce flat leather and should only be used in cases where a very light-coloured leather is required. Phlobaphenes contain a yellow-red colouring matter which is very sensitive to light. The ash of phlobaphenes in the pure state contains traces of heavy metals. —D. J. L.

Depilating; Notes on ——. A. Rogers. J. Amer. Leather Chem. Assoc., 1914, **9**, 42—52.

The view that, owing to the limited solubility of lime in water, there is no danger of destroying a pack of hides by using an excessive amount, is misleading as there is great danger of damage by improper lime treatment. On a practical scale several packs of skins treated with 5 per cent. of lime showed 40 per cent. increase of weight and absorbed 1·3 per cent. CaO in 2 days; with 10 per cent. of lime there was a 50 per cent. increase of weight and 3·65 per cent. CaO absorbed. A new lime has a greater solvent effect on hide substance than an old lime, and a pack of skins treated with a fresh lime every day for several days lost much more hide substance than one remaining in a liquor improved by addition of the same amount of lime. Records of pack weights at different stages of liming showed that the greatest weight occurred on the fourth day; the decrease following the fourth day was due to loss of hair. A typical increase in weight of samples freed from hair and depilated with 5 per cent. of lime made fresh every day (A), and from a series treated with 5 per cent. of lime made up to strength every day (B) was as follows:—

	A.	B.
Percentage increase after 1 day	42·10	42·93
,, ,, ,, 2 days	2·60	2·10
,, ,, ,, 3 ,,	4·14	4·10
,, ,, ,, 4 ,,	1·30	1·41
,, ,, ,, 5 ,,	1·70	1·70
,, ,, ,, 6 ,,	0·30	3·60
Totals	52·14	55·84

Estimations of lime and ash in the hides gave the following results:—

	A.		B.	
	Ash.	CaO in ash.	Ash.	CaO in ash.
Originally	0·66	33·67	0·51	32·80
After 1 day	3·15	59·82	3·14	56·61
,, 2 days	3·30	74·45	3·71	78·98
,, 3 ,,	4·25	76·58	4·19	80·49
,, 4 ,,	4·52	78·46	4·50	90·64
,, 5 ,,	4·21	86·69	4·81	86·07
,, 6 ,,	5·18	82·69	4·67	84·23

Practically all the fat which was saponified became so during the first 24 hours.

The loss of hide substance during 6 days was as follows:—

	A.	B.
After 1 day	0·51	0·55
,, 2 days	0·25	0·39
,, 3 ,,	0·43	0·59
,, 4 ,,	0·66	0·64
,, 5 ,,	0·24	0·17
,, 6 ,,	0·25	0·34
Totals	2·34	2·68

From these results it seems that the proper way to apply a lime solution is to enter the stock into a lime liquor only a few days old and work up through the series to a fresh liquor. Sodium sulphide when used for removing hair should be used before lime as it has no solvent action on hair which has once been treated with lime, although rapidly dissolving clean hair. Good results are obtained by the use of a mixture of sodium sulphide and calcium chloride; the goods are run in a 20° Bkr. sulphide solution containing calcium chloride to a ¼ of the weight of sulphide. —D. J. L.

Tannage; Alcohol —— and photochemical autoxidations. E. O. Sommerhoff. Collegium, 1914, 5—7.

The tanning effect of alcohol is usually explained as being due to its dehydrating action, but this hypothesis is probably incorrect, as the author has found that acetone, which has similar dehydrating properties, has no tanning effect. Dilute (10 per cent.) alcohol has an apparent tanning action in the presence of much air and light, but in an atmosphere of carbon dioxide has no tanning effect. Alcohol in the presence of much light and air has a similar action to dilute formaldehyde and air although much weaker. Practical tanning with spirit is best carried out by soaking a delimed lamb-skin in spirit and hanging in the light and air, remoistening with spirit from time to time. The alcohol is oxidised to acetaldehyde, and an autoxidising action of the aldehyde and hide-albumin takes place. The effect is similar to the resinification of plant juices. Tanning may be regarded as an oxidation of the hide, and polymerised or "resinified" albuminous substances of high molecular weight are produced which are insoluble in boiling water. A delimed lamb-skin is tanned by Italian red wine much quicker than by 10 per cent. alcohol. It appears that the small quantities of tannin in the wine act on the alcohol catalytically as oxygen-carriers and hasten the process. Beer, containing carbon dioxide, has scarcely any tanning action, although containing as much tannin as wine. If raw flesh be boiled in wine in sunlight, acetic acid is produced, and the yield of extract is much less than if water alone is used. No acetic acid is produced if air or light be excluded or if dilute alcohol alone be used. A double oxidation takes place in tanning with wine in the air, albumin being oxidised and acetic acid formed from the wine, both the tannins and the albumins acting catalytically. The tannin has strongest catalytic effects when in the colloidal state; small quantities of quebracho tannin added to spirit produce a much less tanning effect on the hide, being coagulated.—D. J. L.

Tanning with alcohol. W. Eitner. Gerber, 1914, **40**. 17—18.

According to a recent German patent, hide is tanned with dilute alcohol in the presence of oxygen and a catalytic agent. As catalysts, phlobaphenes, vegetable tannins, metallic hydroxides or soaps may be used, all in smaller quantities than in usual tanning processes. The author points out that by the action of strong alcohol a product similar to leather is produced from skin, but there is no real change into leather. The effect of the alcohol is due less to dehydration than to coagulation and precipitation of the colloidal hide components by means of which the clinging together of the fibres during drying is prevented. After washing with water and drying out, the skin is perfectly untanned again. When dilute alcohol is used the precipitating effect is much slower. The hanging in the air, as described in the patent, has no other effect than a removal of water which allows the strong alcohol to penetrate. A calf skin after twice treating with 10 per cent. alcohol was almost unchanged; after 8 treatments a weak tanning effect was produced. It is only when tanning substances, used according to the patent as oxygen-carriers, are added that any real tanning effect is produced which will vary according to the quantity and kind of tannin added. The alcohol in the solution causes a much quicker penetration of the tannin but hinders complete and full tanning. The cost of alcohol has prevented its being used for the purpose of quick vegetable tanning; in mineral tanning it has no effect. Metallic soaps mentioned in the patent as catalysts are quite insoluble in 10 per cent. alcohol and therefore useless for the purpose.—D. J. L.

XVI.—SOILS; FERTILISERS.

Humus; Determination of —— in heavy clay soils. W. Beam. Cairo Scientific J., 1913, **7**, 219—224.

The method described previously (this J., 1912, 695) is improved if very dilute hydrochloric acid (0·02 per cent.) instead of carbonic acid is used for washing after removal of the calcium and magnesium. A small quantity of chloride is retained by the soil in this case, and subsequently extracted by the ammonia, but this can be determined in an aliquot portion of the filtrate and a correction applied. The extraction of the humus is much more rapid under the new conditions. Further data are given showing the accuracy of the author's colourimetric method for determining humus, if the standard and the soil to be tested are of approximately the same composition as regards clay and humus.—W. H. P.

Mono-, di-, and tri-calcium phosphates; Action of ammonium citrate on ——. T. Warynski and J. Langel. Ann. Chim. Analyt., 1914, **19**, 1—6.

The three calcium phosphates are all soluble to an appreciable extent in ammonium citrate solution; so that a rigorous separation of them by solution in ammonium citrate is not possible. The action of the citrate in dissolving them is fairly rapid, equilibrium being attained in about an hour (with manures, containing in addition other substances, probably a longer time is necessary). The differences in the solubilities of the three phosphates are greatest in the cold, and when the citrate solution is saturated.—J. T. D.

Superphosphate-vinasse ("Superphosphatschlempe"), a new fertiliser. H. Stoltzenberg. Chem.-Zeit., 1914, **38** 81—82.

Vinasse is a valuable fertiliser on account of its high nitrogen and potash content, but the residue from the evaporation of the pulp ("*Dickschlempe*") is too hygroscopic for use as a solid manure; this is due to the presence of bases, especially betaine. A non-hygroscopic salt of the latter base is the acid phosphate. On warming a mixture of 3 parts of superphosphate and 2·5 of pulp, acid fumes are given off and the paste breaks up into friable lumps which can be kept for months without change. A sample was found to contain: N 2·25, K_2O 6·33, citrate-soluble P_2O_5 11·53, water-soluble P_2O_5 8·48, fixed residue 57·32 per cent.; one-half of the material was soluble in water, while 30 per cent. consisted of unaltered organic matter, which increases the humus content of the soil.—W. R. S.

Sugar beet; The so-called "catalytic action" of manganese and boron compounds on the cultivation of the ——. H. Pellet. Bull. Assoc. Chim. Sucr., 1913, **31**, 419—424.

Attention is called to the experiments of Munerati, Mezzadroli, and Zapparoli, who have found at the Rovigo (Italy) Experiment Station that different compounds of manganese and boron, both singly and in combination with aluminium compounds, have no effect at all on the growth or yield of the sugar beet, or on the purity of its juice. The results which have led others to attribute a favourable action to the use of these compounds are held to be untrustworthy, principally for the reason that they have been obtained from an insufficiently large number of experiments, and without adequate control experiments.—J. P. O.

Patents.

Waste wool and like animal fibrous waste for utilisation as a manure or fertiliser; Method and means for treating ——. J. H. Kirk, Stalybridge. Eng. Pat. 2982, Feb. 5, 1913.

The waste is heated in a kiln to 300°—400° F. (149°—204° C.) and "converted into an ammoniacal salt" by means of hydrochloric acid or other acid gas.—O. R.

Fertilisers; Manufacture of —— from the residues left after the extraction of alkalis from potash-bearing silicate rocks which have been treated with lime or calcium compounds. Chem. Fabr. Rhenania and A. Messerschmitt. Ger. Pat. 267,875, July 31, 1912. Addition to Ger. Pat. 255,910 (this J., 1913, 439).

The residues are calcined and the resulting fine powder is mixed with a highly concentrated solution of nitric acid freshly neutralised with lime. The lime present in the residues combines with the calcium nitrate to form a basic nitrate and the water is fixed by the double silicates also present, so that the mixture soon solidifies to a dry mass.—A. S.

Fertilisers; Method for production of ——. A. Messerschmitt, Stolberg, Germany. U.S. Pat. 1,083,553, Jan. 6, 1914.

See Ger. Pat. 255,910 of 1911; this J., 1913, 439.—T.F.B.

XVII.—SUGARS; STARCHES; GUMS.

Sugar cane; The most promising varieties of —— under trial at the Tucumán Experiment Station. A. H. Rosenfeld. Intern. Sugar J., 1914, **16**, 12—23.

Thin canes gave the best results, having not only a higher sucrose content, but attaining a greater height, so that the average weight of stalk was generally equal to, and sometimes surpassed, that of the thicker varieties. The thin canes contained more fibre, but the greater difficulty in milling was compensated by the increased fuel value of the bagasse. Comparative trials with 10 "foreign" varieties of plant canes, viz., J. 36, J. 100, J. 139, J. 213, J. 234, Sumatra, Manteica de S. Barbara, Honduras, Bois Rouge, and Kavangire, and native purple and striped canes, showed that though the sucrose content was practically the same in the "foreign" and native canes, the former gave somewhat better yields, namely an average of 2320, as compared with 2201 kilos. of sugar per hectare (2065 and 1960 lb. per acre). Subsequent comparison of the ratoon canes showed that the sugar content was about the same as with the plant cane, but there was a large increase in the yield of sugar from the "foreign" varieties, namely an average of 4439 kilos. as compared with 2417 kilos. of sugar per hectare (3951 and 2151 lb. per acre) for the native canes; two varieties stood out prominently, viz., Kavangire with 8030, and J. 213 with 7296 kilos. of sugar per hectare (7147 and 6493 lb. per acre). The greater yield from the ratoon canes than from the corresponding plant canes is stated to be generally true for Tucumán, though the contrary obtains in almost every other cane-growing country of the world.—J. P. O.

Sugar recovery; Battelle process of ——. R. S. Norris. Special Report, Expt. station, Hawaiian Sugar Planters' Assoc., July, 1913.

In the Battelle process (see U.S. Pats. 1,044,003 and 1,044,004; this J., 1912, 1195), the raw mixed juice from the mill is treated with 2—3 per cent. of calcium saccharate, quicklime or milk of lime, and the defecated juice heated to boiling point, in order to destroy reducing sugars. After single or double carbonatation, depending upon the amount of reducing sugars originally present and the amount of lime used, the subsequent procedure is the same as in a beet sugar factory, and, whether raw or white sugar is being made, after the second boiling the second molasses is treated by the lime separation method. As the result of an exhaustive examination of the process at the Ewa plantation, the following general conclusions were arrived at: The Battelle process may be worked on a manufacturing scale to produce either raw or white sugar, and the lime saccharate method of extraction may or may not be applied to the waste molasses. When operated without the saccharate method of treating the waste molasses, the recovery of sugar, compared with that effected by the ordinary defecation-sulphitation process, is so much less as to make manufacture unprofitable. The increased recovery of sugar by the application of the saccharate extraction method to the waste molasses leads to an increase of profit to the manufacturer of white sugar over that at present obtained by the defecation process, amounting to \$8·34—\$9·97 (£1 14s.—£2 1s.) per ton; but notwithstanding this increased recovery, owing to the greater cost of working, it is less profitable to manufacture raw sugar by the Battelle process than by the ordinary defecation-sulphitation method.—J. P. O.

Sugar refractometer; New —— for determining the apparent dry substance of juices and syrups. O. Schönrock. Z. Ver. deut. Zuckerind., 1914, 10—20.

A simplified form of the Abbe refractometer has been designed for use in the sugar laboratory. It comprises a double prism, capable of being heated, upon which is placed the substance under examination; a compensator, enabling observations made by ordinary light to be read in the equivalent of sodium light; and a telescope tube, controlled by a thumb-screw, which is turned until the border line coincides with the point of intersection of the cross threads. It is so graduated that the percentage of dry substance in the product may be read off directly without reference to tables, the table of the author from 0—60 per cent., and that of Main from 60—85 per cent., having been used for constructing the scale. Two types of instrument are described: one for use at 20° C., and the other for 28° C., a table of corrections being applied for other temperatures. It is stated that with this instrument the difficulty of reading dark-coloured liquids without dilution or previous treatment is overcome by a method of observation with reflected light.—J. P. O.

Sugars; Rôle of magnesia in the carbonatation process of making white ——. W. H. T. Harloff. Intern. Sugar J., 1914, 16, 25—27.

In the double carbonatation process the presence of magnesia introduced by the use of impure lime causes little trouble, since being practically insoluble in an alkaline solution it is almost all removed at the first stage, at which the partially carbonatated juice is filtered while still containing an appreciable quantity of calcium hydroxide. But in the single process, in which the juice is carbonatated almost to neutrality in one operation, the magnesia originally insoluble gradually passes into solution with the decrease of alkalinity, forming magnesium bicarbonate, which subsequently decomposes in the evaporators, increasing the amount of incrustation. Moreover, the presence of magnesia causes oversaturation, since so long as magnesium carbonate be present the reaction will remain alkaline, only approaching neutrality when all has passed into the form of bicarbonate. Such over-saturation causes the re-solution of certain impurities, notably calcium and potassium organic acid salts and colouring matters, so that the clarification is defective, and the yield and quality of the finished product are both very unsatisfactory. Even in the single process, however, limestone containing 0·1—0·5 per cent. MgO may be used, provided that carbonatation be arrested while the juice is still distinctly alkaline, and filtered, the remaining alkalinity being neutralised by sulphurous acid after the juice has passed through the presses.—J. P. O.

Iron; Accurate and rapid determination of traces of —— in invert sugar, starch glucose, and caramel. J. J. Eastick, J. P. Ogilvie, and J. H. Lindfield. Intern. Sugar J., 1914, 16, 23—24.

The sulphide colourimetric process, previously described by the authors for direct application to cane and beet sugar factory and refinery products without the inconvenience of incineration (this J., 1912, 831), also give satisfactory results with invert sugar and starch glucos the values found directly with a solution of the sampl and those obtained with a solution of the ash of th same, being practically identical. Results obtained wit caramel are also given, but in ascertaining these the solutio of the ash was always used, a direct determination i such a dark-coloured substance being impossible.—J. P. C

Maple products, Analysis of ——. II. A comparati study of the delicacy of methods. J. F. Snell and J. Scott. J. Ind. Eng. Chem., 1913, 5, 993—997.

In comparative experiments with three genuine map syrups to which varying quantities of a solution of sucro were added, the conductivity value, the ash-content a the different lead values (see this J., 1906, 830, 95 1908, 1076) all decreased as the maple syrup was dilut with sucrose solution. The Winton lead method (t

J., 1906, 957) gave better agreement of duplicates than the Canadian method (McGill, Lab. Inland Revenue Dept., Ottawa, Bull. 228, 1911, p. 5) but the Canadian value fell away most rapidly. The narrowest range for genuine maple syrups was shown by the conductivity value (this J., 1913, 954). In making a blank determination in Winton's method the use of a solution of sucrose instead of acetic acid as recommended by Bryan (see this J., 1911, 299) is suggested. In the Canadian method washing with water at 80° and 100° C. respectively gave practically the same results; variation of the quantity of wash water from 100 to 150 c.c. was also without effect, but higher results were obtained when only 50 c.c. were used. The results differed according to whether the lead value was determined with a fixed quantity of syrup and calculated to dry substance or determined directly with a quantity of syrup equivalent to a fixed quantity of dry substance. In the Canadian method the calculated results were lower and in the Winton method higher than those determined directly.—A. S.

PATENTS.

Evaporating and boiling apparatus; Vacuum —— for sugar houses and refineries. J. B. Swaryczewski. Ger. Pat. 266,336, March 11, 1911.

THE lower part of the evaporator is hexagonal with two of the opposite sides curved (see Fig. 2). The chambers, 2 and 3, are connected by pipes, 6, and the chambers, 4 and 5, by pipes, 7. All the chambers are divided by horizontal partitions into compartments, and the chambers, 2 and 4, also have vertical partitions; the several compartments are provided with the necessary connections, 9, for the introduction of steam and 10, for the discharge of condensed water. In the spaces, 8, surrounded on all sides by heating surfaces, the syrup is rapidly heated and a vigorous upward circulation is produced, the juice then flowing downwards in the spaces, 16, bounded along one side by a surface which is not heated. The crystals are discharged by opening the door, 19.—A. S.

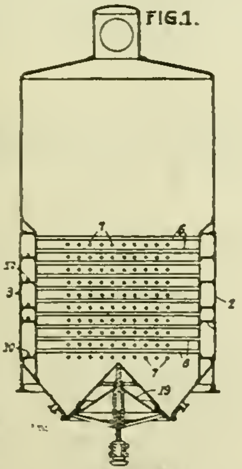

FIG.1.

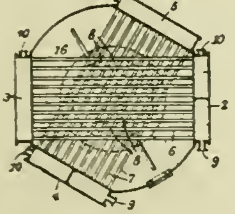

FIG.2.

ugar; Manufacture [sterilisation and purification] of ——. A. Shelmerdine and F. C. Lewis, Liverpool. Eng. Pat. 29,524, Dec. 23, 1912.

UGAR solutions, while passing through a conduit, are bjected to the action of a high-tension alternating lectric current (1000—2000 volts) acting longitudinally rough the conduit. The electrodes are placed at tervals in enlargements or pockets of the tubular conuit, a portion of the electrode standing in the direct path of the liquid, which is thus caused to dip under and round the edges of the electrode, taking a "bent course."—J. F. B.

Sugar solutions; Purification and decolourisation of liquids, especially of ——. F. Tiemann. Ger. Pat. 268,047, Nov. 14, 1912.

THE solution to be treated is brought into contact with porous substances (kieselguhr, bone charcoal, or the like), on which mordants have previously been fixed by the methods used in the dyeing industry, whereby colouring matters, pectin substances, etc., are separated and fixed by the porous material in an insoluble form. Different mordants may be fixed together on the porous material. Tin salts (oxalate, fluoride) are mentioned as being specially suitable.—A. S.

Process for the continuous solution of solid substances, especially for slaking lime with sugar juice or water. Ger. Pat. 268,442. *See* I.

XVIII.—FERMENTATION INDUSTRIES.

Yeast; Determination of glycogen in ——. F. Schönfeld and E. Künzel. Woch. Brau., 1913, 31, 9—12.

THE method is a modification of that described by Pflüger (Arch. ges. Physiol., 1909, 129, 362) for the determination of glycogen in animal tissues. The yeast is washed with water for a short time and pressed; these operations should not be unduly prolonged, for the glycogen-content of the yeast is very liable to change. From 10—15 grms. of the yeast are heated with 25 c.c. of 60 per cent. potassium hydroxide solution for 3 hours in a bath of boiling water. The cooled product, washed into a larger vessel with 50 c.c. of water, is mixed with 200 c.c. of 96 per cent. alcohol and left over night. The supernatant liquid is decanted, with as little solid matter as possible, through a filter connected with a pump. The residue, treated with a few drops of brine, is washed with 66 per cent. alcohol (100—150 c.c.) until the washings are colourless, then twice with absolute alcohol and twice with ether. The glycogen is redissolved by heating with water for some time, the solution is filtered into a 200 c.c. flask, neutralised with hydrochloric acid (sp. gr. 1·19) and made up to the mark. It is then heated in a bath of boiling water for 3 hours with 10 c.c. of hydrochloric acid (sp. gr. 1·19), cooled, neutralised with a 60 per cent. solution of potassium hydroxide, and again made up to 200 c.c. and well mixed. The quantity of dextrose in 25 c.c. of the solution is determined by Allihn's method: 1 grm. of dextrose corresponds to 0·927 grm. of glycogen. A bibliography relating to yeast-glycogen is appended to the paper.—J. H. L.

Yeasts; So-called black ——. H. Will and F. Noldin. Z. ges. Brauw., 1914, 38, 13—16.

EXAMINATION of three "black yeasts" (Forms I., II., and III.) of different origins, shows that they are so similar morphologically and physiologically, that they are very probably only varieties of the same species. The three organisms are *Hypomycetes*, forming a typical and a vegetative mycelium. The typical mycelium appears slightly branched and bears conidia directly or on short lateral branches: no sporulation occurs in the vegetative cells. The surface growth on nutrient solutions is either soft, more or less smooth, and of a shining black colour, or tenacious, thick, velvety or woolly, and grey to dark green in colour. The organisms do not grow at temperatures above 35° C., and their growth in wort is arrested by 4 per cent. of alcohol by volume; they are only slightly resistant to acids and have no fermenting power. The experimental results so far obtained do not justify a systematic classification or a new designation of the species in question and its varieties, but the names *Saccharomyces niger*, *Torula nigra*, and "black yeast," used by earlier workers, should be abandoned.—L. E.

Alcoholic fermentation; Formation of (1) *lactic acid,* (2) *glycerol, in ——.* M. Oppenheimer. Z. physiol. Chem., 1914, 89, 45—62, 63—71.

(1) Yeast juice prepared by Lebedeff's method (this J., 1911, 147) was found to contain small quantities of lactic acid (0·11—0·22 per cent.) which increased slightly when the juice was kept for several days under aseptic conditions. Addition of 1 grm. of dextrose, dihydroxyacetone or glyceraldehyde, to 100 c.c. of the fresh juice increased the quantity of lactic acid formed, by amounts ranging from 0 to 0·12, 0 to 0·11, and 0·02 to 0·23 grm. in the respective cases. Sodium pyruvate on the other hand, lessened the production of lactic acid. The author concludes that lactic acid is formed from sugar during fermentation by yeast juice, and that its immediate precursor is more probably glyceraldehyde than dihydroxyacetone or pyruvic acid (cp. Buchner and Meisenheimer, this J., 1904, 262; 1905, 246; 1906, 998; von Lebedeff and Griaznoff, this J. 1912, 1195). The absence of lactic acid from the products of fermentation of living yeast, which was established by Pasteur and others, may be due to the greater vigour of the process, as compared with the cell-free fermentation, for Pasteur found that other by-products, *viz.*, succinic acid and glycerol, are produced in larger quantities by weak than by vigorous yeasts.

(2) Fresh yeast juice contained 0·17—0·25 per cent. of glycerol, which increased by about 0·04 per cent. in the course of a few days. Addition of 1 per cent. of dextrose, glyceraldehyde or dihydroxyacetone increased the amount of glycerol formed, by 3—12, 9·4—15, and 11·7—19·2 per cent. of the added substance in the respective cases (cp. Buchner and Meisenheimer, this J., 1910, 894).—J.H.L.

Alcohol in beer; Determination of —— by means of Malligand's ebullioscope. J. C. Cain. Chem. News, 1914, **109**, 37.

The method depends on the fact that the solids in beers and wines exert no practical influence on the boiling point, which varies according to the alcohol-content. The apparatus (see Malligand and Brossard-Vidal, Comptes rend., 1874, **78**, 1470) has been found to give very exact results with foreign beers and wine, and the author shows that the same holds for English beers.—L. E.

Vinegar; Canadian standard of quality for ——. Board of Trade J., Jan. 22, 1914. [T.R.]

The "Canada Gazette" of the 27th December last contains an Order-in-Council, dated 19th December, 1913, establishing certain standards of quality and limits of variability for vinegar and similar articles under the Adulteration Act of the Dominion of Canada. Under this Order-in-Council it is stated, *inter alia*, that vinegar shall contain not less than 3½ per cent. and not more than 10½ per cent. of acetic acid. Various standards are specified for certain kinds of vinegar (*e.g.*, wine vinegar, spirit vinegar, grain vinegar, malt vinegar, etc.). Vinegars made by the acetous fermentation of dilute alcoholic liquors whose alcohol may have had its origin in the fermentation of fruit sugars of various kinds, or of ordinary sugar, must bear distinctive names, indicating the source of the saccharine matter.

Superphosphate-vinasse [" *Superphosphatschlempe* "]*: a new fertiliser.* Stoltzenberg. *See* XVI.

Patents.

Distilling apparatus; Continuous ——. A. C. Badger, Newton Center, Mass. U.S. Pat. 1,082,064, Dec. 23, 1913.

A continuous column still is connected with a series of tubular heaters or dephlegmators through which the "mash" or other liquid to be distilled is pumped into the column. By means of suitable valves the amount of vapour brought into thermal contact with the incoming "mash" can be adjusted so that the composition of the uncondensed vapour passing to the final condenser can be varied at will.—W. H. C.

Cellulosic materials; Treatment of —— to obtain fermentable sugars and the like therefrom. G. H. Tomlinson, Fullerton, La., U.S.A. Eng. Pat. 30,072, Dec. 31, 1912. Under Int. Conv., Jan. 29, 1912.

See U.S. Pat. 1,032,450 of 1912; this J., 1912, 832, 833.—T. F. B.

XIXa.—FOODS.

Lactose; Influence of ammonium sulphate on the specific rotation of ——. R. Rosemann. Z. physiol. Chem., 1914, **89**, 133—140.

The specific rotatory power of lactose, which in pure aqueous solutions is +52·53°, is +50·47° in solutions saturated with ammonium sulphate, and +51·55° in solutions containing about 40 grms. of this salt per 100 c.c. The latter concentration corresponds to the conditions prescribed in Salkowski's method for the determination of lactose in milk (this J., 1912, 507). For milk containing 4—6 per cent. of lactose, the results obtained by Salkowski's method should accordingly be 0·07—0·11 per cent. low, but the author does not recommend a corresponding correction, since according to Kretschmer (this J., 1913, 708) the results actually obtained tend to be high.—J. H. L.

Proteins in milk; Decomposition of —— by the action of lactic ferments. W. C. De Graaff and A. Schaap. Ann. Falsif., 1913, 6, 639—645.

The aldehyde figure (see this J., 1911, 148) of butter-milk is much larger than that of fresh milk, the increase being due to the decomposition of the proteins by proteolytic enzymes produced by certain micro-organisms. Of the latter, *Streptococcus lactis* and *B. casei*, are the more numerous and play the greater part in the decomposition. The enzyme which ferments lactose does not peptonise the proteins and, consequently, does not affect the aldehyde figure.—W. P. S.

Mineral waters; Formation of sediment in —— when stored in bottles. Determination of silica, iron, and aluminium in mineral waters. L. Dede. Chem.-Zeit., 1914, **38**, 53—55.

The sediment often found in bottles of mineral waters consists chiefly of hydrated iron oxide, alumina, silica, and calcium carbonate; it does not appear to be due to the presence of considerable quantities of iron and calcium salts in the water, but rather to the content of dissolved alumina and silica or suspended clay, the alumina and silica together with certain other constituents being carried down by hydrated iron oxide produced by the oxidation of ferrous bicarbonate. The presence of alumina and silica seems to be essential, since highly ferruginous waters free from these substances yield only traces of sediment. For collecting samples of mineral water for analysis, the author uses a bottle of about 10 litres capacity, which is treated for 24 hours with 5 per cent. hydrochloric acid, rinsed, dried, filled with carbon dioxide, and then the water introduced through a tube reaching t the bottom of the bottle. For the determination o silica, etc., the water is made neutral to methyl orang with hydrochloric acid, evaporated to a small volum in a silver basin, then transferred to a platinum basi treated with an excess of hydrochloric acid, evaporate to dryness, the residue heated to 110° C. for 30 mins. treated with hydrochloric acid and water, and the insolubl residue of silica, barium sulphate, and titanic acid collecte ignited, and weighed. The weighed residue is treate with ammonium fluoride and sulphuric acid, the loss weight after this treatment giving the silica, and t remaining residue is fused with potassium pyrosulphat the titanic acid being then separated from traces of iro etc., by dissolving the fused mass in dilute sulphuric ac adding ammonia, acidifying the solution with hydr chloric acid, and evaporating to dryness. The iron a aluminium are best separated by precipitating the iron sulphide from an ammonium citrate solution.—W. P. S

Turmeric [in pepper]; Detection of ——. E. J. Parry. Chem. and Drugg., 1914, 84, 34—35.

According to a trade custom white pepper is sometimes tinted with minute quantities (*e.g.*, 0·05 per cent.) of turmeric. Such traces cannot be detected with certainty by microscopic examination or by the boric acid test with silk dyed in the alcoholic extract, but can be detected by Bell's test as follows:—One grm. of diphenylamine is dissolved in 20 c.c. of 90 per cent. alcohol, 25 c.c. of sulphuric acid are added and the mixture cooled. A drop of the reagent is placed on a microscope slide and a little of the sample spread on a cover-glass, which is then inverted so that the powder falls evenly and not in clots. On microscopic examination of the prepared slide, every particle of turmeric is found to be stained a fine purple colour, and the proportion may be estimated approximately by comparison with standard preparations. The stain is not permanent and the slides must be examined soon after mounting.—J. F. B.

Pine-apple by-products; Utilisation of —— in Hawaii. Board of Trade J., Jan. 15, 1914. [T.R.]

Experiments have been made recently in Hawaii with a view of ascertaining what uses can be made of pine-apple by-products. The leaf fibre is of great strength and about 68 inches long; about 70 lb. of fibre can be obtained from a ton of leaves. It is stated that the fibre can be used for the manufacture of paper of a high class and also for cordage; its production, however, on a commercial scale has not yet been undertaken. This is the same fibre that is used for piña cloth, the "pineapple silk" of the Philippines, where, however, fresher leaves are used from which a finer fibre is obtained than would be the case in Hawaii, where fibre would be extracted merely as a by-product from the stumps when dug up every four years or so. Vinegar of excellent quality can be made from the fruit juice, much of which is now wasted. A good deal is, however, utilised more profitably for concentration into syrup, the juice of the fruit ripened on the plant containing 10 to 15 per cent. of sugar. The average of all analyses made at the experiment station shows 4·22 per cent. of reducing or invert sugar and 7·84 per cent. of sucrose, giving a total percentage of sugar content of 12·06. The stumps of the plant contain nearly as much starch as potatoes and cassava, but it is doubtful whether it can be extracted profitably.

Panning or roasting and drying tea leaf and the like; Methods and apparatus for ——. G. W. Sutton, Stevenage. Eng. Pat. 29,641, Dec. 24, 1912.

The materials pass over superposed, hollow, heating plates arranged in an open frame, being pushed forward, gathered together into heaps and again spread upon the plates by curved conveyor blades attached to endless chains at the sides of the plates. Rows of pins project upwards through tubes in the plates and are attached to a frame below by which they are periodically withdrawn at the moment that the conveyor blades pass over the spot. —W. H. C.

Beverages, perfumes and the like; Production of ——. U. E. Wegener, Berlin, Lichterfelde, Germany. Eng. Pat. 20,061, Sept. 5, 1913.

So-called "frosted" beverages—the bottles containing which are covered on the inside with crystals—are produced by the use of the comparatively insoluble sugars, such as lactose, galactose, raffinose, maltose, mannitol, etc., instead of the cane or beet sugar usually employed. Crystallisation may be effected in a number of ways. A solution of the sugar, containing alcohol, may be introduced into the bottles and allowed to crystallise, the mother-liquor being afterwards drained off and the bottles filled with the beverage in which some of the sugar used for crystallisation has already been dissolved. A salt and an acid such as sodium bicarbonate and tartaric acid may be added, in addition to the sugar, sodium tartrate crystallising out with the sugar. The crystal-forming substances may be added in the form of a powder to the pure beverage. A solution in diluted alcohol of the sugar, together with aromatising, colouring, and improving substances, and alcohol sufficient for preservation may be formed and simply added to spirit and water to produce a frosted liqueur. The methods described may be applied to hair-washes and other toilet preparations.—E. W. L.

Apparatus applicable for use in the manufacture of soap, soap powders, cocoa, chocolate, etc. Eng. Pat. 4654. *See* XII.

XIXb.—WATER PURIFICATION; SANITATION.

New sewage process adopted by the Dublin Corporation (Dickson treatment). Presidential Address, J. D. Watson. Inst. Roy. Sanitary Eng., Jan. 7, 1914. (See also Dickson, Eng. Pat. 25,108, Oct. 28, 1910; this J., 1911, 504.

The principle of the Dickson process to be shortly applied to the Dublin sewage, is founded on the fact that the addition of a small quantity of yeast to sewage causes the sludge to rise to the surface, leaving a very tolerably clear effluent beneath; the best results are obtained at a temperature of 95° F. (35° C.). Crude Dublin sludge contains 9—11 per cent. of solids and 89·91 per cent. of water; after fermenting with yeast and drawing off the effluent, the content of solids is 18·22 per cent., so that the cost of drying is cut down to one-half. Further, there is no loss of nitrogen, both the dried raw sludge and the dried treated sludge containing about 3 per cent. of that element. The city sludge, in the new process, passes direct into a mixing tank, where it is treated with about ½ per cent. of yeast and about 3 per cent. of already "fermented" sludge, and the whole is heated to 90°—100° F. (32°—38° C.). From the mixer the material runs into a series of eight parallel troughs made of concrete. Each trough measures about 50×4×2½ ft., and has a capacity of 20 tons, so that the capacity of the whole is equal to one day's output of city sludge. Below the troughs are an equal number of hot-air ducts of the same material, and in this way the temperature is maintained at about 90°—95° F. (32°—35° C.). In less than 24 hours the suspended solids are floating on the surface, but are sufficiently mobile to be run off through sluice-valves into a receiver-trough. In this receiver-trough the sludge may be mixed with phosphates and kainite. The sludge effluent, containing about six parts of solids per 1,000, is run out through a siphon pipe, perforated in such a manner that no clogging takes place. The separated sludge, containing about 80 per cent. of water, is next pumped to the top of the "dryer," in which it is pulverised and completely desiccated. This apparatus consists of a large, vertical, cylindrical tower provided with a number of perforated platforms, which are alternately fixed and rotating. The under-side of each platform is provided with a rake which scrapes the material on to the platform below. A blast of hot air is blown through this tower from the bottom upwards by means of a large fan. The temperature at the base is 400° F. (204° C.), and the waste heat issuing from the top is utilised for maintaining the temperature of the mixing tank and the air-ducts beneath the fermenting troughs: the waste gases pass back into the furnace. By drying at this low temperature practically no organic matter is lost. A final pulverisation in a small air-disintegrator completes the process. The entire plant, which occupies less than one acre of ground, works automatically and continuously, and does not require more than one engineer and four labourers to each shift. The horse-power for all operations is 50, and, except for a slight odour in the trough-house the process is neither unpleasant nor unhealthy. The dried and powdered sludge contains 3 per cent. of nitrogen and 60 per cent. of organic matter, and the greater part of the former is in a state immediately available for plant life. The presence of so much organic matter greatly enhances its value and makes it superior to purely artificial fertilisers. By the addition of phosphates and kainite, a complete manure containing 15 per cent. of soluble phosphate, 2½ per cent. of potash, and nearly 2 per cent. of nitrogen has been prepared and marketed. The great defect of most sewage effluents and also of waste liquors from manufacturing processes, is, that they are deficient in dissolved oxygen, and consequently when they pass into rivers and streams fish life is threatened if not extinguished, and the door is opened to the multiplication of virulent anaerobic microbes. A long series of tests has shown that such effluents may be completely aerated and deodorised, and nearly all the suspended matter contained in them eliminated by a "hydro-extractor," a centrifugal machine, similar to those in use in sugar refineries, in which the cage or basket is provided with a layer of sand or other filtering material through which the effluent has to pass. A simple mechanical contrivance allows of the removal of any desired amount of sand without interrupting the motion, and fresh sand introduced into the effluent, forms a clean new surface for filtration. The "hydro" occupies only six square yards and is calculated to filter 10,000 gallons per hour. This system has been found to be equally effective for treating the effluent from the Dickson process and from that of crude Dublin sewage. Experiments made in September, 1913, with Dublin effluent showed that the total solids were diminished by 10—11 per cent. after passing through the "hydro" and that the dissolved oxygen was raised from practically nil to 99·2 per cent. of the total possible. The treated effluent had no injurious effect on fish-life.

Assuming the average sewage output to be 25 gallons per head per day, the cost of a complete plant for a town of 150,000 inhabitants would be approximately £125,000, and the annual charges (including operating) would be much more than covered by the sale of the fertiliser, for which there is a ready market. If the process could be worked in conjunction with a refuse destructor the cost of treatment would naturally be greatly reduced. The cost of production of the dried sludge in Dublin is 25s. per ton, inclusive of fuel (15s.), labour, power, and all other charges except those of capital and administration. Its market value is at least 50s. per ton. The application to creamery effluents is now an accomplished fact. The Solohead Co-operative Dairy Society, near Limerick Junction, Tipperary, is working the system in conjunction with small precipitation tanks with signal success. The waste matter from such creameries, when mixed with phosphate, makes a high-grade fertiliser containing 44·4 per cent. phosphates (43 per cent. soluble) and 0·42 per cent. of nitrogen.

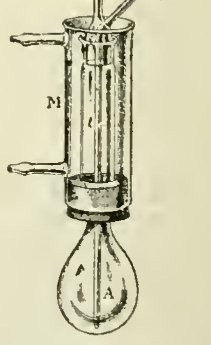
Calcium carbonate; Solubility of —— and its bearing on certain processes for the treatment of water supplies. W. T. Burgess. Inst. Water Engineers, Dec. 13, 1913. 13 pages.

The lime softening process does not remove the whole of the calcium carbonate from water. Water free from dissolved carbon dioxide dissolves calcium carbonate to the extent of 1·5 parts per 100,000. The complete separation of the precipitated calcium carbonate requires a much longer time than is usually supposed; even after the precipitate has settled, the clear water continues to deposit crystalline calcium carbonate for some days. The more perfectly the water is softened the greater the necessity for giving it a long period for subsidence. When it is desired to use the water as soon as possible after the precipitate has settled, it may be treated with a small quantity of carbon dioxide to prevent deposition of calcium carbonate in the mains (compare Archbutt and Deeley's process; this J., 1891, 511); as little as 0·3 part of carbon dioxide per 100,000 of water is sufficient. In the method described by Houston (this J., 1912, 508) for sterilising water by the addition of an excess of lime and subsequent removal of the excess by carbon dioxide or sodium bicarbonate, it would be necessary, owing to the slow deposition of the last portions of the calcium carbonate, to take precautions to prevent the precipitation of calcium carbonate in the water mains.—W. P. S.

Water; Action of —— on lead service-pipes. J. F. Liverseege and A. W. Knapp. Public Works, Jan., 1914. (See also this J., 1913, 881.)

The water contained 5·90 parts of total solids and 2·4 parts of total alkalinity per 100,000; it was allowed to stand in pipes attached to the supply, in detached 6-foot lengths of pipe, closed with corks, and in consumers' pipes. The quantity of lead dissolved was unaffected by sand filtration, increased by addition of carbon dioxide, and usually diminished by a rise in alkalinity; it increased with time of contact up to 44 weeks, and decreased, for daily periods of contact of 17 hours, up to seven months, except in corked pipes, which gave conflicting results. Maximum protection was attained most rapidly in regularly used pipes, and was reached in one year. Pipes which had been used for hard water were as sensitive to soft water as pipes used for much shorter periods with soft water only. A high lead content was in one case attributed to stray electric currents.—O. E. M.

Carbon monoxide from blood; Apparatus for the extraction of ——. M. Nicloux. J. Pharm. Chim., 1914, 9, 57—61.



A flask, A, of 200—40 c.c. capacity, is closed by a hollow ground stopper which bears a tube, t, reaching to the bottom of the flask, and is terminated upwards in the tube, t'. Both these tubes are furnished with stopcocks. The tube, t', ends in an enlargement, s, to which a shallow funnel, C, can be adapted by a ground joint. A small open tube, E, can be adapted by another ground joint to the tube, t. The neck of the flask can be kept cool by a current of cold water passing through the sleeve, M. The flask should be of 200 c.c. capacity when dealing with 15—25 c.c. of blood. For determining the quantity of carbon monoxide in 25 c.c. of blood, 25 c.c. of phosphoric acid of 45° Bé. (sp. gr. 1·453) and 40 c.c. of water are introduced into the flask. Water is allowed to flow round the neck of the flask, the tube, t, filled with distilled water, the stopcock, R, closed and R′ left open The flask is put into a calcium chloride bath at 110° C. and exhausted by means of a water pump. The enlarged portion of the tube, t', is then filled with water. The tube, E, containing the blood is put into position. The blood is allowed to flow slowly into the flask and washed in with water. A quantity of foam is produced, which rapidly subsides except in the neck of the flask. It is removed by filling the funnel, C, with hot water, lifting the flask out of the calcium chloride bath and opening the tap R′, so as to admit water but not air. When the neck has been cleared in this way, the heating is continued for 10—15 mins. The flask is removed from the bath and hot water allowed to flow in from the tube, E, till the contents are at atmospheri pressure. The gas is then transferred to a suitabl tube inverted over the enlargement, s, in the funnel, C The results agree with those obtained by means of mercury pump.—F. Shdn.

Lime-sulphur-lead arsenate spray mixture; Chemical studies on the ——. W. E. Ruth. Oil, Paint and Drug Rep., Dec. 27, 1913.

Lead arsenate (Pb 64·23, total As_2O_5 26·47, water-soluble As_2O_5 0·44 per cent.) was mixed with a large excess of lime-sulphur solution (1 of lime sulphur concentrate of sp. gr. 1·291 to 40 of water) and after several hours, with frequent stirring, the insoluble residue was collected, washed, and dried at 40° C. It contained: Pb 45·62, total S 22·51, free S 19·44, Ca 5·08, As_2O_5 9·09 per cent., and no sulphide, sulphite or sulphate, but a small quantity of thiosulphate; and possibly some of the lead was present as thioarsenate for on adding several drops of concentrated lime-sulphur solution to a small quantity of lead arsenate suspended in water, the same colour change (reddish-yellow through brown to nearly black) was observed as is produced when lead thioarsenate is precipitated by the interaction of lead acetate and sodium thioarsenate. The effect on the composition of the lime-sulphur solution of mixing with lead arsenate was found to be diminution in the content of sulphide and calcium and increase in that of thiosulphate and sulphate (including sulphite). This increase of thiosulphate and sulphite would account for the increased fungicidal value of lime-sulphur when mixed with lead arsenate, if Haywood's view (this J., 1911, 41) that the fungicidal action is due to the presence of thiosulphate and sulphite be correct. (See also this J., 1910, 837, 967.) —A. S.

Patents.

Insecticide. C. Ellis, Larchmont, N.Y., Assignor to Chadeloid Chemical Co., New York. U.S. Pat. 1,082,507, Dec. 30, 1913.

An emulsion composed of wax dissolved in a highly volatile and almost insoluble organic liquid, and an aqueous solution of an inorganic salt having powerful insecticidal properties to which a "thickener" may be added to impart consistence. A solution of paraffin in carbon bisulphide, emulsified with an equal volume of mercuric chloride solution thickened with Irish moss, is mentioned. —F. Sodn.

Sewage; Treatment of ——. T. K. Irwin, London. U.S. Pat. 1,083,833, Jan. 6, 1914.

See Eng. Pat. 16,237 of 1912; this J., 1913, 1125.—T. F. B.

XX.—ORGANIC PRODUCTS; MEDICINAL SUBSTANCES; ESSENTIAL OILS.

Quinine and its derivatives; Some new salts of ——. D. Angeloni. Boll. Chim. Farm., 1913, 52, 675—685. Chem. Zentr., 1914, 1, 154—155.

Preliminary experiments showed that 1000 c.c. of ether dissolve 35·7 grms. of acetylsalicylic acid (aspirin), 8·6 grms. of anhydromethylenecitryldisalicylic acid (novaspirin), 4·0 grms. of succinyldisalicylic acid (diaspirin), 50·0 grms. of salicylsalicylic acid (diplosal), 33·3 grms. of euquinine (quinine ethylcarbonate), 2·0 grms. of aristoquinine (quinine carbonic ester), 2·5 grms. of saloquinine (quinine salicylic ester), and 20 grms. of quinaphenine (the phenetidide of quininecarbonic acid, $C_2H_5O.C_6H_4.NH.CO.C_{20}H_{23}N_2O_2$) respectively. The following salts of quinine and its derivatives with salicylic acid and its derivatives were prepared, except where otherwise stated, by mixing ethereal solutions of the components. Basic quinaphenine salicylate, m. pt. 125°—126° C. after crystallisation from a mixture of alcohol and a little ether: it was slightly soluble in water and was decomposed even by very dilute hydrochloric acid; neutral salt of euquinine and novaspirin, crystalline powder, m. pt. 95° C.; neutral salt of saloquinine and novaspirin, m. pt. 116° C.; neutral salt of quinaphenine and novaspirin, crystals, m. pt. 118°—120° C.; basic salt of quinine and diaspirin, very fine needles, m. pt. 125° C.; neutral salt of quinine and diaspirin: it was necessary to use excess of diaspirin, otherwise a mixture of the neutral and basic salts resulted; neutral salt of quinaphenine and diaspirin, m. pt. 116° C.; basic salt of quinine and diplosal, crystals, m. pt. 105° C.; basic salt of quinaphenine and diplosal, m. pt. 86° C. Neutral quinine salicylate was obtained by mixing aqueous solutions of quinine bisulphate and sodium salicylate. It was a yellowish powder, which melted below 100° C., with decomposition, and was converted into the basic salt (m. pt. 175° C.) by treatment with ether or alcohol. The basic salt of euquinine and novaspirin, pentagonal plates, m. pt. 178° C., and the neutral salt of aristoquinine and novaspirin, m. pt. 89°—90° C., were obtained by mixing alcoholic solutions of the components.—A. S.

Peru balsam; Artificial and genuine ——. K. Dieterich. Ber. deuts. Pharm. Ges., 1913, 23, 622—657.

Samples of genuine Peru balsam gave the following values:—Sp. gr. at 15° C., 1·160; acid value, 74·02—76·92; sapon. value, 214·34—243·07; iodine value, 22·07—25·87; cinnamein, 56·56—77·56 per cent.; sapon. value of cinnamein, 253·61; iodine value of cinnamein, 7·48—7·91; resin esters, 24·95 per cent.; and insol. in ether, 2·45—4·38 per cent. Artificial and "synthetic" balsams gave results differing, as a whole, considerably from the recorded limits, although individual values were frequently normal. Of the tests for the identification, etc., of Peru balsam only the following were found distinctive:—Hager's petroleum spirit test; determination of the solubility in alcohol, chloroform, chloral hydrate and carbon bisulphide; the nitric acid test; the zone reactions (see this J., 1908, 468), and the qualitative tests of the Swiss Pharmacopœia. A new colour reaction of genuine Peru balsam is described:—One drop of the sample is shaken with 5 c.c. of petroleum spirit, and about half of the liquid poured off. The remainder is mixed with 5 c.c. of ether, and shaken with a few drops (10 to 15) of sulphuric acid, added drop by drop, when genuine Peru balsam gives a violet to blue colouration, whilst artificial products give quite different colourations. This reaction is due to the cinnamein of the balsam. As supplementary tests Halphen's bromine reaction, the behaviour towards alkalis and ammonia, determination of resin esters, and substances insoluble in ether, the behaviour of the balsam on exposure to air, and sublimation and distillation tests may be applied. (See also this J., 1897, 829; 1898, 267, 806; 1899, 53.)—C. A. M.

Cineol [eucalyptol]; Addition compounds of ——. *Contribution to the knowledge of oxonium salts.* I. Bellucci and L. Grassi. Gaz. chim. ital., 1913, 43, II., 712—735.

The behaviour of cineol with a number of aromatic compounds was studied by the method of thermal analysis. The results indicated that 1 mol. of cineol combined with 1 mol. of each of the following substances to form definite compounds, the melting points of which are given in brackets: phenol (8° C.), α-naphthol (75° C.), β-naphthol (48° C.), *o*-cresol (50° C.), *m*-cresol (—5° C.), *p*-cresol (1·5° C.), pyrocatechol (39° C.), resorcinol (89° C.), guaiacol (5° C.), methyl salicylate (—15° C.), thymol (4·5° C.): in the case of quinol, 2 mols. of cineol combined with 1 mol. of quinol, the compound melting at 106·5° C. Negative results were obtained with *o*-, *m*-, and *p*-nitrophenol, *o*- and *m*-aminophenol, *o*- and *m*-hydroxybenzoic acid, and phenyl and naphthyl salicylates. With *p*-hydroxybenzoic acid a compound appeared to be formed which decomposed before melting.—A. S.

The Japanese mint industry. Chem. and Drugg., Jan. 31, 1914, 214.

The bulk of the mint grown in Japan is cultivated on the sides of the hills, but that grown on low-lying ground, which can be alternately used for rice, is the richest in menthol. Although mint is grown in various parts of Japan, the best oil is produced in Okayama and Hiroshima

Prefectures, where three crops are obtained—viz., in May, June, and August. The first crop yields on distillation an oil containing about 47 per cent. of menthol, the second about 53 per cent., and the third about 60 per cent. In Yamagata Prefecture two crops are obtained, and in the Hokkaido only one, but the acreage planted in Hokkaido is far larger than that in the other districts, so that even though Hokkaido oil contains only about 45 per cent. of crystals and there is only one crop, more than half the menthol comes from that province. The process of distilling the oil is the same throughout the different producing districts. It lasts four hours, and 82 lb. of dried herb of the first crop should produce 14 oz., of the second crop 24 oz., and of the third crop 21 oz. of oil, the figures depending on the quality of the herb and the extent to which it is dried. The second crop is the most plentiful—a field, for instance, which will produce 300 lb. of herb for its first crop will give 800 lb. for the second, and 600 lb. for the third. Roughly speaking, one acre produces 5000 lb. of dried herb, which should produce 80 lb. of crude oil. The oil having been distilled, is sold to the large refiners. In the Okujoto, Bingo, and a few other districts there are "Peppermint Guilds," which examine the oil and give a certificate as to its weight and purity, but from many districts the refiner has to take his chance. When the oil has been dementholised in Yokohama or Kobe, as the case may be, the menthol and oil are put separately in tins of 5 lb. each, twelve in a case, and are ready for export. The oil is of an inferior character as compared with English and American peppermint, but it enters into cheap confectionery to a large extent, and competes with the better-class oils.

Camphor; Yield of oil from Tansui —— tree. U.S. Consular Reports, Oil, Paint and Drug Reporter, Jan. 5, 1914.

It is stated that Tansui, an island just north of the Philippines, seems specially a field for the production of the camphor tree. Two kinds of oil are specially mentioned in this report as being products of the Island of Tansui; one, the chong-guh oil, is an essential oil with a sweet aromatic odour, and the other is yu-chin oil, produced from a tree growing in Southern Tansui, closely related in properties to the camphor tree, but which fails to yield camphor.

According to a statement by a member of the Kosempo camphor distillery, the comparative output of camphor and the oil is in the proportion of 25 to 75, indicating that an enormous amount of oil is producible. In Banshoryo, Shinkoko, Naiboryu, and Dateku, noted for the rich growth of the real yu-chin tree, the yield of camphor is not over 10 per cent. of the oil produced.

Ketones; Comparative value of catalysers in the preparation of ——. J. B. Senderens. Bull. Soc. Chim., 1914, **15**, 84—89.

In view of the work of other investigators (see this J., 1913, 806) the author draws attention to his previously recorded experiments on the action of catalysts in the preparation of ketones (see this J., 1909, 489; 1912, 660; 1913, 767). There is no doubt that the activity of the various oxides varies in so far that they behave differently when used with alcohols or organic acids respectively for the preparation of ketones.—W. P. S.

Succinic and malic acids; A reaction of ——. W. O. de Coninck. Bull. Soc. Chim., 1914, **15**, 93—94.

When a concentrated solution of succinic acid is added to a few grms. of calcium salicylate moistened with a small quantity of water and the mixture is heated gently, a red colouration develops gradually; this colouration is stable for many hours even when exposed to sunlight. Under similar conditions, malic acid also yields a red colouration, but the colour fades after a few hours and the solution is then coloured yellowish-brown; the colouration also disappears gradually when the mixture is boiled.
—W. P. S.

Chlorohydrocarbons; Properties of some —— and their use in chemical analysis. L. Gowing-Scopes. Analyst, 1914, **39**, 4—20.

The author has made a study of the series of chlorohydrocarbon solvents ranging from *cis*-dichloroethylene, boiling at 48·8° C. to hexachloroethane, boiling at 185·5° C., chloroform and carbon tetrachloride being included for purposes of comparison. Physical constants have been established, including boiling and freezing points, density, coefficient of expansion, heat of vaporisation, refractive index, viscosity at various temperatures, specific heat. For purifying these solvents the liquid is shaken vigourously with a strong solution of ammoniacal silver nitrate, washed free from ammonia, dehydrated over lime for 12 hours and distilled, the distillate being again fractionated from phosphorus pentoxide. The boiling points of binary and ternary mixtures with water and alcohol have been determined for certain members of the series. The action of the more important members of the series at their boiling points upon a number of common metals is tabulated. It would appear that nearly all are attacked to some extent in presence of water. Aluminium has a vigorous action upon the chloroethanes and is practically resistant to the chloroethylenes. The solubility of certain inorganic substances in the chlorohydrocarbons has been studied; tetra- and pentachloroethanes are excellent solvents of sulphur. Tables are given indicating the solvent action of the various liquids upon 248 organic substances and 45 dyestuffs, and the possibility of separations in certain cases is discussed. As general rules it is stated that if a compound contains only one hydroxyl group it is generally soluble, whilst if it contains two or more hydroxyl or carboxyl groups or one of each, it is more or less insoluble. Ortho-compounds are generally more soluble than meta- or para-compounds. The solubility of a compound generally decreases as the chlorine content of the solvent increases. An accumulation of nitro groups tends to decrease solubility. Certain uses of the chlorohydrocarbons as solvents in chemical analysis are discussed and the chemical reactions and tests for various members of the series described. Aluminium trichloride reacts only with the chloroethanes and tetrachloroethylene to form double compounds. Pentachloroethane reacts in a characteristic manner with phenylhydrazine, forming a solid compound with evolution of gas.—J. F. B.

Ether for narcosis. J. Herzog. Apoth.-Zeit., 1914, **29**, 68—69.

When ether is left in contact with ordinary cork it dissolves substances from the cork which give a yellow to yellowish golden colour when tested with potassium hydroxide, thus rendering the ether incapable of satisfying the tests of the German Pharmacopœia.—F. Shdn.

Ethyl iodide and ethyl alcohol; Relation between the boiling point and composition of mixtures of ——. S. C. Jana and J. N. S. Gupta. J. Amer. Chem. Soc., 1914, **36**, 115—118.

The boiling points, at atmospheric pressure, of mixtures of ethyl iodide and ethyl alcohol were as follows:—

Percentage of ethyl iodide.	B. pt., ° C.	Percentage of ethyl iodide.	B.pt., ° C.
26·69	70·2	78·36	61·9
35·69	68·8	84·87	61·4
41·38	67·0	88·35	61·3
52·86	64·8	90·5	61·5
57·28	64·0	94·50	62·0
62·70	63·3	97·63	64·0
69·42	62·2		

A mixture of 87 per cent. of ethyl iodide and 13 of eth alcohol distilled as a homogeneous substance at 61·2°
—A. S.

Iodine tincture; Permanent ——. Courtot. J. Phar Chim., 1914, **9**, 69—71.

100 grms. of iodine, and 36 grms. of sodium iodide, 40 grms. of potassium iodide, are made up to 1000 gr

in strong alcohol. The use of smaller proportions of iodine, or heating during the solution, tends to produce a tincture which develops hydriodic acid on keeping.
—F. Shdn.

Patents.

Aldehydes; Method of producing condensation products of ——. E. C. R. Marks, London. From E. I. du Pont de Nemours Powder Co., Wilmington, U.S.A. Eng. Pat. 22,621, Oct. 4, 1912.

See Fr. Pat. 449,604 of 1912; this J., 1913, 507.—T. F. B.

Products for medical, surgical, and hygienic purposes; Manufacture of ——. F. R. von Walther, Dresden, Saxony, and W. Dederich, London. Eng. Pat. 27,733. Dec. 2, 1912.

See Fr. Pat. 451,446 of 1912; this J., 1913, 672.—T. F. B.

Bismethylaminotetramino-arsenobenzene; Manufacture of a —— and of an intermediate product. A. G. Bloxam, London. From C. F. Boehringer und Söhne, Mannheim-Waldhof, Germany. Eng. Pat. 996, Jan. 13, 1913..

See U.S. Pats. 1,075,279 and 1,081,079 of 1913; this J., 1913, 1128; 1914, 41.—T. F. B.

Hexanitrodiphenylsulphide; Manufacture of ——. H. Wade, London. From C. Hartmann, Schlebusch, Germany. Eng. Pat. 18,353, Aug. 12, 1913.

See Fr. Pat. 460,571 of 1913; this J., 1914, 44.—T. F. B.

Fatty acid containing arsenic; High-molecular ——. *Pharmaceutical compound.* E. Fischer, Berlin, Assignor to Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. U.S. Pats. 1,082,509 and 1,082,510, Dec. 30, 1913.

See Eng. Pat. 18,732 of 1912; this J., 1913, 109.—T. F. B.

Oxycarboxydiarylcarbinols; Manufacture of ——. M. Weiler, Assignor to Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. U.S. Pat. 1,082,574, Dec. 30, 1913.

See Ger. Pat. 254,122 of 1911; this J., 1913, 189.—T. F. B.

Pharmaceutical compounds [esters of 2-piperonylquinoline-4-carboxylic acid]. A. Thiele, Assignor to Chem. Fabr. auf Actien, vorm. E. Schering, Berlin. U.S. Pat. 1,082,780, Dec. 30, 1913.

Production of beverages, perfumes, and the like. Eng. Pat. 20,061. *See* XIXa.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

Sulphite-quinol solutions; Oxidation and protection of ——. J. Pinnow. Z. wiss. Phot., 1913, 13, 41—45. Chem. Zentr., 1914, 1, 102.

The stability of the sulphite-quinol developer is stated to be increased about four-fold by the addition of a small quantity of acetic acid (0·05 grm.-mol. per litre). (See also this J., 1913, 214, 451.)—A. S.

Patent.

Development of photographic images. W. H. Caldwell, Inverness. U.S. Pat. 1,082,622, Dec. 30, 1913.

See Eng. Pat. 14,744 of 1911; this J., 1912, 747.—T. F. B.

XXII.—EXPLOSIVES; MATCHES.

Patents.

Gunpowder and process of making the same. C. D. McDowell, Pontiac, Mich. U.S. Pat. 1,083,371, Jan. 6, 1914.

Seven oz. of granulated sugar are dissolved in a boiling solution of glycerin (1 drachm) in water (2 drachms). While the mass is heated, but below the boiling point, 8 oz. of potassium chlorate are stirred in until dissolved, and the final product is granulated by passing through a sieve.—T. St.

Nitrocellulose; Process for the production of ——. Verein. Kunstseidefabriken A.-G., Kelsterbach on Maine, Germany. Eng. Pat. 5553, March 5, 1913. Under Int. Conv., March 5, 1912.

See Fr. Pat. 455,011 of 1913; this J., 1913, 886.—T. F. B.

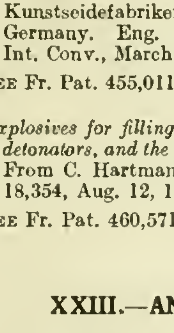
Explosives for filling projectiles, mines, torpedoes, primers, detonators, and the like; Use of ——. H. Wade, London. From C. Hartmann, Schlebusch, Germany. Eng. Pat. 18,354, Aug. 12, 1913.

See Fr. Pat. 460,571 of 1913; this J., 1914, 44.—T. F. B.

XXIII.—ANALYTICAL PROCESSES.

Thermo-regulator; An electrical contact vapour-pressure ——. A. L. Feild. J. Amer. Chem. Soc., 1914, 36, 72—76.

The thermoregulator described was devised for the purpose of keeping constant at 30° C. the temperature of a water-bath of 350 litres capacity, heated by means of carbon filament electric incandescence lamps, supplied with current by two dry batteries, the thermoregulator and a 150-ohm relay being interposed in the circuit. The regulator (see fig.) consists of a U-tube provided with a three-way cock, A, and a tap, B, for filling. In the closed shorter limb is a layer of ether (or other suitable volatile liquid), above which is ether vapour mixed with air; in the other limb, above the mercury, the air is displaced by dry carbon dioxide. The thermoregulator (after proper adjustment of the mercury level) being immersed in the bath, if the temperature of the latter rises too high, the mercury rises in B, till it reaches the upper platinum contact, whereupon the relay is operated and the heating current cut off. The regulator rapidly acquires the temperature of the bath and has proved sensitive to 0·1°—0·005° C.—A. S.

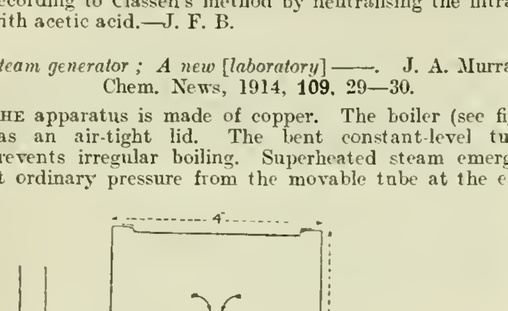


Calcium and magnesium; Separation of ——. F. Halla. Chem.-Zeit., 1914, 38, 100.

In presence of an excess of magnesium, in ammoniacal solution, the calcium is only incompletely precipitated by ammonium oxalate, but a quantitative precipitation is obtained in neutral solution when an excess of solid ammonium oxalate is added. When the proportion of magnesium chloride to calcium chloride is less than 12 : 1, the calcium oxalate is contaminated with some magnesium, but with larger proportions of magnesium the results come within the limits of experimental error. The neutral solution is treated at boiling point with an excess of solid ammonium oxalate until the precipitate of magnesium oxalate, at first produced, is redissolved and the residue of calcium oxalate remains unaltered. The solution is allowed to stand for some hours, filtered and the crystallised ammonium oxalate dissolved by warming with a little water. The precipitate is washed at first with hot water, then with cold and the calcium precipitate after incineration is covered with a little alcohol and a few drops of sulphuric acid, ignited and weighed as sulphate. The magnesium oxalate dissolved in the form of a double salt is precipitated according to Classen's method by neutralising the filtrate with acetic acid.—J. F. B.

Steam generator ; A new [laboratory] ——. J. A. Murray. Chem. News, 1914, **109**, 29—30.

THE apparatus is made of copper. The boiler (see fig.) has an air-tight lid. The bent constant-level tube prevents irregular boiling. Superheated steam emerges at ordinary pressure from the movable tube at the end of the coiled delivery tube (½ in. between the folds) into the bath, oven, etc. to be heated. The latter may be made of zinc or tin. Using a Bunsen burner for heating the steam generator, a bath measuring 9 × 4½ × 4½ inches was heated to 140° C. in 14 minutes.—J. R.



Aluminium ; Detection of traces of ——. G. H. Petit. J. Pharm. Chim., 1914, **9**, 66—69.

THE hydroxides of iron, chromium and aluminium precipitated in the usual way are washed thoroughly, transferred to a beaker by means of water, heated to boiling with solid barium hydroxide and filtered. The filtrate is acidified with hydrochloric acid, boiled and made alkaline with ammonia which has been kept over barium chloride. Aluminium when present is immediately precipitated. Where traces only of aluminium are present, the filtrate obtained after boiling the precipitate with barium hydroxide is made slightly acid with sulphuric acid, concentrated, filtered and ammonia added drop by drop (not more than 4—5 drops). It is then heated just to boiling and allowed to stand, when the aluminium hydroxide settles down if present. This method will detect 5 mgrms. of aluminium in the presence of 5 grms. of iron.—F. SHDN.

Mercury ; Determination of —— *as metal.* C. Duccini. Gaz. chim. ital., 1913, **43**, II., 693—699.

THE method of Purgotti (Gaz. chim. ital., 1899, **26**, II., 559 ; see also Rimini, this J., 1904, 208), in which the mercury salt is reduced to metal by hydrazine sulphate in presence of alkali, and the liberated nitrogen measured, gives accurate results if at least 1 grm. of the mercury salt be used. If instead of measuring the nitrogen, the reduced mercury be washed by decantation with dilute hydrochloric acid and water, collected on a weighed filter, washed successively with cold water, 98 per cent. alcohol, and ether, dried in a desiccator over calcium chloride and weighed, accurate results can be obtained even with 0·2—0·25 grm. of the sample. The method can be applied directly to the chloride and nitrate of mercury and to mercury potassium chloride, but the cyanide must be first converted into the chloride.—A. S.

Vanadium ; Volumetric determination of ——. G. Wegelin. Z. anal. Chem., 1914, **53**, 81—99.

TITRATION with permanganate after reduction with sulphur dioxide gives a maximum error of 0·2 per cent. The error caused by chloride can be eliminated by adding manganese sulphate. In presence of iron the reduction is effected with alcohol. The iodometric estimation, involving the use of potassium ferrocyanide, is very reliable. The production of the very pure pentoxide from vanadium oxychloride is described ; but for ordinary purposes it is sufficient to ignite commercial ammonium vanadate which has been four times recrystallised.—J. R.

Silica ; Modification of the usual method of correcting ——, *for included salts.* S. B. Kuzirian. Amer. J. Sci., 1914, **37**, 61—64.

THE silicious residue, obtained by evaporation of the hydrochloric acid solution of the substance, filtration, and ignition, is treated with sulphuric acid, gently ignited, and weighed again. It is now treated with hydrofluoric and sulphuric acids, the residue ignited to the same degree as before, and the loss of weight taken as silica. The error is not wholly eliminated by this treatment, but is in ordinary cases so lessened as to be negligible. A Bunsen burner is sufficient for the ignitions. (See also this J., 1914, 44.)—J. T. D.

Oxygen ; Determination of —— *in organic compounds.* M. C. Boswell. J. Amer. Chem. Soc., 1914, **36**, 127—132.

THE method previously described (this J., 1913, 383) having been found to give high results in the case of compounds containing less than 40 per cent. of oxygen, a modified method has been devised by which oxygen can be determined to within 0·3—1 per cent. and hydrogen to within 0·3 per cent. A quartz tube, 12 mm. internal diam., and 980 mm. long, is filled for a length of 570 mm. (starting 110 mm. from one end) with asbestos which has been impregnated with a solution of about 4 grms. of copper in nitric acid and then heated to convert the copper into oxide. The available oxygen in the copper oxide is determined by heating in hydrogen for 90 mins. and absorbing the water vapour produced, and the reduced copper is then re-converted into oxide by heating in oxygen for 45 mins. after the glow ceases. A quartz boat containing 0·2 grm. of the substance is placed in the quartz combustion tube which is supported in a combustion furnace without the usual iron trough and tiles. After passing a rapid stream of nitrogen for 20 mins., the whole layer of copper oxide is heated to the highest attainable temperature, the flow of nitrogen diminished to about 1 bubble per second, and the substance heated very gently at first, and later at the highest temperature attainable, after which the heating is continued for 20 mins. longer with a more rapid flow of nitrogen ; the water produced is absorbed by sulphuric acid and carbon dioxide by soda lime. After replacing the absorption apparatus by another absorption tube containing sulphuric acid, the copper oxide is reduced completely by heating in hydrogen for 30 mins. after the gas passes freely from the combustion tube. By subtracting the total oxygen available from the copper oxide from the sum of the quantities present in the water, carbon dioxide, and unreduced copper oxide, the oxygen derived from the sample is obtained ; the hydrogen is calculated from the quantity of water. The reduced copper is oxidised by heating in oxygen for 45 mins. after the glow ceases and is then ready for another determination.—A. S.

Nitro- and nitroso-compounds ; Volumetric determinatio of —— *by means of titanium trichloride.* H. Salvaterra Chem.-Zeit., 1914, **38**, 90—91.

KNECHT's method (see this J., 1903, 232 ; 1905, 154 is modified by the author in the following manner in orde

to render it more rapid and to make the end-point of the titration more definite. The solution of the nitro- or nitroso-compound is treated while boiling in an atmosphere of carbon dioxide with a definite excess of titanium chloride solution; after a short time, a measured quantity of methylene blue solution (standardised against the titanium chloride solution) is added, and the hot mixture is titrated with titanium chloride solution. At the end of the titration the green colouration changes sharply to yellow.

Patents.

Pyrometers; Optical ——. Siemens Bros. and Co., Ltd., London. From Siemens und Halske Akt.-Ges., Berlin. Eng. Pat. 17,927, Aug. 6, 1913.

In pyrometers of the kind in which a small incandescence lamp is arranged within the barrel of a telescope, the regulating resistance for varying the luminosity of the lamp is mounted on the telescope so that the hands need not be removed from the telescope in making an observation. Greater accuracy is also obtained by using a yellow or green screen in the eyepiece, together with a screen of tinted glass, in place of the usual red screen. The connecting socket for the leads of the lamp circuit is arranged opposite to the lamp on that side of the barrel which is the underside when the lamp-filament is in a vertical position.—A. T. L.

Extraction apparatus. H. J. Cary-Curr, Assignor to E. H. Sargent and Co., Chicago, Ill. U.S. Pat. 1,082,304, Dec. 23, 1913.

The distilling flasks of the extraction apparatus are heated by a rotatable hot plate arranged above and heated by a second electrically-heated hot plate fixed on a stand. The condenser tubes are cooled in a rotatable and adjustable tank supported on a central adjustable rod.—W. H. C.

Gases, liquids, and solids; Process for the determination of the density of ——. A. Kalähne. Ger. Pat. 268,353, May 12, 1912.

The process depends upon the fact that the frequency of the vibrations of a sounding device varies according to the density of the surrounding medium. A solid sounding device (tube, plate, bell, or the like), fixed in a holder and set in vibration either directly or by resonance in any suitable manner, is placed in the medium of which the density is to be determined, and is connected with mechanical or electromagnetic devices by which the change in the frequency of vibration can be measured and indicated. The process is specially applicable to cases in which the density of a gas or liquid may be altered by the introduction (*e.g.*, by diffusion) of another gas or liquid, for instance in controlling the purity of the gas in balloons and airships, detecting firedamp in mines, etc.—A. S.

XXIV.—MISCELLANEOUS ABSTRACTS.

Freezing mixtures containing solid carbon dioxide; The temperature of ——. A. Thiel and E. Caspar. Z. physik. Chem., 1914, 86, 257—293.

Despite conflicting statements in the literature, the equilibrium temperature of mixtures of solid carbon dioxide and ether, alcohol or acetone is, as theoretical considerations based upon the phase rule would indicate, practically identical with the subliming temperature of the pure solid phase, which has the mean value —78·35° C.

In accordance with this result the partial pressure of the solvent is negligible. Air was excluded during the experiments, and slight discrepancies of not more than +0·1° C. were traced to the effect of the hydrostatic pressure of the liquid above the thermometer bulb. The appreciably lower temperatures on record are due to the considerable absorption of heat attendant upon solution. Such temperatures would naturally be temporary. The temperatures were compared in a novel and effective manner by means of a "vapour-pressure" thermometer charged with solid carbon dioxide free from air which was solidified in the bulb beforehand: commercial carbon dioxide "snow" was found to contain considerable quantities of air.—J. R.

Biological action of chemical reagents; Cause of error in studying the ——. Presence of traces of zinc in glass. M. Javillier. Comptes rend., 1914, **158**, 140—142.

Experiments on the action of zinc compounds on the growth of *Aspergillus niger*, conducted in vessels of quartz or of Bohemian glass, showed them to have a considerable influence; but the same experiments in vessels of Jena glass showed the same effect as when zinc was present in the other cases, whether zinc had been added or not. Investigation showed that the Jena glass contained zinc, and that the small amount dissolved by the culture medium was sufficient to produce the effect of that added in the other cases.—J. T. D.

Ectoproteases; Specificity and other properties of ——. C. Fermi. Zentr. Bakter. u. Parasitenk., 1913, I. Abt., **69**, 465—474. Chem. Zentr., 1913, **2**, 1931—1933.

Experiments were made with preparations of trypsin, pepsin, and papain and of proteolytic enzymes from different bacteria, with regard to the effect of different influences and treatments on their power of decomposing albumin, serin, fibrin, casein, and gelatin respectively. By exposure to heat and to light, by filtration through porous porcelain, and by dialysis, in all case the enzymes lost their albumolytic activity first and their gelatinolytic activity last. Treatment of the enzyme preparations with acids, alkalis, salts, alkaloids and narcotics respectively gave, on the whole similar results, as also did fractional precipitation with alcohol of different concentrations, treatment with natural anti-enzymes (normal serum and albumin), and selective absorption with the corresponding proteins (gelatin, albumin, serin, and casein); and the conclusion is drawn that the proteolytic enzymes are not specific, but that if present in sufficient concentration and with the requisite degree of activity, each enzyme is capable of effecting simultaneously the hydrolysis of albumin, serin, casein, fibrin, and gelatin. When the activity and concentration of the enzyme were diminished, it became successively incapable of decomposing albumin, serin, fibrin, casein, and gelatin respectively, in the order given; hence it was possible to obtain preparations capable of decomposing only gelatin, or only casein and gelatin, but not only albumin and serin. An enzyme capable of hydrolysing albumin and serin was also always capable of hydrolysing fibrin, casein and gelatin. In the experiments on the action of chemicals on the enzymes, it was observed that phenol had a much more injurious action than thymol or toluene, especially on the serolytic, caseinolytic, and fibrinolytic activity. Hydrochloric, acetic, lactic, butyric, formic, and malic acids were less injurious than sulphuric and nitric acids. The activity of trypsin diminished more rapidly in water than in solutions of sodium carbonate or sodium chloride; of the two salts the chloride was the better preservative. The gelatinolytic power of pepsin was inhibited by hydrochloric, propionic, butyric and valeric acids, but became apparent after neutralisation. The inhibition of the secretion of proteases by bacteria in saccharine nutrient media was found to be due to the formation of lactic acid, which prevented the development of the bacteria: normal growth and secretion of protease resulted after neutralisation of the acid. The formation of lactic acid was greatest with dextrose, less with sucrose, and least with lactose. Of the different proteins, gelatin was most readily hydrolysed by chemical reagents (acids and salts), followed by fibrin, casein, serin and albumin in the order given. Fibrin was more readily attacked than casein and gelatin by a 1·5 per cent. solution of potassium hydroxide. Casein was more resistant to 75 per cent. sulphuric acid than to 25—50 per cent. lactic acid.—A. S.

Trade Report.

Russian chemical industry; Development of ——. U.S. Consular Reps., through Oil, Paint and Drug Rep., Jan. 22, 1914.

According to a report prepared by the U.S. Consul at Moscow and issued by the Bureau of Foreign and Domestic Commerce, U.S. Dept. of Commerce, the chemical industry of Russia has developed to such an extent in recent years that the annual output has now a value of about £15,500,000. For statistics relating to the production of sulphuric acid and soda, see this J., 1913, 532. The alkali works are mostly situated near the salt mines in the provinces of Perm and Viatka and in the southern part of the province of Ekaterinoslav, but the sulphuric acid factories are located in the districts where the acid is consumed. The factories near the Black Sea and the Baltic use pyrites from Asia Minor and Portugal; those nearer Moscow and on the river Volga obtain pyrites of good quality from the Urals. The high selling price of soda is due to the high freight charges from the factories which are about 700 miles distant from the places of consumption. This applies also to chloride of lime the price of which is about 6s. per 100 lb. at the works, whilst the freight charge amounts to about 50 per cent. of the selling price at Baltic ports. In 1911, the production of chloride of lime was about 54,000,000 lb. and the imports 722,000 lb. In 1912, 464,940 tons of fertilisers were imported (see also this J., 1913, 1079): this total included 187,750 tons of superphosphate and 52,110 tons of natural phosphorites, the corresponding figures for 1911 being 169,663 and 31,878 tons respectively. In 1910, only 14,000,000 lb. of superphosphate were produced in Russia, but two new factories were opened in 1912 and the industry is making considerable progress, though having to depend upon imported raw material. A deposit of phosphorite in Kostroma province was investigated by the Ministry of Agriculture and although the material was of lower grade than that found in Podolia province, it proved suitable for the manufacture of superphosphate and a factory on the Volga is now using it. The Russian production of organic dyestuffs, in the districts of Riga, Warsaw and Moscow, is based exclusively on the working up of partly manufactured foreign materials. Attention is called to the development of coke production in by-product ovens in the Donetz district (see this J., 1913, 478). There is a considerable demand for sodium sulphate, which cannot be produced in sufficient quantity in Russia owing to the impossibility of disposing of the hydrochloric acid. The natural deposits cannot be utilised t any considerable extent owing to the high freight rate due to the requirement of the railway companies that th material shall be transported in sacks. The imports o Stassfurt (potash) salts increased from 74,808 tons in 191 to 91,350 tons in 1912, and the imports of sodium nitrat rose from 34,866 tons in 1911 to 60,736 tons in 191 There is a vigorous demand and ready sale for Norwegia saltpetre (calcium nitrate). The centre of the Russia chemical industry is gradually moving towards the eas the raw materials (*e.g.* pyrites, salt and fuel) being tran ported by way of the Volga, whilst the development the railway lines crossing this river offers facilities f exportation; this region is also favourably situated f supplying the Persian and Siberian markets.—A. S.

Brazil; Position of chemical industries in ——. Chem Zeit., 1914, **38**, 57—58.

Chemical industries are, as yet, little developed in t country. The few small factories and works are confin to Rio de Janeiro, Sao Paulo and a few other ports. There is, for instance, a small sulphuric acid chamber-plant in Sao Paulo which utilises American sulphur, but which is barely able to compete with the imported product. Extensive progress is to be anticipated, however, upon the alteration of the present unfavourable conditions of government. There is a great demand for pharmaceutical preparations and cosmetics, which are all imported from Europe and N. America. Despite the high quality and abundance of the ores, the iron industry is quite undeveloped. This is largely due to the lack of suitable coal, practically all of which is imported from England; and probably no considerable advance will be made until it is found possible to utilise the cheap water power of the country in the industry. There is a fair number of breweries, except in the north. The cellulose and wood industries are neglected, although much first-class material is available. The textile industry is growing rapidly. The position of the works-chemist, in view of the cost of living, undesirable climate, and uncertain legislation, is at present unenviable.—J. R.

Books Received.

Handbuch der Arbeitsmethoden in der anorganischen Chemie. Unter Mitwirkung von Zahlreichen Chemikern und Physikern. Herausgegeben von Dr. Arthur Stähler. Privatdozent an der Universität Berlin. Dritter Band. Allgemeiner Teil. Physikochemische Bestimmungen. Erste Hälfte. Verlag von Veit and Comp. in Leipzig. 1913. Price M.22. Bound M.25.

Volume (9⅞ by 6⅜ ins.) containing 692 pages of subject matter, with 354 illustrations. The contents of this first half of the third volume, are classified as follows:—I. Weight determinations. II. Volume determinations. III. Determining the density of solid and liquid substances. IV. Determining the densities and molecular weights of gases and vapours; (A. Laboratory methods. B. Methods of extreme accuracy). V. Determination of the molecular weight of dissolved substances (osmotic methods). VI. Determination of osmotic pressures. VII. Critical points. VIII. Determination of compressibility. IX. Determining the compressibility of liquid and solid substances. X. A practical thermostat. XI. Determining surface tensions. XII. Determinations of expansion by heat. XIII. Estimating melting points. XIV. Metallography. XV. Estimation of boiling and sublimation points. XVI. Determinations of solubility, adsorption and absorption. XVII. Determination of the solubility of gases in liquids. XVIII. Viscosity. XIX. Diffusion. XX. Conduction of heat. XXI. Calorimetry. XXII. Specific heat. XXIII. Measuring thermal effects (Wärmetönungen).

Handbook of Photomicrography. By H. Lloyd Hind and W. Brough Randles. George Routledge and Sons, Limited, Broadway House, 68–74, Carter Lane, London, E.C. 1913. Price 7s. 6d. net.

Volume (8⅜ by 5⅜ ins.) containing 278 pages of subject matter, with 44 plates, comprising 8 three-colour reproductions of direct colour-photomicrographs, and 85 half-tone reproductions of photomicrographs, with further 71 text-illustrations. There is an alphabetical index of subjects. This is an account of the methods employed in photomicrography, with a description of the apparatus and processes. The subject matter is classified as follows:—I. Apparatus. II. The microscope. III. Objectives and eyepieces. IV. Lamps and illuminants. V. Condensers. VI. Experiments on illumination. VII. Low power photomicrography. VIII. Photomicrography. IX. Colour screens and colour sensitive plates. X. Exposure. XI. Oblique and dark-ground illumination. XII. Opaque objects. Metallography. XIII. Colour photomicrography. XIV. Photographic operations. XV. Applications of photomicrography. XVI. Appendix of formulæ, etc.

Die Chemie und Technologie der Natürlichen und Künstlichen Asphalte. Von Dr. Hippolyt Köhler. Zweite vollständig umgearbeitete und stark vermehrte Auflage, Herausgegeben von Dr. Hippolyt Köhler und Dr. Edmund Graefe. Verlag von Friedr. Vieweg und Sohn, Braunschweig. 1913. Price M.18. Bound, M.19.20 net.

Volume (9⅝ by 6¼ ins.) containing 491 pages of subject matter, with 259 illustrations and numerous tables. The subject matter is subdivided and classified as follows:—I. Scientific section: Introduction. I. Historial; on the occurrence, origin, and employment of asphaltum. II. Occurrence of the natural asphaltum. III. The origin of the bitumens, etc. IV. Physical and chemical properties, composition, and constituents of the asphaltums and asphaltites (hard asphaltums). V. Artificial asphaltum; origin, properties and composition (Asphaltums from coal tar; lignite tar; petroleum; from the gasification of mineral oils). II. Technical section: Introduction. VI. Asphalt ("*Stampfasphalt*") and its preparation. VII. Cast asphalt, and its preparation. VIII. Rolled asphalt; preparation and working. IX. Street-making, and use of tar for tar-macadamised roads. X. Manufacture of roofing-material (paste-board basis), roofing-paper, etc. XI. Use of roofing-paper; also lacquers, varnishes, and mixed asphaltums, etc. Electrotechnical insulating materials; rubber substitutes; cements and adhesives, etc. III. Analytical section. XIII. Physical methods for examining the natural and artificial asphaltums. XIV. Chemical methods for examining natural and artificial asphaltums. XV. Technical examination and testing of asphaltic substances. (i. and ii.) Preased asphalt and cast asphaltum. (iii.) Testing mixtures for rolled asphalt. (iv.) Roofing paper, boards; insulating plates; etc. (v.) Tars, cements, adhesives, wood cements, etc.

Die Industrie der Cyanverbindungen; Ihre Entwickelung und ihr Gegenwärtiger Stand. Von Dr. Hippolyt Köhler, Direktor der Rütgerswerke-Aktiengesellschaft, Berlin. Verlag von Friedr. Vieweg und Sohn, Braunschweig. 1914. Price M.8. Bound M.9 net.

Volume (9⅝ by 6¼ ins.) containing 188 pages of subject matter, with 30 illustrations, and alphabetical indexes of names and subjects. The text is subdivided and classified as follows:—I. Scientific section: Chemistry of cyanogen and cyanogen compounds. II. Technical section: II. Manufacture of cyanogen compounds from animal deposits and remains, and products of dry distillation. III. Obtaining cyanogen compounds from atmospheric nitrogen. IV. Cyanogen compounds from ammoniacal nitrogen. V. Preparation of various cyanogen compounds from sulphocyanides and ferrocyanides, etc. III. Analytical section: VI. Testing and investigating the cyanogen compounds. (i.) Qualitative and quantitative analysis of the cyanogen compounds. (ii.) Testing and investigating the raw materials. (iii.) Testing the residual gas-purifying materials of the gas works. (iv.) Cyanide mud and wash liquors. (v.) Testing and examining the final products.

PROF. W. R. HODGKINSON IN THE CHAIR.

OXYGEN AND METALLIC ANTIMONY IN CRUDE ANTIMONY.

BY W. R. SCHOELLER, PH.D.

In a previous paper read before this Section (this J., 1913, 260) I have shown that the percentage of sulphur in crude antimony was much lower than that corresponding to the formula Sb_2S_3, and that the result of the complete analysis of crude disclosed a more or less considerable deficiency; this was ascribed to the presence of oxygen, and the assumption supported by the observation that crude, unlike stibnite, was partly dissolved by cold solutions of sodium bitartrate. The present investigation was undertaken with a view to obtaining more convincing evidence of the presence of oxygen.

I. *Analysis of the material.*—The material experimented upon (Hu-nan crude) was crushed to pass a 90-mesh and analysed like the previous samples. The figures show a shortage of over 3 per cent., with low sulphur and unusually high antimony content:—

	per cent.	
Antimony	73·56	
Sulphur	22·45	As, Zn: traces.
Iron	0·70	Cu, Pb, Ag not determined.
Insoluble	0·05	
	96·76	

II. *Determination of oxygen.*—Oxygen was next tested for by fusing the material in a current of hydrogen sulphide. Hydrogen reduces both antimony oxide and sulphide to metal, whereas hydrogen sulphide acts only upon the oxide, thus:—$Sb_2O_3+3H_2S=Sb_2S_3+3H_2O$. Crude antimony containing oxide would thus increase in weight, and give off water.

The sample was dried for two hours at 107° C. and weighed out into a bulb tube connected at one end with three calcium chloride tubes for drying the hydrogen sulphide, and at the other with a condenser and a calcium chloride tube for collecting the water. After the air had been displaced from the apparatus the crude was gently heated, when water soon began to condense. The heat was increased until the mass had fused. It was then left to cool under hydrogen sulphide which was displaced by air before weighing. In this way 3·18 per cent. of oxygen was found, which accounts for the deficiency as 96·76 + 3·18 = 99·94. The residue showed an increase in weight of 3·53 per cent. and was found to consist of nearly pure sulphide: antimony 71·13 per cent.; sulphur 27·56 per cent.; iron and insoluble 0·73 per cent.; total 99·42 per cent. The presence of oxygen in Chinese crude is thus placed beyond doubt.

III. *Action of bitartrate.*—The original crude and the product obtained by fusion under hydrogen sulphide were tested as to their behaviour towards cold sodium bitartrate solution of the same strength as the one previously used. After 20 hours' digestion the following quantities of antimony were dissolved:—Original crude, 8·72 per cent.; fused sulphide, 0·89 per cent. The result of the replacement of oxygen by sulphur is the comparative insolubility of the fusion product.

IV. *Antimonious oxide is present in crude.*—The amount of oxygen found, viz., 3·18 per cent., is equivalent to 15·90 per cent. of antimony in the form of trioxide. That the lowest oxide is present in crude was proved by the following three tests in which the total antimony and that existing as trioxide were estimated in aliquot portions of solution, the former by precipitation with hydrogen sulphide, solution of the sulphide in sulphuric acid and titration with permanganate, the latter by addition of sodium bicarbonate and titration with iodine.

1. It was shown above (III.) that cold bitartrate solution dissolved 8·72 per cent. of antimony. The estimation of the antimonious oxide in the same solution gave 8·35 per cent. of metal.

2. An attempt was made to extract the whole of the oxide by boiling 5 grms. of crude with 100 c.c. of 7 per cent. tartaric acid solution for 45 minutes. The determination of the total and trivalent antimony in the filtrate gave: Total antimony, 10·69 per cent.; antimony as Sb_2O_3, 10·81 per cent. The residue from this extraction was not pure sulphide, as it assayed 72·40 per cent. of antimony.

3. The preceding test was carried out on 90-mesh material. A sample was now ground down to extreme fineness, and 1·25 grm. boiled with 100 c.c. of 10 per cent. tartaric acid for 45 minutes. The filtrate contained 13·29 per cent. of antimony, against 12·88 per cent. determined by iodine titration.

The last experiment shows that at least four-fifths of the total oxygen is present as trioxide; whether the remaining fifth exists partly as pentoxide could not be ascertained, as the test for pentoxide fails when sulphide is also present. I think, however, it is safe to assume that practically the whole of the oxygen is combined with antimony in the form of trioxide, because an excess of oxygen is necessary for the formation of the pentoxide. The experiments further show that part of the oxide is easily soluble in the cold, while a small proportion remains insoluble even on boiling and after most thorough crushing. As a possible explanation for this behaviour I would suggest that the bulk of the oxide is present in the free state, either dissolved in, or intermixed with, the sulphide, while the remainder has combined with the sulphide to form an oxysulphide. I shall have an opportunity later on of referring again to this matter. (VI.)

V.—*Presence of metallic antimony in crude.*—By recasting the complete analysis, the composition of the sample of crude is represented by the following figure:—

Analysis.		Calculated composition.		Calculated increase after fusion under H_2S.	
	per cent.		per cent.		per cent.
Insol.	0·05	Insol. ..	0·05	Insol.	0·05
Fe	0·70	Fe_2	1·10	FeS	1·10
S	22·45	SbS_3 ..	77·17	Sb_2S_3	77·17
O	3·18	SbO_3 ..	19·08	Sb_2S_3	22·27
Sb	73·56	Excess Sb	2·54	Sb_2S_3	3·55
Total ..	99·94		99·94		104·14

Apparently 2·54 per cent. of antimony remains uncombined. If these figures are correct, the metal should remain undissolved when crude is treated with hydrochloric acid. This was verified by experiment, by extracting powdered crude repeatedly with hot strong hydrochloric acid. The residue was washed with water and alcohol, and dried at low temperature; it showed the characteristic light-grey colour of powdered regulus, easily distinguishable from the bluish tinge of antimony sulphide: 0·5 grm. was assayed for antimony, giving 97·17 per cent. of metal: this is conclusive proof of the presence of regulus in crude antimony. The separation of the metal from the sulphide was also accomplished by caustic alkali which dissolves the latter, as well as the oxide. It is no doubt due to the presence of metallic antimony in the crude that its increase in weight in the oxygen determination is 0·61 per cent. lower than the calculated increase (see table): for, while antimony oxide is easily converted into sulphide when heated in a current of hydrogen sulphide, the metal itself combines less readily under the same conditions. This is also borne out by the low sulphur content (27·56) of the fused product and its slight solubility in bitartrate solution which is known to have a strong solvent action on regulus. (Cf. my previous paper, *loc. cit.*)

VI. *Glass of antimony.*—A fragment of black glassy crust, sometimes found on the surface of ingots of crude, was also examined. The glass is soft and heavy, and on crushing yields a powder the colour of which is more violet than that of ferric oxide. The quantity at my disposal was not sufficient for a thorough investigation, and its composition as far as ascertained is given by the following figures: Soluble antimony 73·28 per cent.; antimony tetroxide and insoluble 1·23 per cent.; sulphur 16·18 per cent.; oxygen 6·32 per cent.; iron 1·35 per cent.; total 98·36 per cent. Part of the soluble antimony was found to be present in the metallic state, remaining as a grey residue insoluble in hydrochloric acid but soluble in *aqua regia*; the amount of metal appeared to be at least as large as that observed in crude. The colourless residue from the *aqua regia* treatment consisted chiefly of antimony tetroxide. The determination of oxygen was carried out as described for crude, the substance showing an increase in weight of 6·70 per cent. after fusion.

Judging from the behaviour of crude towards bitartrate solution and the high oxygen content of glass of antimony, one would expect the latter to be strongly attacked by that solvent, but the reverse was found to be the case: after 18 hours' contact in the cold, the dissolved antimony amounted to no more than 1·31 per cent.; this was present as trioxide. The oxysulphide which is the chief constituent of glass of antimony is thus insoluble in bitartrate, and this may account for the incomplete extraction ot the oxide from crude, by assuming that the latter contains a subordinate quantity of oxysulphide. (IV.) Other tests bearing on this point could not be carried out for want of material.

VII. *Conclusions.*—The results of the above experiments prove that Chinese crude antimony contains a considerable proportion of antimonious oxide together with a less important amount of metallic antimony. These facts are in contradiction with the generally accepted notion that crude antimony obtained by liquation is pure unaltered sulphide, as no mention is made in the standard books on metallurgy and chemistry of a possible contamination with oxide due to absorption of oxygen by the molten sulphide. No doubt in an inert atmosphere the latter melts without undergoing decomposition, and a liquation process in which air is excluded will yield a sulphide free from oxide, but this is difficult to attain in practice. For this reason liquation in vertical tubes should give a purer product than in reverberatory furnaces. In the type of furnace used in China, the molten sulphide discharges continuously into a cavity which is only separated from the outside air by a loosely fitting cover, where the material remains in the liquid state until ladled into moulds two hours after the beginning of the operation. During this time absorption of oxygen takes place, which sometimes leads to the formation of a film or crust of glass of antimony on the surface of the crude. The liquation residue (which was described in my previous paper) is of course subject to oxidation like the crude itself.

It seems strange that the absorption of oxygen by, and consequent oxidation of, fused antimony sulphide should not be mentioned in modern technical literature, all the more so because the effect of the fusion was known long before the establishment of chemistry as an exact science. The iatro-chemists, with whom antimony compounds were great favourites on account of their vigorous physiological action, were well acquainted with the fact that stibnite undergoes a change on being fused, though they were unable to assign a cause to it. They taught that the natural sulphide, "on account of the Regulus being corrected by the Sulphur, is not only safe, but in many cases a medicine ot great service; *that by simple fusion, it acquires a degree of malignity*; . . . that equal parts of Antimony (*i.e.*, stibnite) and Nitre, melted together, yield a virulent mass."[*] In other words, the emetic properties become more pronounced as the solubility increases with the progressive replacement of sulphur by oxygen. Decoctions of crude antimony appear to have been used as diaphoretics,[*] and the following experiment shows that it is actually attacked by water: 1 grm. of 90-mesh material was boiled with 100 c.c. of distilled water for five minutes. The acidified filtrate treated with hydrogen sulphide gave a stable fluorescent solution of colloidal antimony sulphide. This was coagulated by adding salt and passing more gas through the boiling solution: 1·66 per cent. of soluble antimony was found.

The simultaneous presence of sulphide, oxide, and metal in crude seems difficult to explain if we accept the statement, found in most books, that sulphido and oxide of antimony, unlike the corresponding lead or copper compounds, are incapable of reacting upon one another with formation of metal and sulphur dioxide, but fuse together to a glass of oxysulphide. The fact that metallic antimony occurs in crude makes it more than probable that the reaction $Sb_2S_3+2Sb_2O_3=6Sb+3SO_2$ takes place, though to a very limited extent. I have found at least one statement, reproduced in Bloxam's Chemistry,[†] to the effect that the fusing together of oxide and sulphide results in the formation of metal, though the reaction is represented as taking place between sulphide and tetroxide. As regards the formation of glass of antimony, this does not, apparently, take place when the relative amount of oxide falls below a certain minimum: for the ratio of oxide to sulphide in the glass of antimony is very nearly 1 : 1·4, whereas in the case or the crude under examination it is almost exactly 1 : 4, and this material retains the crystalline structure and physical properties of antimony sulphide, while unlike glass of antimony it gives up most of its oxide content to bitartrate or tartaric acid solution.

Within a few years of opening up her mineral resources, China has become the foremost producer of antimony and especially of crude. The latter has been shown to be a more complex product than was generally supposed, and this knowledge may be of practical interest. Thus the purchase and sale of crude is not done on a certificate of assay, on the assumption that the article is pure sulphide containing 70—71 per cent. of antimony. Not only does this percentage vary within wider limits, but it may also be found desirable to ascertain the amount of metallic antimony and oxide in the material. In the preparation of antimonious chloride and other salts from crude the presence of metal is objectionable because it remains insoluble in hydrochloric acid, whereas it is rather advantageous in smelting for regulus by the precipitation method. Finally, the accidental formation of metallic antimony in the liquation process raises an interesting question, namely, whether it would be possible to convert the sulphide into metal by applying bessemerizing in the production of regulus from sulphide ores.

In conclusion I desire to thank Messrs. G. T. Holloway and Co., Ltd., for their courtesy in permitting the publication of this investigation which was carried out in their laboratory.

THE ESTIMATION OF ZINC IN COINAGE BRONZE BY VOLATILISATION.

BY T. K. ROSE, A.R.S.M., D.SC.,
Chemist and Assayer of the Mint.

This is not a new method, but a very old one, the origin of which has been lost. A similar method for zinc ores is referred to by Percy[‡] as having been used "formerly" and he states that the process is "still" (*i.e.*, in 1861) "occasionally resorted to by some assayers." Percy gives the reasons for regarding the method as untrustworthy in the case of ores. The method was unknown to Agricola (1556), Ercker and Sir John Petty (1686), and is not mentioned in Thenard's Chemical Analysis, 1818, or in Vauquelin's Manuel de l'Essayeur, 1836. It is described by Makins,[§] who says that "at the Mint, the bronze, mixed with exactly twice its weight of pure tin, is enclosed in a porous carbon pot, luted up in a crucible and strongly heated in an assay muffle for eight hours." According to tradition at the Mint the charge was embedded in anthracite in a wind furnace and left all night. The method was allowed to pass out of use in 1870, probably because the temperature was often too low to be efficacious. It is also possible that the use of proof assays in this connection was not understood. The addition of tin appears to be objectionable. I tested the process in 1913 and found it trustworthy and useful, if due precautions are observed.

[‡] Metallurgy: Fuel, Copper, Zinc, &c., 1861, p. 956.

[§] Manual of Metallurgy, 2nd Edn., 1873, p. 524.

The method consists simply in heating the bronze in a carbon crucible, driving off the zinc by volatilisation and weighing the residue. The old crucibles are still used. They are made of gas carbon and are hexagonal prisms outside, about 2·2 cm. across and 2·2 cm. in height. A receptacle for the bronze is hollowed out inside, 1·1 cm. in diam. and 1·5 cm. deep, and is provided with a closely-fitting lid. They can be used many times before being worn out.

The crucibles each containing 1 gram of bronze are placed close together inside a salamander crucible and completely covered by powdered charcoal. The cover pot is then strongly heated for two hours in an ordinary gas injector furnace. The final temperature by thermocouple was found to be 1375°, but probably higher temperatures would be equally good. The boiling point of zinc is 905·7°.* A number of the carbon crucibles are disposed in a ring inside the large pot. The number in a ring at the Royal Mint is eight, but a second ring of eight can be placed above, making 16 determinations, of which four are check assays made on pieces of trial plate of known composition. The pot is rotated through 90° every 15 minutes to ensure uniform heating. When the cover pot and its contents are cold the carbon crucibles are taken out, and the bronze residue is cleaned by brushing and weighed. A cover pot is necessary in a gas furnace as otherwise the carbon crucibles burn completely away. The high temperature is absolutely necessary. Attempts to drive off the zinc in a gas assay-muffle urged to the highest attainable temperature, about 1200°, proved unavailing. In two hours in the muffle furnace, the loss of weight was insignificant, only about one-tenth of the 1 per cent. of zinc present being expelled.

The use of check or proof assay pieces is necessary, as the loss varies considerably with the temperature. Coinage bronze contains copper 95 per cent, tin 4 per cent, and zinc 1 per cent., and the usual loss by volatilisation is about 1·2 per cent. The difference between two duplicate assays varies from 0 to 0·1 per cent., the average difference being about 0·02 to 0·03 per cent.

It is obvious that accuracy depends on the whole charge being uniformly heated. This work is successfully done at the Mint by Mr. W. E. Jenkins, who has exercised much care and skill in overcoming the difficulties in the furnace work.

The following are specimens of results which have been obtained :—

Charge 1.

Bronze bar. Composition by ordinary analysis.

	per cent.
Zinc	1·055
Iron	0·08
Tin	4·07
Copper	94·70
	99·905

Loss by volatilisation : (1) 1·160 per cent. ; (2) 1·155 per cent. ; (3) 1·170 per cent. ; (4) 1·165 per cent. ; Mean, 1·162 per cent.

The residues contained 0·03 per cent. of zinc. It is clear, therefore, that 0·13 per cent. of copper and tin have been volatilised.

Charge 2.

	Loss per cent. by volatilisation.	Corrected results.
	per cent.	per cent.
Trial plate (Cu 95, Sn 4, Za 1·00)	1·235 1·215	1·01 0·99
Penny blank	1·185 1·17	·96 ·945
Another blank	1·14 1·20	·92 ·98

Charge 3.

	Loss per cent. by volatilisation.	Corrected results.
Trial plate	1·15 1·15	1·00 1·00
Penny blank	1·10 1·065	0·95 0·915
Another	0·98 0·91	0·83 0·79
Bronze bar, containing about 1·2 per cent. zinc	1·31 1·355	1·16 1·205

Although most of the determinations have been made on coinage bronze, there seems to be no reason why the method should not be applicable to brasses and bronzes containing any proportion of zinc, if proper precautions are taken. The volatilisation of zinc causes volatilisation of copper, and if much zinc is present it is better not to hasten the operation until most of the zinc has been boiled off. The zinc is soon reduced to about 5 per cent. at a temperature of 1000°.

The following are losses of copper and tin with different proportions of zinc :—

Alloy.	Loss by volatilisation.	Loss of copper and tin by volatilisation.	
		On whole alloy.	On copper and tin.
	per cent.	per cent.	per cent.
Cu 96 Sn 4 Za 0	0·14	0·14	0·14
Cu 95 Sn 4 Zn 1	1·22	0·22	0·22
Cu 92·35 Zn 7·26	7·69	0·43	0·48
Cu 8·75 Za 91·25	91·55	0·30	3·44

Duplicate determinations are in about as close agreement with high percentages of zinc as with low ones, and by using pieces of the one per cent. trial plate as check assays, results from brasses are obtained which are only about 0·1 to 0·2 per cent. too high in zinc. With suitable trial plates correct results should be obtainable.

The sources of error in the determination are as follows :

(1) The presence of volatile constituents other than zinc, such as cadmium. These would all be reckoned as zinc. In coinage bronze, however, there is only about 0·1 per cent. of impurities other than copper, tin and zinc and part of this is oxygen, and iron.

(2) The presence of oxygen in the alloy. This is in the form of oxide of zinc. The oxygen is almost entirely removed during the heating and would be reckoned as zinc. The amount is trifling in coinage bronze. A large addition of zinc oxide to the assay piece makes practically no difference to the result all the zinc being reduced and volatilised.

(3) The retention of zinc in the residual metal. This has been found to be about 0·03 per cent., under ordinary conditions, when the loss on heating had been about 0·2 per cent. more than the zinc present. The amount of 0·03 per cent. of zinc is retained whatever had been the original amount of zinc present. The use of check assays removes this error.

(4) The loss of copper and tin by volatilisation. This usually amounts to about 0·2 per cent., and is determined and allowed for by means of the check assays.

(5) The adhesion of dirt to the residual metal. This appears to be sulphide of copper, due no doubt to the entry of gases into the cover pot. The results are defective and must be rejected. The defect seldom occurs.

The advantage of the method is merely the saving of time. The errors may reach about 0·03 per cent., or about the same as may be expected in the gravimetric or volumetric processes. The time saved is very great, as an assistant looks after the heating and cleans the buttons. The assayer merely weighs the metal in and out, the time for a duplicate determination being about five minutes, including the necessary entering of the result in the books.

---

* Heycock and Lamplugh, Proc. Chem. Soc., 1912, **28**, 3.

Discussion.

The Chairman made some remarks as to the eminently satisfactory character of the operation and on the boiling-point of zinc.

Mr. Edward Gardner asked what weight sample was taken. He also asked whether Dr. Rose had had any experience of what he termed artificial carbon crucibles, made in the same way, and of the same materials as electric light carbons. He saw that the crucible used by Dr. Rose was made from gas retort carbon, and he had had some experience with crucibles made from both materials.

Mr. Arnold Philip asked how exactly the correction was applied from the trial plate to the actual sample under test. Dr. Rose had said he had examined other alloys. In his own practice, he rather shrank from making determinations of zinc: even with the most careful work such determinations tended to come out high; separation of the sulphide was always avoided if possible; the best method they found was to precipitate the carbonate, but then the results were high even with the most favourable and careful work. At Portsmouth they were specially interested in determining zinc in gun metals, containing about 2 per cent. of zinc, and a really rapid method for determining it would be very useful in checking other results. The present practice was to determine very carefully everything else except the zinc. Would Dr. Rose explain exactly how the correction for the trial plates was applied and whether he had made any determinations on alloys of the character of the Admiralty gun metal which contained 2 per cent. of zinc, 88 per cent. of copper, and 10 per cent. of tin? He was also surprised to hear that Dr. Rose did not lay very great stress on the loss due to volatilisation of tin. He, himself, would have imagined that tin would have been more readily volatile than copper. About a year or so ago Professor Turner had described the determination of zinc and other volatile metals by heating alloys *in vacuo*: that, of course, must necessitate very special apparatus and possibly difficulties, which this extraordinarily simple method Dr. Rose had described did not require.

The Chairman said he thought Professor Turner's experiments were to see if all the zinc could be driven out of different kinds of brasses by heating in a current of hydrogen. He did not know it was intended to be a quantitative operation, but simply to find whether zinc could be driven out. He thought it was mainly a question as to whether the zinc was retained as a compound or as a common mixture.

Dr. Rose, in reply, said that the weight of alloy taken for the determination was one gramme. The hard gas carbon crucibles in use were very durable, and did not appear to be altered in any way after being used many times. None had been worn out yet. He had had no experience with soft carbon crucibles, but he should have expected that any carbon crucible would do. He was interested to hear about Mr. Philip's problem. In preparing a trial plate at the Mint, they melted together 95 parts of copper, 4 of tin, and 1 of zinc, cast an ingot, rolled it out, and analysed it carefully by the usual methods. They had made one trial plate, by good luck, that contained exactly 1·00 per cent. of zinc, but what the exact composition was did not matter, provided that it was accurately known. As an example of the use of the trial plate, the author quoted the following results:—

Charge D. Nov. 24, 1913.

Loss of weight on the trial plate, duplicate results, 1·235 per cent. and 1·215 per cent.: mean loss 1·225 per cent., when the zinc present was 1·00 per cent. Penny blank: loss of weight, 1·185 per cent. and 1·17 per cent.; mean loss 1·177 per cent. The percentage of zinc in that penny was obtained by deducting 0·225 per cent. (the loss of copper and tin in the trial plate determinations) from the loss of weight in the penny assay pieces. Deducting 0·225 per cent. from 1·177 per cent., they obtained as the result 0·95 per cent. of zinc in the penny. Another penny gave losses of 1·14 per cent. and 1·20 per cent. Deducting 0·225 from the mean of these figures, they obtained 0·945 per cent. of zinc as the amount contained in the second penny, or as individual determinations, 0·915 per cent. and 0·975 per cent. generally the difference between duplicate results was less than that. He would be glad to try Mr. Philip's two per cent. alloy if he would send him a piece. His impression was that tin did not volatilise any more easily than copper, and that the loss on 88 per cent. of copper and 10 per cent. tin would not be very different from the loss on 95 copper and 4 of tin; it would be of the same order. Consequently, if a trial plate was made up of that composition, the error due to the difference between duplicate results would probably be no greater in that gun metal than with their coinage bronze. As he had stated in the paper, he considered that the error in the reported result was not more than ±0·05 per cent. when a trial plate was used.

NICKEL TANNATES.

BY PURAN SINGH.
Forest Research Institute, Dehra Dun, India.

I. While working with nickel hydroxide as a substitute for hide powder in tannin estimation, it was considered of interest to examine the nature of the salts yielded by the interaction of nickel hydroxide and tannic acid. It seems that two different salts of nickel with tannic acid are formed according to the conditions of precipitation. By precipitating the solution of nickel hydroxide in ammonium salts by adding a tannic acid solution in the presence of an excess of nickel hydroxide, a salt with higher content of NiO is formed, while the salt precipitated in presence of an excess of tannic acid by adding to a tannic acid solution the solution of nickel hydroxide in ammonium salts, has about one-third the NiO content of the other salt.

It is extremely difficult to prepare tannic acid salts of standard purity for the salts are all amorphous, and there is no suitable solvent for them for subsequent purification. I have only been able to judge of their purity by observing the nickel content of the salts on incineration. Thus their comparative purity has only been apparent to me after the nickel contents of the two salts on repeated incinerations have been uniform.

II. Nickel hydroxide freshly precipitated and washed free of alkali and sulphates was dissolved in ammonium chloride. To this nickel hydroxide solution which was kept stirred, a solution of Kahlbaum's "extra pure" tannic acid was added, leaving an excess of nickel hydroxide solution. The salt when freshly precipitated was greenish white which slowly changed into deep brown. On drying it became blackish brown. It was insoluble in water and other solvents, dissolving only in strong alkalis and in strong solution of tannic acid with evident decomposition. The salt was washed thoroughly by decantation till it was free from chlorides.

The well-washed salt was first dried over sulphuric acid *in vacuo*, it was then incinerated and its moisture determined at the same time, this latter being determined at 100° C. This salt was prepared on different occasions, at times after the lapse of months, and the following are the results of incinerations:—Percentages of NiO found, 28·15, 28·50, 28·40, 27·94, 28·67.

III. In a second series of experiments, the nickel hydroxide solution was added to the tannic acid solution and the salt was precipitated in the presence of some excess of tannic acid. The salt was almost white when freshly precipitated but slowly acquired a slight greenish-yellow tinge. Unlike the salt mentioned in I., this salt changes its colour but little and that only superficially. Owing to the presence of tannin, it was slightly soluble in water. It was also washed by decantation till free from chlorides. The results of incineration done on different occasions were:—NiO, 7·44, 8·17, 8·94, 8·96, 9·85, 10·0 per cent.

IV. The same as in II., but instead of using nicke hydroxide dissolved in ammonium chloride, the sam dissolved in ammonium acetate was used. Two trial were made and the washing of the salt was considere defective till it gave a similar NiO content as obtain in II. The results of the two trials were :—NiO, 23·76 and 28·29 per cent.

V. The same as in III., only the nickel hydroxide solution used in IV. was employed in this case also. The results of the two trials were :—NiO, 8·61 and 10·12 per cent.

VI. In this case nickel hydroxide was dissolved in liquor ammoniæ fort. and tannic acid solution was added in excess. Owing to the presence of excess of ammonia, the salt precipitated was completedly dissolved. The solution became dark brown out of which a deep brown salt was precipitated by adding an excess of alcohol. The precipitate was filtered and washed completely with alcohol and dried at 100° C. till constant. On incineration this salt gave 10·25 per cent. of NiO.

Though it has not been possible to obtain absolutely pure salts, it can safely be said from the results obtained that only two theoretical salts have been formed. The one with lower nickel content is the normal salt represented by the following equation :—

$$(C_{14}H_{10}O_9)_2+Ni(OH)_2=(C_{14}H_9O_9)_2Ni+2H_2O.$$

According to this formula the calculated NiO in this salt is 10·69. The salts prepared on different occasions have towards the end of these experiments yielded 10 per cent. NiO.

The second salt with the higher nickel content comes nearest to the empirical formula $Ni_3(C_{14}H_7O_9)_2$. The percentage of NiO required by this formula is 27·53. The average result of the incinerations mentioned in II. is 28·33 per cent. This percentage is also supported by the final result given in IV., viz., 28·29.

Discussion.

Professor Donnan thought the author had not brought much evidence forward to show that the amorphous substances which he analysed were really definite and pure chemical compounds, and not mixtures or "adsorption-complexes."

Dr. E. K. Rideal said he had found they could not get any definite compound by the action of an iron salt on tannic acid, although he had tried for a long time. The exact composition of tannic acid was unknown; indeed, according to some investigators chemically pure tannin contained at least three distinct acids. When in solution, tannin was present, partly, at any rate, as a colloid, as was evident from the hide powder test.

THE OXYGEN CONTENT OF THE GASES FROM ROASTING PYRITES.

BY LEWIS T. WRIGHT.

MR. T. W. LOVIBOND IN THE CHAIR.

SOME OF THE TERNARY ALLOYS OF IRON, CARBON AND PHOSPHORUS.

BY J. E. STEAD, D.SC., D.MET., F.R.S., ETC

Introduction.

Part I.

Note.—A Bibliography of the researches referred to is given in Appendix III.

In order to understand intelligently the alloys of iron, carbon and phosphorus, it will be necessary to allude briefly to the binary alloys iron-carbon and iron-phosphorus.

Since my original work on iron and phosphorus was published, together with notes on the ternary alloys Fe, Fe_3C, Fe_3P, much careful work has been done, mainly in Germany. Saklatwalla repeated my own experiments on the alloys of iron and phosphorus and supplemented them with an equilibrium diagram.

Iron and phosphorus—binary alloys.

First.—Iron and iron phosphide form solid solutions (see Appendix I.) in all proportions up to the point of saturation when about 1·7 per cent. phosphorus and 98·3 per cent. iron, or 10·9 per cent. phosphide of iron (Fe_3P) and 89·1 per cent. iron are associated. It is, however, only by long continued heating at temperatures above 1000° C. of rapidly solidified alloys containing 1·7 per cent. phosphorus that saturation can be effected.

Alloys containing between 1 per cent. and 1·7 per cent. phosphorus, if cast in small moulds, will not be homogeneous but will consist of an aggregate of crystal grains enveloped by a eutectic. The centre portions of the crystals will contain relatively less phosphorus than the outer parts, the proportion increasing gradually with the distance from the centres of the crystals and are saturated at the points where they meet the eutectic envelopes.

By long continued heating of these eutectic enveloped alloys at temperatures just above the fusion point of the eutectic, the phosphide will diffuse towards the centre of the crystals and eventually the whole mass will consist of homogeneous crystals which will meet without there being any intervening eutectic.

On annealing alloys containing 2 per cent. phosphorus and 0·12 per cent. carbon in ore so as to remove the carbon, or even in charcoal at temperatures below 1000° C. much of the phosphide will separate and will be found in the cold alloy, apparently along the cleavages of the iron crystals.

Second.—When the proportions of phosphide and iron saturated with phosphide are as given below :—

			Constitutional Composition.
Iron saturated with phosphide	38·6	=	0·65 per cent. phosphorus
Free iron phosphide	61·4	=	9·55 ,, ,,
	100·0		10·20 ,, ,,

the mixture will be the binary eutectic which has only one freezing point at about 1000° C., and when cold is composed of cells of iron saturated with phosphorus in a mass of iron phosphide.

In very grey pig irons containing little manganese and much silicon the phosphorus always exists in the binary eutectic derived by decomposition of the ternary eutectic which is the last portion to freeze in all phosphorettic pig irons, whether grey or white in fracture. (Photo 1.)

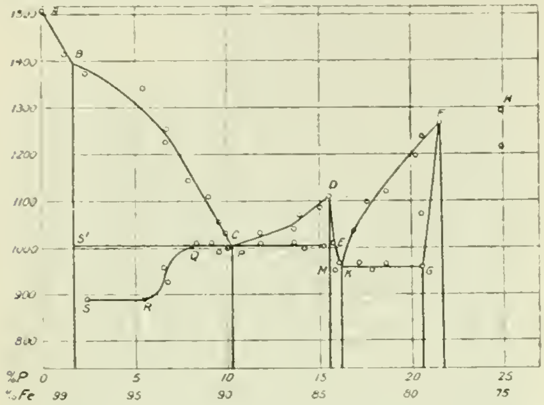
It not infrequently happens that the cell substance of the binary eutectic in grey pig iron consists of pearlite. In such cases it is certain that at the point of solidification the cell substance can contain little phosphide in solid solution and must consist of austenite. Whether phosphide diffuses into the cells in cooling down cannot be determined, but judging from the way austenite resists the diffusion of phosphide into it, it may be accepted that until the carbide separates at Ar. 1-2-3 (700° C.) it would not, and at lower temperatures than 700° C. the diffusion would be exceedingly slow.

The eutectic containing pearlite cells, although three elements are present, would at the point of solidification contain only two constituents, viz., phosphide, and solid solution of carbide in iron, and must therefore be considered as binary, not ternary. If the carbide entirely replaced the phosphide in the cell substance it would probably have the following composition, viz. :—

Free iron phosphide	61·4 per cent.
Austenite	38·6=0·35 carbon
	100·0
Phosphorus about	9·55 per cent.

All the alloys containing between 1·7 per cent. and 10·2 per cent. contain crystallites of iron more or less saturated with phosphide of iron which crystallise out in advance during the solidification and are found in the alloy, when cold, embedded in the eutectic containing 10·2 phosphorus.

The diagram slightly altered from that drawn by Saklatwalla indicates this and other points of interest.



The remarkable feature in this diagram is the apparent erratic freezing point of the eutectic along the line SRQ. Commenting on this, the author suggests "that this strange behaviour may be due to the existence of a definite phosphide corresponding to somewhat between 6·5 per cent. and 8 per cent. phosphorus, and that what freezes at below 900° C. may have a different composition to that which freezes at about 1000° C." As an alternative he suggests that it is of the same composition along the whole line, but undergoes a thermal change at the lower temperature.

My own more recent trials have shown that the eutectic, whether present in minute quantity or in greater amount, as in the alloys containing 2 per cent. and 9 per cent. respectively, melt at the same temperature and that the line SRQ on the melting point diagram should be straight. A new line has been introduced to the diagram showing this. Whether there is a thermal change, as suggested, I have no proof, negative or positive. It seems, however improbable, that there is a definite chemical substance with less phosphorus than is represented by Fe_3P.

Third.—When the alloy is of the composition of Fe_3P, it contains 15·56 per cent. phosphorus and consists of homogeneous crystals of iron phosphide. (Photo 2.)

Fourth.—With increasing proportions of phosphorus, according to Saklatwalla, a second eutectic appears consisting of Fe_3P and Fe_2P containing about 16 per cent. phosphorus freezing at 980° C.

Fifth.—The mixtures containing between 15·56 per cent. phosphorus and 24·6 per cent. (Fe_2P) consist of crystals of Fe_3P in the second eutectic. I had previously isolated the compound Fe_2P, but the second eutectic escaped my notice.

Sixth.—Some of the properties of the compounds Fe_3P and Fe_2P have been studied. The former is soluble in HCl and HNO_3 and is strongly attracted by the magnet. It is hard and brittle and appears to crystallise in rhombic prisms. The compound Fe_2P is only with difficulty soluble in nitro hydrochloric acid and cannot be attracted by an ordinary magnet.

Brinell hardness.

The hardness of pure Fe_3P is under that of quartz, and it is not so hard as Fe_3C. It is too brittle to test by Brinell's method. Saklatwalla says it corresponds to No. 6 on Mohr's scale, or of the hardness of felspar.

The hardness of saturated solid solutions of phosphide of iron in iron increases with the phosphorus content by about 1·3 points for each 0·01 per cent. phosphorus. The resistance of solid solutions of phosphorus in iron to corrosion is proportional to the amount of phosphide present.

Seventh.—Iron containing phosphide in solid solution is more resistant to the attack of etching reagents than pure ferrite or iron containing less phosphide in solid solution. It is more rapidly oxidised on heating—a property which enables one to ascertain whether or not the phosphorus is evenly distributed in commercially produced iron and steel, for when polished specimens are heated to about 300° C. the phosphorus rich portions become coloured blue by the time the purer have assumed a red or brown tint. This method of identification has for convenience been called "heat tinting."

Iron and carbon binary alloys.

A.—Iron and carbon combine to form a definite chemical compound which may be represented by the expression Fe_3C. It contains :—

Iron	93·334 per cent.
Carbon	6·666 ,,
	100·000 per cent

It is present in all annealed steels and may be isolated by dissolving out the associated free iron.

It may be produced in an almost pure state by the action of certain carbonaceous gases on pure iron when they are heated together at temperatures below 700° C.

B.—Solid iron carbide dissolves in solid iron, or, expressed differently, the two bodies interdiffuse to form what are described as solid solutions (see Appendix I.). They are saturated, the one with the other, at about 1130° C. when about 30 per cent. carbide and 70 per cent. iron saturated with 2 per cent. carbon are together. On cooling from 1130° C. this saturated solid solution gradually parts with carbide and as the temperature falls the separated carbide appears as plates or is crystallised on the cell walls.

The remaining solid solution, just above 700° C., is the eutectoid of iron and carbon, and contains :—

Iron	86·5 per cent.	
Carbide	13·5 ,,	= 0·90 per cent. carbon
	100·0 per cent.	

On cooling further a critical change occurs. Much heat is absorbed, as is indicated by a long arrest of temperature at the point called Ar. 1-2-3, and during this arrest the carbide and iron completely separate from each other and appear in the alloy when cold in the form of laminæ of iron carbide, and free iron in juxtaposition. This portion of the alloy contains, both before and after the critical change, 0·90 per cent. carbon or 13·5 per cent. Fe_3C, and 86·5 per cent. iron, and is called "pearlite" after the dissociation.

Dr. Arnold describes it as saturated steel, but when using this expression it must be remembered it is only when heated to just above the critical point Ac. 1 about 730° C. that the term is admissible. After cooling slowly through Ar. 1-2-3 the two substances—iron and carbide—are no longer in solution, but in the free state.

On heating pearlite for a long time at about 670° C. to 680° C. just under the critical point Ar. 1, the laminæ or thin plates of carbide slowly break up and form minute globules. These, on touching each other, behave just as if they were drops of water, and under the influence of surface tension, coalesce and form larger globules, and after this the enlarged globules come into contact with others and coalescence again occurs. By long heating the globules have been obtained so large as to be easily seen with a simple magnifying glass. If time were afforded there can be little doubt they would assume much greater dimensions and would probably eventually form idiomorphic crystals of Fe_3C similar to the carbide crystals called Cohenite in certain meteoric irons.

D.—If the carbon is between 2 per cent. and just under 4·3 per cent. when the fluid alloy completely solidifies at a temperature of about 1130° C. it is composed of fir-tree crystallites of iron saturated with carbide (=about 2 per cent. carbon) bedded in a eutectic containing 4·3 per cent. carbon.

E.—If there is 4·3 per cent. carbon and 95·7 per cent. iron in the alloy it freezes at one single point 1130° C. and consists entirely of a eutectic mixture composed of honey combed Fe_3C, the cells of which are filled with iron saturated with iron carbide, in the following proportions. (Photo 3.)

Carbide of iron	— 50 per cent.	
Iron saturated with carbide	— 50 „	15 per cent. Fe_3C.
	100 per cent.	

In cooling down, the excess carbide over the eutectoid proportion falls out of solid solution and crystallises on the cell walls of the eutectic cementite and co-incidentally reduces the size of the cells. On cooling through the critical point Ar. 1-2-3 the remaining solid solution is resolved into pure iron and iron carbide. The analyses of the binary eutectics at the point just above and below the critical temperature are as follows :—

	Above Ar. 1.2.3.	Below Ar. 1.2.3.
	per cent.	per cent
Iron carbide (free)	59·0	59·0
Iron saturated with 13·5 per cent. carbide in solid solution	41·0	—
Pearlite consisting of free carbide and free iron	—	41·0
	100·0	100·0
Carbon in the eutectic	4·30%	

In alloys containing more than the eutectic proportion of carbide, the excess Fe_3C falls out of solution above 1130° C. —the eutectic point—in the form of flat plates and finally when the excess is all out of solution and the eutectic proportion of 50 per cent. Fe_3C and 50 per cent. iron saturated with carbon is reached the whole residue solidifies at about 1130° C.

Commercial white irons, free from phosphorus, containing more than 4·3 per cent. carbon, never contain plates of carbide bedded in the eutectic, for silicon is always present and this element induces the excess carbide to decompose at, or near to, the eutectic point, into graphite and iron saturated with carbide, and the alloys, when cold, are grey or mottled.

F.—All solid solutions of carbide in iron are called Austenite and contain the iron in the gamma allotropic state and are non-magnetic, but it is only the saturated or nearly saturated alloys that can be essentially retained in that condition by sudden quenching in ice-cold water from a temperature of about 1000° more or less.

Iron-carbon-phosphorus ternary alloys.

In my paper on iron and phosphorus (Journal of the Iron and Steel Institute, 1900, Vol. II, page 87) the ternary eutectic of iron phosphorus and carbon was first described as "a complex compound mixture of the binary eutectic iron and phosphorus, and thin plates of carbide of iron." It was not fully described but it was suggested that it contained about 2 per cent. carbon.

In 1876 I described an experiment in which Cleveland iron was, when partly frozen, subjected to hydraulic pressure and a part of the last liquid portion was squeezed out of the mass. The analysis of the metal used and the liquid pressed out are given below :—

	Metal.	Substance pressed out.
	per cent.	per cent.
Iron (by difference)	93·37	90·27
Carbon	3·00	1·75
Manganese	0·35	0·29
Silicon	1·63	0·79
Sulphur	0·12	0·06
Phosphorus	1·53	6·84

When allowance is made for the carbon equivalent to the silicon, which the latter replaces, in the proportion of about 1 carbon to 5 silicon (0·79 per cent.=0·16 per cent. carbon) the total becomes 1·75 per cent.+0·16 per cent.=1·91 per cent. carbon. Excluding the silicon and sulphur, etc., the analysis of the remaining mass calculated into percentages would be, viz. :—

		Per cent.
Iron and manganese	90·56	— 91·19
Carbon	1·19	— 1·92
Phosphorus	6·84	— 6·89
		100·00

This corresponds most closely with the analyses of the ternary eutectic as determined later by Wüst and Goerens, which were as follows, namely :—

	Wüst.	Goerens.
	per cent.	per cent.
Iron	91·30	91·15
Carbon	2·00	1·96
Phosphorus	6·70	6·89

It was shown in 1900 that in ternary alloys containing 0·12 per cent. carbon and about 2 per cent. phosphorus the last portion to freeze contained both phosphorus and carbon in a eutectic, and during cooling down after complete solidification the carbon diffused out of this into the surrounding metal. It was further shown that in white pig iron the eutectic always contained three constituents while that in very grey irons, high in silicon, was always binary containing only two. Photo 2, 3, 4, 5.

It was shown that phosphide of iron diffuses in iron and tends to become intimately mixed with it to form homogeneous solid solutions, and that the presence of carbon greatly retards the diffusion and prevents it entirely if the quantity is great.

In the early days of the pyrometer, many of the records were sometimes lower than the truth and the melting point of the binary eutectic—about 910° C.—given by Osmond and myself, is about 35° C. below the truth.

The very careful and elaborate researches of Wüst on the ternary alloys are an important addition to the preliminary work published eight years previously. The same may be said of the work of Goerens and Gutowsky and others.

Wüst was the first to fully study and prepare the ternary eutectic, the melting point of which he found to be about 945° C.—a result confirmed by Goerens, Gutowsky and Carpenter. He proved that each 1 per cent. phosphorus added to pig iron reduced the initial melting point about 27° C.

Gutowsky confirmed what I had previously shown that the eutectic remaining in cold grey pig irons containing phosphorus, is sometimes of a binary character. His work is of high order of merit, and contains much valuable information as it shows the gradual changes that occur during freezing and melting of phosphorettic pig iron. He says that the melting of grey pig iron begins with the fusion of the binary eutectic at about 980° C., but that the melting point is lowered as the binary eutectic (by absorption of iron carbide) passes into the ternary eutectic, melting at 944° C.

A research published by Goerens and Gutowsky, bearing indirectly on the ternary alloys, on the formation of graphite in pig iron when cooling is of the greatest importance. They conclude, confirming Wüst and others, including myself :—

(*a*) That the formation of the graphite which remains in the solid iron occurs during the solidification process.

(*b*) That it occurs only after the previous separation of the eutectic cementite, and that graphite in pig iron is a disintegration product.

(*c*) That the graphite plates become coarser the slower their formation, and more copious the slower the eutectic interval is traversed.

These conclusions practically coincide with the careful observations of practical metallurgists long before the more refined methods of research were available. It had long been noticed that if the cooling of cast iron were accelerated —as it is in making chilled rolls—the carbides of iron first to form remain undecomposed in the chilled outer layer, and that below the chill, where the cooling is slower, graphite plates appear which increase in size with the distance from the chilled surface, and that the graphite plates are smaller in thin than in large castings—due to the less rapid cooling in the former as compared with the latter.

Although the author's remarks applied to non-phosphorettic iron, they equally apply to phosphorettic pig irons. It is for that reason they are here referred to.

Phosphorus, like silicon, if added to highly carburetted white iron when molten containing about 4 per cent. carbon, causes the iron to become grey on cooling, due to the separation of graphite, indeed, if the quantity of phosphorus added is 16 per cent. practically the whole of the carbon will be thrown out of solution even when the metal is still liquid and will appear as graphite on the surface.

By calculation, the constitution of the ternary eutectic is as follows, namely :—

	Per cent.
Iron phosphide (free)	44·3
Iron free from phosphide	26·3
Carbide of iron	29·4
	100·0

If, however, the third constituent contains iron saturated with phosphorus it will have the following composition :—

	Per cent.
Iron phosphide (free)	41·5
Iron saturated with phosphide	29·1
Carbide of iron	29·4
	100·0

It is possible that the constitution of the cold alloy varies with the rate of cooling.

Difference in microstructure between iron-carbon, iron-phosphorus and iron-carbon-phosphorus eutectics.

The iron-carbon and iron-phosphorus eutectics are very similar so far as structure is concerned: indeed the phosphide-iron eutectic previous to 1900 was mistakenly called iron carbide.

Solidified under like conditions the honeycomb cells are larger in the iron-carbon eutectic than in the other, but by cooling the iron-phosphorus eutectic very slowly and the other rapidly, the order of size of cell can be reversed. The iron-carbon eutectic, when cold, consists of massive cementite containing cells filled with pearlite, whilst that of the iron-phosphorus eutectic consists of massive phosphide of iron (Fe_3P) with similar cells, but the cell substance consists of iron saturated with phosphide in solid solution.

The main difference between pure iron-carbon eutectic and pure iron-phosphorus eutectic is that the former contains pearlite and the latter does not, but one can conceive that on heating the iron-carbon eutectic at just below Ar. 1-2-3 for a long time the carbide of iron (Fe_3C) of the pearlite cells will globularise and join the preformed massive cementite, leaving pure ferrite cells, but these will not blacken on treatment with acid, while the others—iron-phosphorus cells—always do.

In the perfectly pure binary iron-phosphide eutectic, the cell substance is homogeneous solid solution, but slight traces of carbon yield pearlite cells and therefore the presence of pearlite in the cell substance is not a proof that it is the carbide eutectic.

Phosphide of iron of the eutectic, on heating polished sections to 325° C. assumes a purple colour by the time the carbide has become a deep red. It is by this means that one can distinguish the two substances when together in an alloy. The purple colour of the phosphide is different from the blue colour assumed by the carbide when heated past the red stage—being heliotrope in shade. With a little experience one can judge by this alone whether a eutectic is that of phosphide or carbide.

The photos (3 and 2) show the structure of the iron-carbide eutectic as it appears in white Swedish iron containing 4·3 per cent. carbon, and of the iron-phosphide eutectic in very slowly cooled siliceous Cleveland pig iron. A peculiarity in the latter is that it differs in one material feature from the carbide eutectic: the elongated cells are frequently divided by a white band of solid phosphide never present in the other. This is clearly shown in the photograph No. 1.

The ternary eutectic, having carbide in plates embedded in what appears to be the binary eutectic is only capable of being resolved by the heat tinting process. Developed properly the carbide has a red colour, the phosphide a purple colour, while the tint of the iron-phosphide solid solution or pearlite, if present, will be nearly white. In the photographs 4 and 5 the darkest portion represents the carbide, the half-tone the phosphide, and the white parts represent the third constituent.

Part II.

A STUDY OF SOME OF THE IRON-CARBON-PHOSPHORUS ALLOYS.

Having given a brief account of what has been previously published on the ternary and other alloys, the more recent researches on some of the alloys which may be, and are, commonly met with, will now be discussed under the following headings, viz. :—

First.—An alloy containing about 2 per cent. phosphorus and 0·12 per cent. carbon, its constitution and the effect of carburising it by cementation.

Second.—An alloy containing 1·2 per cent. phosphorus and the influence of increasing proportions of carbon alloyed with it by fusion.

Third.—Alloys containing about 0·3 per cent. carbon and 0·5 per cent. phosphorus, and a study of what occurs during the solidification of steels in general.

Fourth.—The alloys represented by phosphorettic pig metals, and a study of what occurs during freezing, including a description of the metal in the centre of a "bear" found in the hearth of a blast furnace at the Skinningrove Iron Works.

No. 1.—An alloy containing about 2 per cent. phosphorus and 0·12 per cent. carbon.

One of the most interesting alloys referred to in my paper on "Iron and Phosphorus" (Iron and Steel Inst. 1900) has since been a constant source of interest, wonder, and research. It was made by melting puddled iron and phosphorus together in a crucible and allowing the metal to cool down in the furnace. It contained :—

	Per cent.
Iron (by difference)	97·9
Carbon	0·12
Sulphur	0·02
Phosphorus	1·96

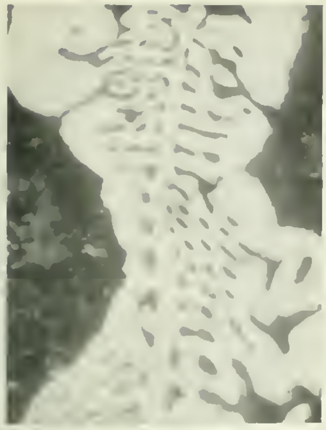
Photographs 6 and 7 give the micro-structure of a portion of this alloy.

As will be observed, the structure is that of a plain ground in which is embedded irregular shaped masses of the binary eutectic surrounded by a peculiar fringe of hair-like particles. The question as to how the eutectic got into the positions shown, why it is surrounded by a fringe, what the fringe consists of, and what phenomena underlie this particular arrangement, have been carefully studied.

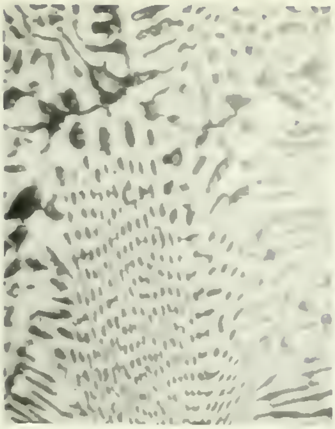
In my original paper I described the fringe as being pearlite, which was true as it contained laminæ of carbide of iron and iron plates in juxtaposition, but more recent research has proved the presence of laminæ of free iron phosphide.

When the alloy was slowly reheated to above 1200° C., and was then quenched in water, the eutectic areas were free from any fringe and had increased in volume; the whole of the carbide originally in the fringe together with the phosphide joined the pre-existing binary nucleus and contained iron, carbide of iron, and phosphide in a eutectic. We may assume that the alloy just at a point a little before the eutectic solidified was exactly of this ternary character without any fringe whatever. The fringe must therefore have been formed after complete solidification.

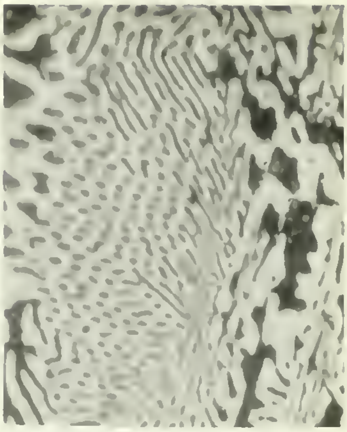
On heat tinting the original metal, it was clearly seen that there were three differently coloured laminæ in the



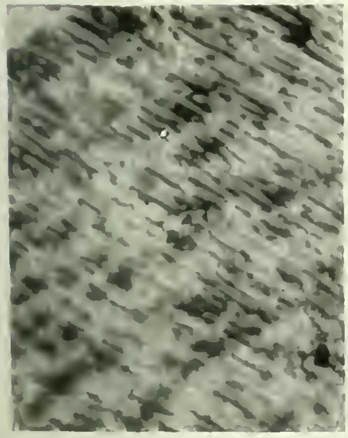
No. 1.—Binary eutectic of iron-phosphorus in grey pig iron. x 330.



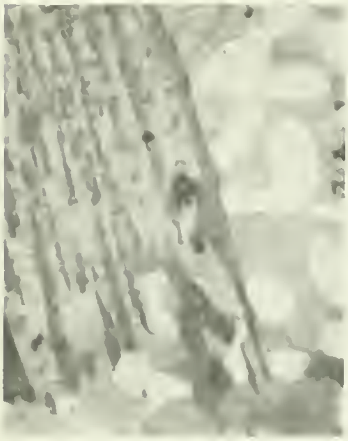
No. 2.—Pure binary eutectic of iron-phosphorus containing 10·2 per cent. phosphorus. x 330.



No. 3.—Binary eutectic of iron-carbon containing 4·3 per cent. carbon. x 330.

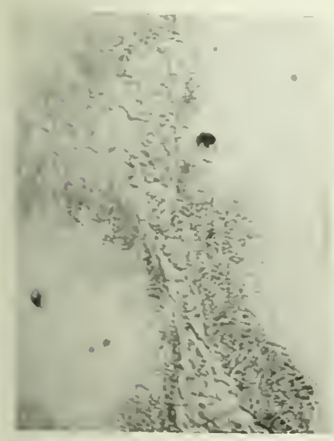


No. 4.—Ternary eutectic of iron-carbon-phosphorus in slowly cooled pig iron. The specimen was heat tinted.
Dark parts, carbide of iron; white parts, iron saturated with phosphorus; half tone, iron phosphide. x 330.

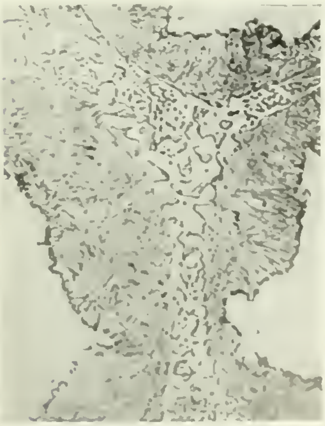


No. 5.—Ternary eutectic iron-carbon-phosphorus. A portion of what was squeezed out of the Skinningrove "bear" during cooling. Very slow cooling has led to the segregation of the constituents into relatively large masses. x 330.

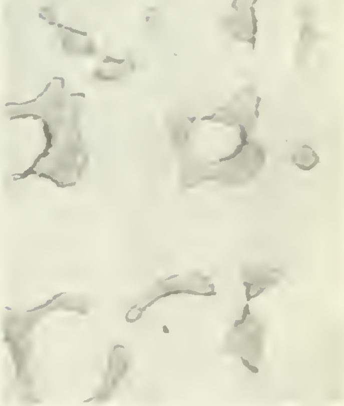
No. 6.—Alloy containing 2 per cent. phosphorus and 0·12 per cent. carbon slowly cooled. x 50.



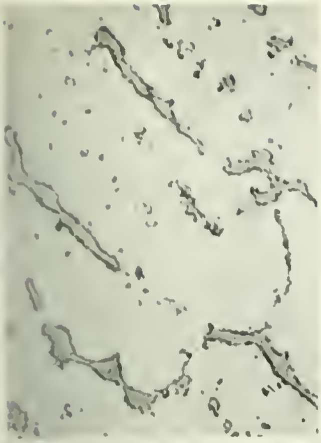
No. 7.—Same alloy as No. 6. Highly magnified—330 diameters. The central portion is the binary eutectic of iron-phosphorus: the outer part of the fringe, laminæ of iron phosphide, the darker part near to the eutectic, iron phosphide, iron, and iron carbide.



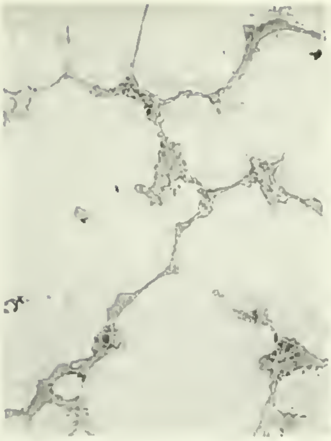
No. 8.—Same alloy as No. 6. Heated to 900° C., and quenched in water. Carbide diffused outwards between the phosphide plates shown in No. 7, and has been fixed in solid solution as Martensite. x 330.



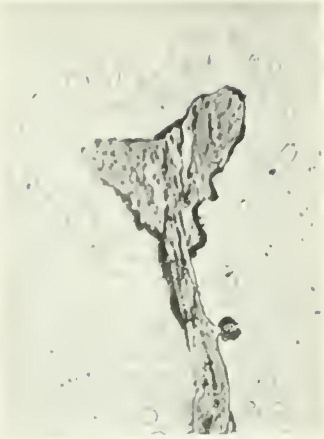
No. 9.—Same alloy as No. 6. Heated slowly to 1200° C. and quenched in water. x 50.



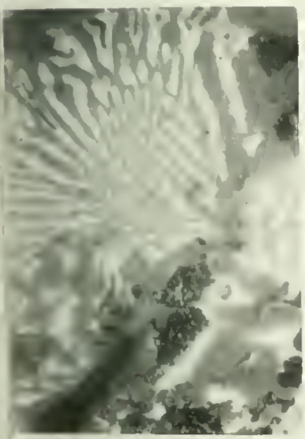
No. 9b.—Same alloy as No. 6. Heated to 1100 C. and cooled rapidly. x 50.



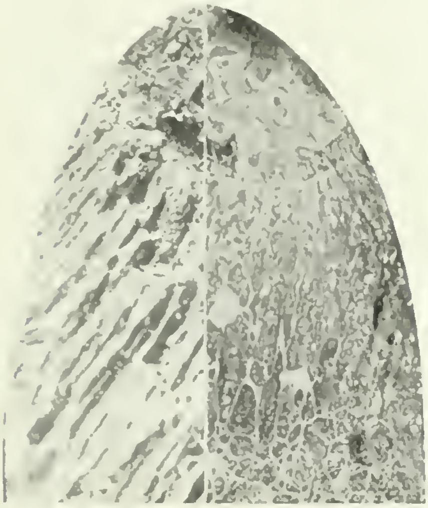
No. 10.—Same alloy as No. 6. Heated rapidly to 1200 C. and quenched in water.



No. 11. Same as No. 10, showing that the terminations of the original phosphide had liquefied and that the carbides have fallen into the original eutectic.



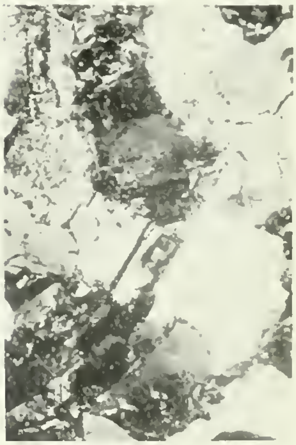
12 The ternary eutectic liquated on rising by cementation of the same as No. 6. Owing to slow cooling the dark parts in the photo—have segregated, leaving the binary eutectic in patches. x 330.



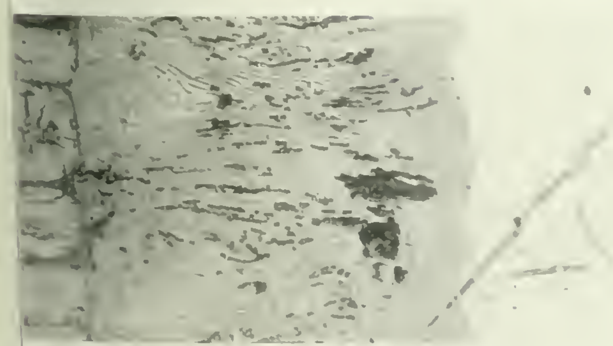
No. 13. No. 14

No. 13.—Fractured section of the cemented alloy showing the columnar arrangement and the nucleus at the top of the photograph of apparently unaltered metal. x. 5.

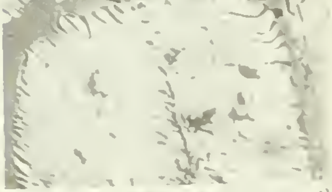
No. 14. Same as No. 13 after polishing and etching the specimen. x 5. The white patches represent pools of the binary eutectic.



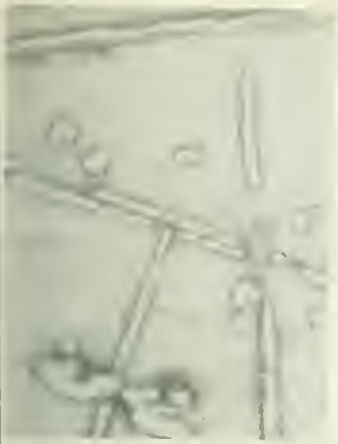
No. 15.—Fracture of the original alloy No. 6. Natural size.



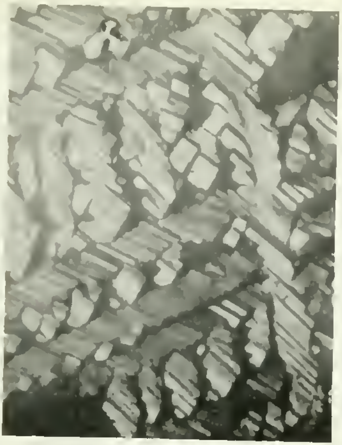
No. 16. Structure of the junction between the unaltered and carburised portion of the cemented alloy. Half tone laminæ, phosphide of iron; the darker portions, segregated carbide of iron, the layers between the phosphide laminæ, iron. x 200.



No. 17. Carburised portion of the cemented alloy in which the half tone portions represent phosphide of iron. The very dark portions are carbide of iron in spear-like particles projecting from the patches of binary eutectic. x 330.

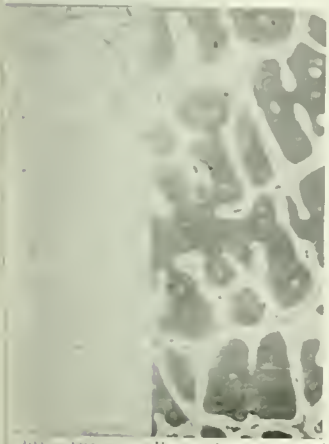


18.—Portion of the uncarburised ma-
ss of the cemented alloy, in which the
ite lines represent imperfect plates of
n phosphide, surrounded by a border
ntaining little phosphorus, the ground
ass being iron more or less saturated with
phosphide of iron.

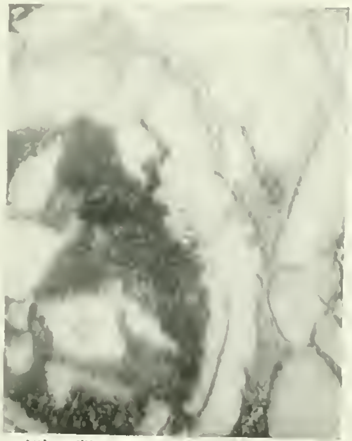


No. 18a.—Side of one of the plates shown in 18, after removing the iron by acid. x 330.

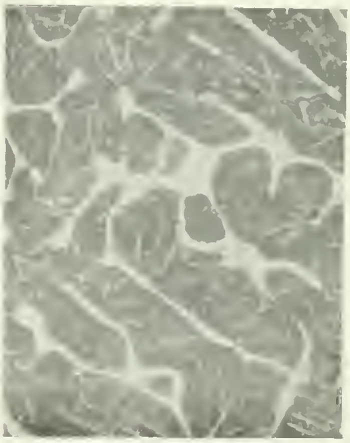
No. 19.—Alloy containing 1·2 per cent phosphorus in solid solution in iron and 0·12 per cent. carbon. The dark patches represent pearlite and the ground mass, phospho-ferrite. x 50.



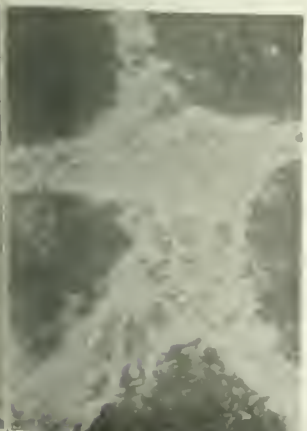
19a.—The same alloy as No. 19 melted
h arbon to give 0·30 per cent. The
k lines on the left-hand side of the
t represent the ternary eutectic of iron-
n-phosphorus. On the right is
wn the heat tinted structure in which
dark parts represent pearlite; the
te portions, iron rich in phosphorus;
and the half tone, the eutectic.



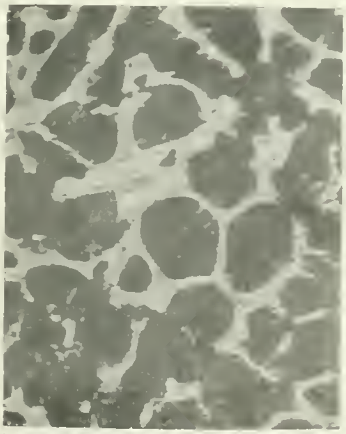
No. 19b.—The same as No. 19a magnified 330 diameters, etched with picric acid.



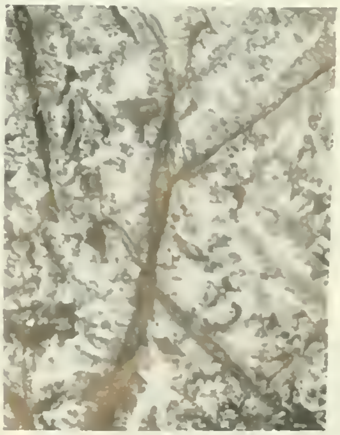
No. 20a.—Alloy containing 1·2 per cent. phosphorus and 1·2 per cent. carbon. The broad white patches are the ternary eutectic; the dark parts, pearlite with embedded carbide plates. x 50.



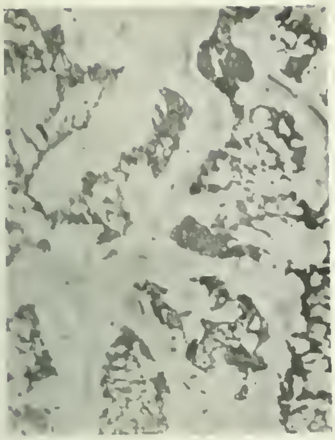
2 b.—Detail of No. 20a showing the
ture of the ternary eutectic. x 330.



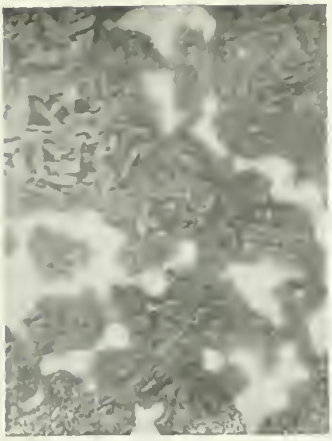
No. 21.—Alloy containing 1·2 per cent. phosphorus and 1·5 per cent. carbon, in which are broad white plates of carbide of iron in the eutectic. x 50.



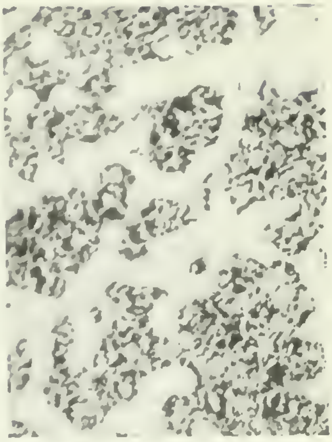
No. 22.—Alloy containing 1·2 per cent phosphorus and about 4 per cent. carbon. Dark bands graphite; half tone, pearlite; white portions, ternary eutectic. x 50.



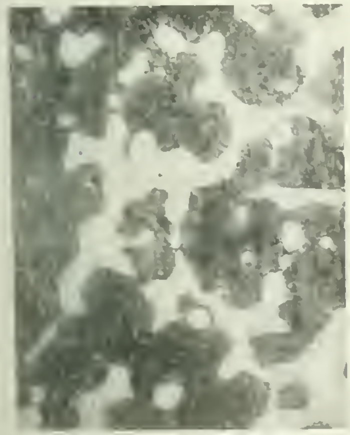
No. 23.—Alloy as cast containing 0·5 per cent. phosphorus and 0·30 per cent. carbon. Dark parts, pearlite; white, ferrite; half tone, iron rich in phosphorus.



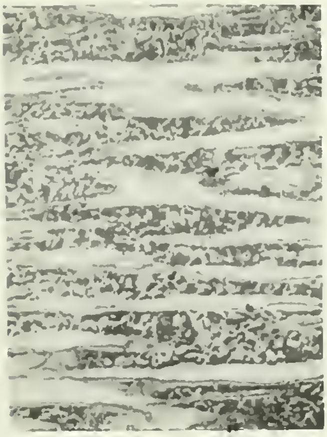
No. 24. Same as No. 23. Heat tinted so as to show the phosphorus concentrations, white on a dark ground. x 50.



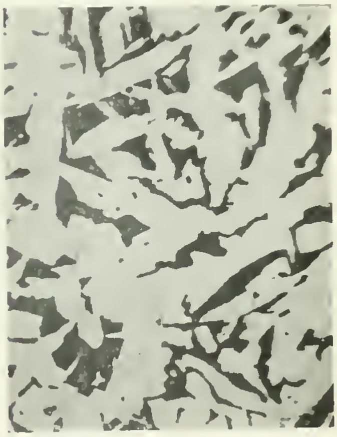
No. 25.—Same as No. 23. Heated to 1000 C. and cooled in the air. x 50.



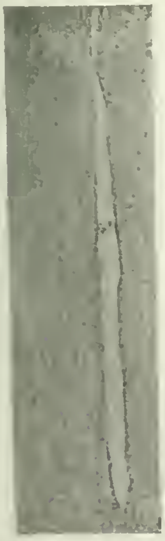
No. 26.—Same as No. 23. Heated to 1000 C. and quenched in water. Dark portions, Martensite; white, phosphorus-rich concentrations into which carbon would not diffuse at 900° C. x 50.



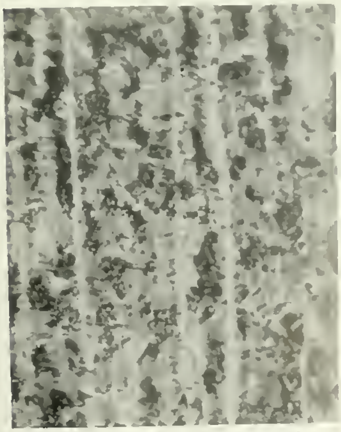
No. 27. Same as No. 23. Forged. The specimen was heat tinted. White parts, phosphorus-rich concentrations; half tone borders, ferrite containing little or no phosphorus; dark patches, pearlite. x 50.



No. 28.—Same as No. 27. Heated to a high temperature and cooled very slowly. Dark patches, pearlite; white, homogeneous solid solution of phosphorus in iron. x 50.

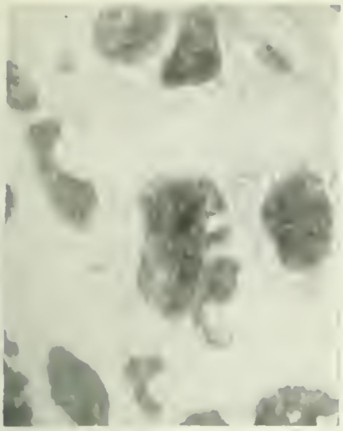


No. 29.—"Ghost" line in a steel forging very rich in phosphorus. Natural size.



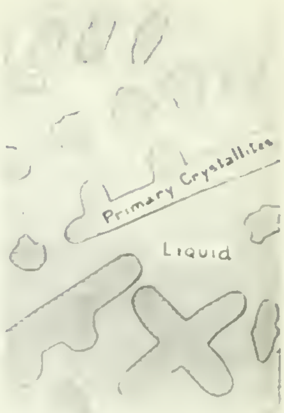
No. 30.—Micro-ghost lines in a steel tyre slightly etched showing white portions rich in phosphorus passing through pearlite and ferrite. x 50.

No. 31.—Horizontal section, through a "ghost plate" slightly etched showing border rich in carbon. x 330.

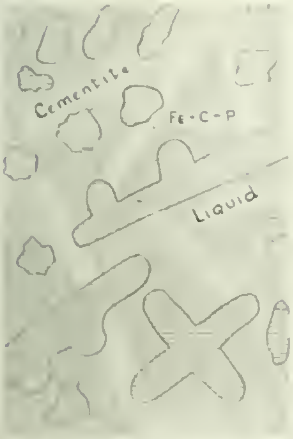


No. 32.—Structure of white iron containing 1·5 per cent. phosphorus.

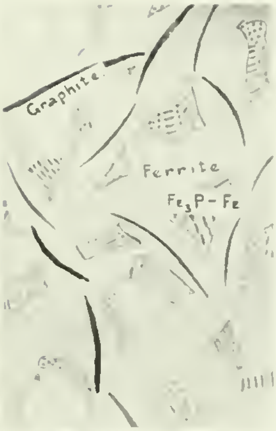
No. 32a.—Structure of grey iron containing 1·5 per cent. phosphorus. x 330.



No. 33a. Progressive changes in cooling metal. Crystals which first form.



No. 33b. Same crystals with addition of crystals of cementite or carbides and liquid ternary eutectic.



No. 33c. Structure of the grey metal after solidification by very slow cooling. Graphite, ferrite and binary eutectic of iron-phosphorus.

No. 34.—Fractured surface of the Skinningrove "bear" half size.

No. 34a.—Polished section of No. 34. Dark portions, porosities between the columns, half size.

No. 35.—Decarburised speck in portion of the columns shown in No. 34.

No. [illegible].—Steel plate, with central segregation rich in phosphorus, heated at one end and quenched in water. The critical line A . 1-2-3 is shown higher in the phosphorus zone than the other parts.

fringe and that the eutectic nucleus contained only traces of carbide, and was therefore nearly pure binary eutectic. The phosphide of this latter was coloured blue and some of the laminæ of the fringe were of the same blue tint and evidently consisted of iron phosphide. Between the blue laminæ there were strips of a brownish red colour and other strips of a bright red. The latter were carbide of iron, and the brownish red strips, iron containing no carbon and probably little or no phosphorus.

It must be remembered that the metal surrounding the phosphide eutectic "pools" just before solidification, must have been fully saturated with phosphide of iron, and that being saturated the carbide could not enter this zone without displacing some of the phosphide. As will be presently shown carbide of iron drives phosphide of iron out of liquid solution previous to and during solidification, but it is now evident that solid carbide is capable of driving out *solid* phosphide from solid solution.

The eutectic solidified at about 945° C., but long after it froze the carbide was capable of diffusing into iron, whilst as the temperature fell the phosphide itself would be held less strongly in solid solution and would tend to separate in the free state, proof of which will be given later.

Knowing these facts, let us follow exactly what most probably took place when the metal slowly cooled.

As soon as the ternary eutectic solidified, and the temperature fell, the iron of the surrounding metal would begin to weaken in its power to hold the phosphide in solid solution, and the carbide's opportunity thus developed, it would take away the iron from the phosphide to form with it a solid solution of carbide of iron in iron or austenite. At first the precipitated phosphide would be in the form of minute ultra-microscopic particles embedded in austenite, but these—due to surface tension—would coalesce into larger globules at minute distances apart. Between them, at the boundary of the central eutectic, the carbide, free to diffuse radially, would then attack the iron phosphide solid solution beyond the first layer and the particles of freed phosphide would naturally join themselves to the larger particles of previously separated phosphide, and in this way would be forced to lengthen radially. As the carbon continued to diffuse outwards between the growing walls of solid phosphide the inevitable result would follow—the walls or laminæ of phosphide would develop into long radial plates surrounding the eutectic, interstratified with radial layers of solid solution of iron and carbide (austenite). These layers would constitute passages along which the carbide could readily diffuse. Just as in the ordinary process of carburisation by cementation, the greater amount of carbide is located near to the source of the carbon.

As the temperature fell the diffusion of the carbide would become less active, and when the critical point Ar. 1·2·3 was reached, or even before, it would stop completely. During the passage through the point Ar. 1·2·3, the carbide and iron would then separate to form pearlite.

On very slow cooling through the following hundred degrees Centigrade, 700 to 600, the carbide would globularise, coalescing into larger masses concentrating towards the point where it had first entered. The colour photo-raphs (shown at the lecture) clearly show this con-entration and that the outer portion of the fringe consists entirely of iron phosphide and iron free from carbide. The darker parts in photo No. 7 represent the carbide ear to the eutectic nucleus.

On heating to about 900° C., the carbide again passed into solid solution forming austenite, and on quenching the specimen, martensite and austenite replaced the iron us carbide areas. (Photo 8.) On *slowly* heating the loy to 1200° C.—a temperature well above the melting point of the eutectic—and then quenching it, eutectiferous asses free from any fringe remained—a condition we may assume that existed at the same temperature on slowly cooling down the original molten alloy. (Photo 9.) On heating another portion of the alloy rapidly, instead slowly, to about 1200° C., the terminations of the nge, formed with a portion of the surrounding metal ible globules of eutectic which were retained *in situ* by sudden quenching. The greater part of the fringe close to the original eutectic had evidently melted also and must have flowed into the existing nucleus increasing its volume, for there is an absence of independent globules close to the eutectic. (Photos Nos. 10 and 11.)

In order to determine the effect of carburising this alloy containing 2 per cent. phosphorus and 0·12 per cent. carbon, a piece of the highly crystalline metal was kindly cemented for me by Messrs. T. Sorby and Sons, and a careful examination was made of the carburised metal. To what was the under side of the metal when in the furnace adhered a solidified drop of metal evidently liquated from the mass. This was detached and examined; it contained about 5 per cent. phosphorus and about 1·4 per cent. carbon. It consisted of primary crystallites of pearlite surrounded with masses of the ternary eutectic. The structure is shown in photo 12.

The cemented lump when broken up had the fractured surface illustrated in photo 13. The central part was of the original coarse crystalline structure and was a striking example of how phosphorus completely prevents the gamma change at about 1100° C. and coincident recrystallisation. Radiating from this unaltered and, as was proved by analysis, uncarburised portion, there were columns of metal cased more or less completely with a brittle substance. (Photos 13, 14, and 15.) Analysis and microscopic examination proved that the brittle material was the binary eutectic, while in the centre of the columns there were globules of the ternary eutectic occasionally enveloped by massive carbide.

The main volume of the columns consisted of pearlite containing little or no phosphorus. The junction between the columns and the unaltered central part consisted of a phosphide-carbide-iron fringe of exactly the same character as the fringes round the eutectic particles in the original alloy, but as the result of the very slow cooling in the cementing furnace, the components were of much greater size and were further apart. Photo 16.

Analysis showed that the phosphorus diminished in the columnar portion of the metal with the distance from the centre, and with the increase of carbon, as is shown in the following analysis.

	Carbon.	Phosphorus.
		per cent.
Centre of nucleus	Traces	1·96
1 Outside the nucleus, 1st layer ..	0·89 per cent	1·52
2 Below 1st layer	0·93 ,,	1·30
3 Below 2nd layer	1·20 ,,	1·05
4 Below 3rd layer	1·31 ,,	0·91

There was very much more imprisoned eutectic near to the kernel than in the outside layer.

On making laboratory trials by cementing the original metal in a crucible and quenching the cemented metal in cold water so as to arrest or prevent the changes that occur when cooling slowly, it was possible to see under the microscope exactly how the carbide on diffusing into the metal caused the phosphorus to leave it as a fusible eutectic.

At the extreme point where carbon had diffused, there was no fringe but a multitude of minute globules of the eutectic. These were inversely proportional to the distance from the carburising source, then finally joined together to form continuous streams, radiating from the kernel or uncarburised portion.

The streams terminated in what had been a liquid rich in carbon and phosphorus. It is evident that as the carbide diffused inwards at a temperature of about 1100° it expelled the iron phosphide, and this, with a portion of the carbide and the iron, liquefied in the form of dew-like drops, and these with time coalesced to form larger drops and eventually to make separate streams along which the liquid ran from the point of its genesis to the outside of the metal where it accumulated as a fusible liquate.

The presence of the ternary eutectic in the centre of the columns while only the binary mixture existed at the junctions is explained on the probable assumption that the internal eutectic being imprisoned got supersaturated with carbon and, in cooling, it was only the excess of dissolved carbide that had time to diffuse outwards, resistance also being offered to it doing so by the carbide in the surrounding austenite. This view is supported by the fact that many of the globules were surrounded by thick layers of carbide.

The original ternary eutectic between the columns as soon as it was formed flowed away and liquated out of the metal, and what remained would become solid and could not therefore become supersaturated with carbide.

As soon as the temperature fell sufficiently the carbide diffused into the columns, leaving only the binary eutectic behind, and appeared in section in the form of spear-like projections of free carbide. Photo 17.

The remarkable feature in this cemented metal is that the centre of the kernel, where the original coarse crystalline structure persisted, was quite free from carbon although it originally contained 0·12 per cent.; that the eutectic of iron and phosphide with its fringes had been concentrated near the junction; and that free phosphide in plates had appeared. Photo 18.

We must conclude that the carbon together with some of the iron and phosphorus had become liquid and flowed outwards and that the flat plates of phosphide—nonexistant in the original alloy—must have crystallised out of solid solution during cooling.

The analyses of this peculiar kernel and of the original metal are as follows:—

	Original alloy.	Kernel.
	per cent.	per cent.
Phosphide in solid solution	10·8	6·00
,, in the free state	1·8	6·00
Iron carbide	1·8	Nil
Phosphorus	1·96	1·86
Phosphide that passed out of solid solution	--	4·8

The total phosphorus in the kernel is a little in excess of that required to make with the iron a saturated solid solution. Although one cannot be certain it appears to be probable that at some undetermined temperature the whole of the phosphide was in solid solution and that in cooling the excess crystallised out in the cleavages of the iron crystals in the form of imperfectly formed plates.

The examination of the heat tinted section proved that the metal immediately surrounding the plates contained little or no phosphorus and that it gradually increased in that element with the distance from them. Photo 18a. This observation leads to the second conclusion, that after the excess of phosphide had crystallised out by crystallic attraction it induced more Fe_3P to leave the solid solution and join the preformed free phosphide.

Whether a saturated solid solution of Fe_3P in iron free from any excess of iron phosphide would part with phosphide under similar conditions of heating and cooling remains to be determined.

The greater coarseness of the fringe of phosphide-iron-carbide near to the point at which the carbon had penetrated from the external charcoal in the cementation furnace enabled one more perfectly to study its composition and structure. The main difference between it and the fringes round the eutectic "pools" in the original less slowly cooled metal was in the carbide which had segregated into larger masses leaving the plates of phosphide and intervening iron practically free from any laminæ of carbide. Photo 16.

If the conjecture just advanced—that free phosphide once formed attracts phosphide from solid solution, one would expect that the outer terminations of the phosphide fringe would have the same influence. After the carbide had ceased to diffuse and precipitate free phosphide the ends of the phosphide plates would terminate in a saturated solid solution of phosphide in iron and these quite independent of the influence of the carbide should attract phosphide from the solution.

That such actually happened was proved by the microscope, for at some distance beyond their terminations the iron contained little or no phosphorus, and as the attraction must have been radial the phosphide would be drawn from a large reservoir of phosphide in solution to the ends of the plates, and these would naturally be obliged to thicken and form thickened rims, or ends, exactly such as were found.

(*No.* 2)—*An alloy with* 1·2 *per cent. phosphorus and* 0·12 *per cent. carbon.*

From what has preceded it will be inferred that if a fusible eutectic is formed by introducing carbon into phosphorus-iron alloys by cementation, the eutectic would also be formed on carburising the same alloys by melting carbon with them. That such an inference is correct it is now proposed to demonstrate.

The alloy selected containing the 1·2 per cent. phosphorus and 0·12 per cent. carbon when rapidly cooled from the liquid state consisted of crystallites containing less phosphorus in the central portions than at their boundaries, while more or less completely surrounding them were thin and non-continuous strips of eutectic. When this alloy was cooled very slowly through the solidifying range only very large crystallites remained, no eutectic was present, while the carbon was located in isolated patches of pearlite. On heating polished sections at 270° C. these pearlite segregations assumed a brown tint by the time the surrounding metal had become blue, proof that they contained less phosphorus than the parts that assumed a blue tint. It was with the object of determining what amount of carbon in austenite would be completely antagonistic to association with phosphide of iron in solid solution that the following trials were made.

Mixtures of the alloy and carbon were melted in magnesia crucibles and the melts slowly cooled in the furnace in about half an hour. The proportion of carbon varied between 0·2 per cent. and 4·6 per cent.

The photographs Nos. 19—19a, 19b, 20—20a, 21 and 22 sufficiently illustrate the effect of carbon in throwing out the phosphorus, or rather in preventing it from remaining in solid solution.

The first example—shown in Photo No. 19—is that of the original alloy in which no eutectic is present. The polished specimen was heated until the surface appeared to be blue—shown white in the photograph. The pearlite areas, on examination under the microscope, appeared as brown patches and are the dark parts in the photograph.

In the first alloy mixture the carbon was 0·3 per cent., and its structure is clearly shown in the photos No. 19a—19b, which were taken from a polished specimen, "heat tinted" to the degree when pearlite assumed a brown tint. The central portion of the crystallites consiste mainly of pearlite in which were globular inclusions of th eutectic surrounded by phospho-ferrite. The oute portions adjoining the eutectic were free from carbon and were coloured sky blue—an indication that they wer rich in phosphide in solid solution. They correspon with what is called phospho-ferrite. Between the crystallites, in irregular formation, the eutectic was locate containing that portion of the free phosphide prevente from remaining in solid solution by the dominatin influence of 0·3 per cent. carbon.

As the carbon is increased little by little the centr areas of pearlite in the primary crystallites increase i volume, while the areas of phospho-ferrite boundari decrease, and the eutectic increases until eventually, wh about 1 per cent. carbon is present, there is no longer a phospho-ferrite, and the alloy consists of pearlite crysta lites enveloped by the ternary eutectic of iron carbi and phosphide.

Photos 20a—20b are those of an alloy etched with pic acid containing 1·2 per cent. carbon in which the round masses consist of pearlite and free carbide in the form plates. These primary crystallites were surrounded b network of the eutectic. With a further quantity carbon the volume of the eutectic does not appear increase and the excess carbon appears in the form thicker and thicker plates of carbide (Photo 21), a finally when the carbon approaches 4 per cent. th carbide plates decompose on cooling into graphite a austenite, which is resolved into pearlite after passing critical point Ar. 1-2-3 (Photo 22)

It is possible that if the rate of cooling of the alloys with 0·5 per cent. and less carbon were to be varied, there would be variation in their constitution; consequently the results given must be regarded as being those obtained when cooling down from the fluid to the solid and cold state in about half an hour.

With the evidence available it is possible to follow out the changes which occur progressively when the alloys described pass from the liquid to the solid state.

In the alloy containing 0·3 per cent. carbon, the first solid substance to fall out of solution could contain very little phosphorus and carbon, the greater part of these elements at this stage would remain in the liquid. As the temperature fell the ability of the pure solid crystallites to retain carbon in solid solution would increase and some of the carbon would pass from the liquid to the solid; the remainder would be concentrated with the phosphorus in the liquid.

Near to the point of complete solidification the remaining liquid would continue to part with carbon which would pass into the central parts of the primary crystallites. When the eutectic proportions of iron-carbon-phosphorus in the still liquid part approached 1000° C. the solid metal surrounding the eutectic would be nearly saturated with phosphorus and would have little solvent power for carbide of iron. Incidentally the concentration of the carbon in the primary solid crystallites would force out of solid solution some of the phosphide initially crystallised with the iron, and this would then appear in the form of globulæ of ternary eutectic. There is no other explanation for the actual appearance of these globules in the crystallites.

As the metal cooled down the carbides migrated inwards away from the solid border of the solid solution envelopes of phosphorus and iron, leaving a border of ferrite containing little or no phosphorus only slightly coloured by aqueous solution of picric acid—a reagent that readily colours dilute solutions of phosphorus in iron.

The eutectic itself contained very little carbide and must be regarded mainly as binary in character.

When the carbon was increased to 1·2 per cent. the cold alloy consisted of crystallites surrounded by meshes of the ternary eutectic. The crystallites themselves must have contained too much carbon to enable them to hold any phosphorus at the time they fell out of solution. As they cooled, just as in the alloy containing 0·3 per cent. carbon, their capacity to absorb carbon would increase, and some of that element in the liquid would pass into them making them more and more resistant to the entrance of phosphorus.

As a result probably all of the phosphorus would be concentrated in the eutectic the very last portion to freeze.

The absence of globules in the primary crystallites in the higher carbon alloy justifies the conclusion that no phosphorus was included in the crystallites that first fell out of solution.

No. 3. *Alloy containing* 0·3 *per cent. carbon and* 0·5 per cent *phosphorus.*—This alloy was specially prepared for me by Messrs. Wm. Shaw and Co., Ltd., Wellington Cast Steel Foundry, Middlesbrough. To a steel casting charge in a ladle there were added sticks of pure phosphorus. The metal was stirred to effect perfect incorporation. and it was then cast into a 6 in. cube in a sand mould.

This alloy, containing the same carbon and a little less han half the phosphorus present in one of the alloys escribed in the previous section, is useful in showing ow the carbon may cause local concentration of hosphorus without the formation of any eutectic. The icrostructure was similar to that of the alloy containing ·2 per cent. phosphorus and 0·3 per cent. carbon, with is important difference that eutectic envelopes were uite absent. In freezing, pure crystallites first fell out solution and the carbon passed back to them from the rtion last to freeze, leaving thick bouodaries of ferrite uite free from carbon. In the centre of the ferrite velopes is located the residue of what was the last rtion to freeze, and, just before freezing, was a conntrated solution of phosphorus, carbon and iron, from ich the carbon diffused as the alloy cooled. The two otographs, Nos. 23 and 24, one heat tinted and the other etched with picric acid, clearly show the final structure. The ferrite immediately surrounding the central portions of pearlite contain little or no phosphorus, while the phospho-ferrite probably contains nearly 1·5 per cent., or even more. After re-heating a piece of this alloy to 900° C., and cooling in the air, the carbon in the cold alloy was found to be distributed evenly in patches, intermixed with ferrite, round the phospho-ferrite concentrations, into which the carbide was incapable of diffusing at 900° C. (Photo 25). Another specimen, heated to 900° and quenched in water after etching, is shown in Photo 26, which indicates that the carbon has diffused only up to the borders of the phosphorus rich concentrations.

The dark parts are martensite; the white parts, phosphorus rich concentrations.

On forging the specimen heated at 900° C. the phospho-ferrite, of course, extended with the surrounding metal and appeared in lenticular-shaped forms in a mass of metal containing probably about 0·5 per cent. carbon (Photo 27). On heating this specimen to about 1300° C., in a ladle of blast furnace slag containing about 3 tons of slag, and allowing it to cool down with the slag, the structure when cold was completely reorganised (Photo 28). There were patches of pearlite equally distributed, and the whole of the external ferrite was quite homogeneous and free from concentrations rich in phosphorus The exceedingly slow cooling had admitted of the diffusion of the phosphide into the ferrite previously quite free from it. The lenticular-shaped phosphorus-rich ferrite lines suggest an explanation for the presence of streaks called "ghost lines," so common in steel forgings, which are always the more pronounced in steel the higher the phosphorus and the larger the casting. Photo 29 is an example of a "ghost" streak in a large steel shaft. It represents the residue of the last portion of the steel to freeze, and is free from carbon, which, although originally present, had diffused out of it during the cooling of the steel. Sometimes the segregations are so slightly enriched with phosphorus that the carbon during cooling has not time to diffuse out of them completely, and not at all if the cooling has been accelerated. Photos 30—31 illustrate these two conditions.

Photo No. 30 represents a steel cooled in oil in which the carbon had insufficient time to diffuse out of the phosphorus rich portions. Heat tinting, however, and feeble etching proved that phosphorus-rich lines or plates were present.

Experience has shown that in commercial steels it is only when less than 0·9 per cent. carbon is present that ferrite ghost lines can be obtained, which, interpreted, means that even in somewhat impure steels, when the steel is hot, the solution pressure of the carbide in iron resists the reception of more carbide and no ferrite can appear. The phosphorus, nevertheless, exists in richer concentration the higher is the carbon, and this phosphorus-rich portion more or less surrounds the crystals of purer metal, and, being very brittle, makes the whole mass fragile. This is the reason why a given amount of phosphorus is more dangerous in high than in low carbon steels, and why it is absolutely necessary to reduce the phosphorus in steel rails, &c., if the carbon is increased in order to have non brittle material.

It will be noticed that in the paler central portions in the photograph, the pearlite patches are in half tone, while they are darker in the surrounding metal. It will also be noticed that surrounding the paler portion there is a concentration of carbon as is indicated by the greater proportion of pearlite. There can be no doubt that the phosphorus-rich portion at its freezing point was richer in carbon as well as phosphorus than the average of the steel, and that, when cooling, the carbon began to diffuse out of it and was arrested before the exodus was complete, and that the excess carbon at the boundaries is a portion of what had migrated.

Photo 31 represents a section of steel containing in the central part a portion slightly richer in phosphorus in one part than the metal exterior to it. This was primarily proved by heat tinting, and confirmed by etching with very dilute acid in alcohol, a reagent which with other weak reagents, more vigorously attack pure than phosphorised steel so that the pearlite in the former is more rapidly developed than that in the latter.

The effect of phosphorus on raising the critical point Ar. 1-2-3.

Professor Arnold has stated as the result of his trials that when the amount of phosphorus is high in steel the critical point Ar. 1-2 3 is raised.

I have confirmed this repeatedly and Professor Carpenter, experimenting on the same specimens, has confirmed my results. The steels contained 0·3 per cent. carbon. and 0·05 per cent., 0·30 per cent., and 0·50 per cent. phosphorus respectively.

The carbon and other constituents were constant, the phosphorus only being variable.

		Ar. 1-2-3.
	per cent.	
Phosphorus	0·05	698°
,,	0·30	710°
,,	0·50	720°
Average rise for each	0·1 Phos. = 4·9°	

The effect of phosphorus in raising the Ac 1-2-3 point can be graphically shown by heating small bars of soft steel, containing an axial segregation of phosphorus, at one end only in the manner described in my paper on a simple method for determining critical points, and then quenching in water and afterwards polishing and etching longitudinal sections. Working in this way the critical division between the hardened and unhardened parts of the phosphorus-rich segregate is always found to be higher than it is in the metal surrounding the segregate. This is shown in photo 36.

The slightest difference in the phosphorus has its effect, and as a consequence when steels containing about 0·05 per cent. or even less are tested by the method referred to the slight normal variation of phosphorus in different parts makes the critical division line always more or less uneven.

The practical significance of this peculiarity of phosphorus is great for it shows that in reheating steels containing 0·05 per cent. or more phosphorus either in the cast or worked condition it is necessary to heat to a higher temperature than that suggested by the equilibrium diagram of the iron carbon series in order to break up the coarse structure throughout the mass.

All steel castings contain crystals more or less surrounded by ferrite envelopes richer in phosphorus than is present in their central portions.

It will be obvious that if the temperature of heat treatment has to be raised higher than is necessary to refine the purer part of the steels in order to also refine the phosphorettic parts, the former will be coarser in structure than the latter, *i.e.*, if the temperature has been correct for the breaking up of the structure of the phosphorettic portions.

No. 4.—Commercial ternary alloys such as pig irons.

Pig irons of commerce can scarcely be called ternary alloys, as apart from the small amount of sulphur and manganese present they invariably contain silicon and should therefore in correct terms be called quaternary. As, however, they do contain the three elements, iron, carbon and phosphorus, and are of such practical interest they are referred to here.

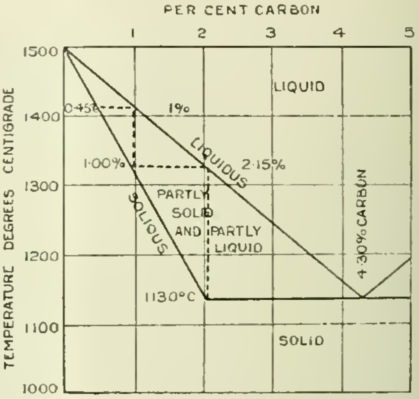
Although much has been written about the metallography of pig irons, there is still much to learn.

The equilibrium diagram of the iron-carbon series of alloys teaches much, but when phosphorus and silicon are present it must be altered materially.

A portion of the original diagram of Carpenter and Keeling is here introduced, which indicates that the first portions to freeze of any of the carbon-iron steels contain less carbon than the last portions that solidify.

From what has been stated in previous sections it may be tentatively assumed that in metal containing anything like 3·6 per cent. carbon it is impossible for any phosphorus to crystallise out with the primary crystallites because they would contain more than 1 per cent. carbon.

It is not at all proved what part the silicon plays when pig iron solidifies, but from the work that has been done it is certain that it behaves in a similar way to carbon and tends to prevent phosphorus from remaining in solid solution. It is known that some silicon crystallises with the first portions to freeze in the octahedral crystallites always present in commercial foundry irons.



When the silicon is high there is some evidence to show that a portion only so crystallises and the balance forms carbo-silicides which decompose readily almost as soon as formed during the solidification period.

The rôle played by silicon, however, cannot be considered at length in this paper. It is sufficient to note that whether the silicon is 0·6 per cent. or 6 per cent. in grey pig iron the phosphorus eutectic segregations are invariably in the same position with relation to the graphite plates, always at a distance from them.

The photo 32a shows the typical structure of all grey pig irons that contain much phosphorus. The white portions represent the eutectic; the black stripes the graphite plates; while the half tone intermediate spaces may be either pearlite or carbonless ferrite. These spaces or areas between the graphite and the eutectic have great significance, and there can be little doubt they represent a decomposition product of what at an early stage of the solidification were either carbide or silico-carbide plates which were solid before they decomposed.

By calculation it is found that the relative specific gravity and volumes of iron carbide and its decomposition products are as follows:—

Carbide of iron	Sp. gr.	7·6
Iron	,,	7·8
Pearlite		7·8
Graphite	,,	2·2

Decomposition product by volume.

	Fe_3C 100 vols.	
Iron	—	90·3
Graphite	19·8	22·7
Carbide of iron	—	—
Pearlite	91·8	—
	111·6	113·0

The volume by decomposition, partially to graphite a pearlite, and totally into graphite and iron, is great by 11·6 per cent. and 13 per cent. respectively, and t volume ratio of graphite to iron, and graphite to pearli are as 1 to 4·0 and 4·5 respectively.

It is clear then that if solid carbide is first forn and completely decomposes afterwards there should for each 1 volume of the graphite plates about 4 volur of iron, which should be found on one side or the othe divided on each side of the graphite. This concept being correct it sufficiently accounts for the phosph free strips on each side of the graphite plates.

In order to have a better idea of how the ternary eutectic is imprisoned originally during the cooling process, reference to the structure of white phosphorettic Cleveland iron must be made, for according to the hypothesis advanced all grey iron before it becomes grey must be very similar to white iron. This is shown in photo 32. The globular dark portions represent the primary crystallites; the white smooth parts the carbide plates that crystallised later; and the mixed structure—white and dark—the ternary eutectic which was imprisoned between the other constituents and the last to freeze. Imagine just such a structure as this in the cooling of grey iron before the carbide commenced to decompose. If a thick line in ink one-fifth of the diameter of the carbide plates is drawn through their centres, one then obtains some idea of the spaces that will be left between the phosphorus eutectic and the graphite.

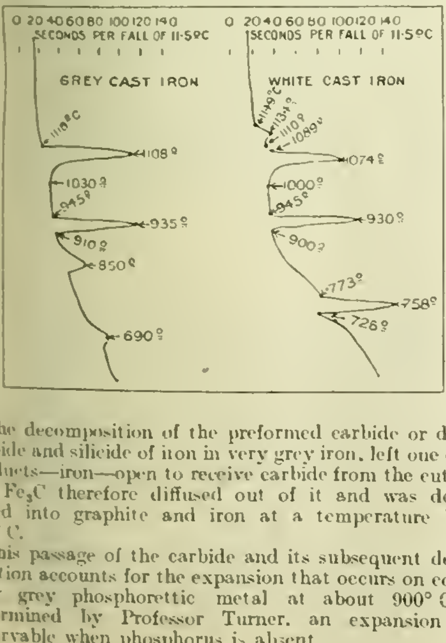
In order to enable one to follow the progressive steps that follow one another when grey pig iron passes from the liquid state, diagrammatic sketches are given in photo 33a, b, c, the first showing the primary crystallites; the second, the same after the carbide plates have formed: and the third, after the plates have decomposed into graphite and iron.

The evidence seems strong enough to dispose of the theory held by some, that the graphite falls directly as such from solution, for if it did it would be found in positions having no relation to the positions taken by the phosphide eutectic.

Professor Carpenter some years ago took for me the cooling curves of two phosphorettic Cleveland irons, one white and the other very grey and rich in silicon. The analyses are as follows:—

	White.	Grey.
	per cent.	per cent.
Combined carbon	2·98	Trace
Graphite	Traces	3·300
Manganese	0·29	0·676
Silicon	1·89	4·321
Sulphur	0·27	0·025
Phosphorus	1·62	1·660

The cooling curves show a long and pronounced arrest at about 935° to 945° C., the solidifying range of the ternary eutectic. When slowly cooled the eutectic in the white iron was ternary, and in the grey iron binary.



The decomposition of the preformed carbide or double rbide and silicide of iron in very grey iron, left one of the oducts—iron—open to receive carbide from the eutectic, e Fe_3C therefore diffused out of it and was decomsed into graphite and iron at a temperature below 5° C.

This passage of the carbide and its subsequent decomsition accounts for the expansion that occurs on cooling y grey phosphorettic metal at about 900° C. as ermined by Professor Turner, an expansion not ervable when phosphorus is absent.

The character of phosphorettic grey foundry iron as compared with similar irons free from phosphorus at temperatures a little above the point when the eutectic solidifies at 945° must be profoundly different, for in the former the metal will be more or less plastic containing as it does in Cleveland iron about 20 per cent. of fluid, whereas in the latter the whole mass must be quite rigid. It is on this account one explains why the total apparent contraction on cooling the long bars of phosphorettic iron in Professor Turner's trials was so much less than that of similar bars of non-phosphorettic iron.

The phosphorettic bars being plastic at a time when the others were quite rigid the friction on the sides of the former by the sand of the mould would check the longitudinal contraction in the early stages of cooling above 945° C.

The final and true contraction assuming that the same amount of graphite is formed in each case should be equal, but distributed over a longer range in the case of the phosphorettic metal than in the metal free from phosphorus.

On a "bear" from the hearth of a blast furnace at the Skinningrove Iron Works.

It has previously been stated that the primary fir-tree crystallites which form in pig iron and in alloys rich in carbon and phosphorus must be free from phosphorus.

On subjecting partially solidified cast-iron to pressure it is possible to express some of the more fusible portions, but no one has ever succeeded in squeezing out practically all the phosphorus ternary eutectic so as to leave only the primary crystallites behind. Fortunately, however, Nature has actually done this for us in the hearth of a blast furnace.

The furnace referred to is one of several furnaces owned by the Skinningrove Iron Co., Ltd., Carlin How, Yorkshire, and the metal was a portion of a huge mass which had solidified in the hearth.

Mr. T. C. Hutchinson, the managing director, having supplied me with a specimen and its analysis, I made a careful examination of it with the results that follow:—

The specimen handed to me consisted of a series of columnar masses of iron 3 to 4 inches in length. These were separated at intervals by porosities and by oxide scale and free carbon. The analyses were as follows:—

	Stead.	Skinningrove.
	per cent.	per cent.
Iron	93·400	—
Combined carbon	0·562	0·480
Graphite	1·640	1·050
Manganese	0·173	—
Silicon	1·166	1·410
Sulphur	0·103	0·082
Phosphorus	0·155	0·090
Oxygen, etc.	2·801	—
	100·000	

Specific gravity .... 7·14
Phosphorus squeezed out .... about 90 per cent.

The metal represented such interesting features that by the courtesy of Mr. Hutchinson, I visited the works and examined portions of the "bear" which had been blasted out of the hearth. There were about 500 tons of broken up pieces. From information kindly given me it appeared that the lining at the top of the furnace fell in when the furnace was being blown out more than ten years ago, and the blast was turned off while the furnace shaft still contained unburnt coke and other material. The whole mass, including the liquid metal below the hearth level, was then allowed to cool naturally. When blasting out this "bear" the workmen came upon a quantity of metal exactly in the centre of the mass exceedingly tough and difficult to break. When broken up it presented the appearance of a columnar basaltic formation with vertical columns one-eighth inch to one-quarter inch in diameter and above a foot in length. Photos 34 and 34a. On analysis it was found to be nearly free from phosphorus, and as nothing but phosphorettic pig iron had been made in the furnace during its life, it surprised everyone.

On examination of the pieces of metal I noticed the columnar arrangement of the iron referred to and immediately surrounding this, metal which was coarsely graphitic in character and quite different from the portion in the centre. This on fracturing I found had a schistose appearance; other pieces were found which resembled in fracture the ternary eutectic, and others which had protruded into the ground outside the hearth. The fracture of the latter at the outer extremity was white and granular and evidently contained very little carbon. All these specimens were carefully examined. The results of examination are given below, viz.:—

First.—The central basaltic mass with columns at least three feet in length contained little phosphorus. The columns were coated with magnetic oxide and free carbon.

Second.—The iron columns were decarburised at their boundaries where oxide of iron existed.

Third.—The ferrite juxtaposed to the oxide was radial in structure—a condition which proved that decarburisation had occurred at temperatures between 700 and 900° C. Photo 35.

Fourth.—The little masses outside the columns, found in portions of the lumps, had a fracture corresponding to that of the ternary eutectic, and was proved to consist of that substance. Photo 5.

Fifth.—The columns in the metal from the second ring contained 1·3 per cent. phosphorus, and were divided by more or less vertical plates of graphite and had a schistose appearance.

Sixth.—The tongue-like piece of metal which had penetrated into the ground outside the hearth contained only 1·7 per cent. carbon and consisted of grains of pearlite surrounded by the ternary eutectic. The partial decarburisation had evidently been effected by moisture and steam from the damp soil; moreover the iron itself had been oxidised, for a thick layer of oxide had formed which adhered to the surface.

With the evidence available before us, it is possible to trace what had occurred after the stoppage of the furnace. The huge mass of liquid iron, considerably over 600 tons, had cooled with extreme slowness, being under the ground level and covered with a mass of hot material. The outer portions would, of course, solidify first and the enormous solid cylinder of metal so formed in cooling must have contracted and compressed the fluid inside, and as long as the latter was quite fluid the central mass would rise vertically, but in course of time it would begin to freeze and the first purer crystallites of the fir-tree type would separate from the liquid and eventually the whole central column would become a mixture of pure solid interlacing crystals with the liquid ternary eutectic between their branches.

When this stage was reached and the surrounding solid ring continued to contract round the pasty mass, only one thing could happen, the same as what occurred when I squeezed nearly solid Cleveland iron, the eutectic was forced to pass away from the solid crystallites, and in doing so was obliged to pass upwards and make a series of parallel vertical passages along which to flow. The solid crystallites were thus pressed together into solid vertical columns, while along the junctions continuous streams of the eutectic would flow upwards and escape into the upper layers. After the inside of the columns had been freed from liquid the continued pressure would finally squeeze out practically all the phosphorus rich liquid still existing between the junctions of the columns. At this point, when no more liquid could be expressed, the whole plastic highly heated mass—probably at a temperature of 1000° C.—would itself have to elongate upwards, and it was at this stage the columns must have been sliding one against another along the original junctions where traces of the mother liquor remained mechanically imprisoned. Incidentally, the cylinder of grey metal which enveloped the columnar central mass and which had retained most of the phosphorus originally present, not being able to freely compress the solid mass inside of it and being itself surrounded by a greater mass which was contracting on it, must have vertically elongated, and in doing this it separated into a series of vertical columns, the free graphite plates forming gliding planes at their junctions.

As cooling was continued and the outer mass ceased to contract or to contract slowly, the central portion being the last to cool must at one stage have exerted tensional pull on the metal surrounding it, but not being able to pull it inwards it partially separated along the original planes of flow, into loosely attached vertical columns, leaving porous passages between them. The material in the furnace above the hearth when still warm and exposed to rain which was free to fall upon it, evaporated the water as it percolated downwards, and this would pass into the central mass along the contraction passages, not only oxidising the surfaces of the columns but actually decarburising the iron. It is difficult to offer any other explanation to account for the oxide of iron which more or less completely covered the surface of the columns themselves. How long 600 tons of metal took to cool down none can tell, it would probably be more than three months.

Mr. Hutchinson has expressed his willingness to supply colleges and museums and other institutions with specimens of the central portions of the "bear," a courtesy which should be taken advantage of by all who are interested in the constitution of foundry irons.

Summary.

1. The constitution of the alloys of iron and phosphorus have been described in chemical terms. The more important of these are the binary eutectic containing 4·18 per cent. phosphide of iron in solid solution in iron and 61·4 per cent. free phosphide of iron, and the solid solutions of iron and phosphide of iron saturated, when 10·8 per cent. of the latter and 89·2 per cent. of the former are associated. These solid solutions increase in hardness with the increase of dissolved phosphide of iron. Each 0·01 per cent. phosphorus added to pure iron increases the hardness by about 1·3 Brinell degrees.

The resistance to corrosion appears to be proportional to the phosphide in solid solution, but more work is required in this specific direction.

2. The eutectic of iron and carbon contains about 50 per cent. free carbide of iron and 50 per cent. iron saturated with carbide of iron at 1130° C. Some of the carbide crystallises out of the solid solution in cooling and at about 700° C. the eutectic contains 59 per cent. free carbide of iron and 41 per cent. iron saturated with carbide.

3. On subjecting phosphorettic iron to great pressure when it is in nearly a solid condition, practically pure ternary eutectic of iron-carbon-phosphorus is expressed which has the composition of iron 91·19 per cent., carbon 1·92 per cent., phosphorus 6·89 per cent. This eutectic solidifies at about 945° C. and the arrest found by Carpenter when cooling both grey and white phosphorettic iron at 945° C. is that due to the solidification of the eutectic which is the last portion to freeze in pig irons containing phosphorus. The analysis of the ternary eutectic, expressed constitutionally, is:—

	Per cent.
Free iron phosphide	41·5
Iron saturated with phosphide	29·1
Iron carbide	29·4

4. The ternary eutectic in very grey iron decompose on cooling into the binary eutectic and pearlite or iron.

5. In Part II. a few of the triple alloys are describe and the changes which occur during solidification, reheati and slow cooling. When the phosphorus is high—abou 2 per cent.—and the carbon low, the first crystallites grow are free from carbon. The carbon and some of t phosphorus and iron form a eutectic which is found in t cold alloy between the branches of the primary crystallit and surrounding the crystals. On slow cooling, the carbi diffuses out of the eutectic and forms a pearlite fringe rou the eutectic, but in diffusing into the surrounding sol solution of phosphorus and iron, the carbide throws so of the phosphide out of the solid and this appears as f laminæ in juxtaposition to the pearlite carbide. A frin is thus formed consisting of three constituents iron carbide—phosphide.

On carburising this alloy by cementation, as the carbon enters at 1100° C. it displaces the phosphide, and a fusible eutectic is formed which liquates entirely out of the metal to such an extent that only half of the original phosphorus remains in the outer layers.

6. On melting an alloy containing 1·2 per cent. phosphorus and 0·12 per cent. carbon and cooling rapidly, eutectic envelopes surround the crystals in the cold alloy, but if cooled slowly the phosphorus diffuses into the centre of the primary crystallites and no eutectic is visible, the carbon remaining as pearlite in patches.

On gradually increasing the carbon, more and more eutectic is found in the cold alloy and when about 1 per cent. carbon is present practically the whole of the phosphorus is concentrated in the eutectic envelopes.

On further increasing the carbon the excess appears as plates of free carbide cutting through the body of the primary crystallites and when 4 per cent. is present graphite appears in the cold alloy, which is grey in fracture.

7. When an alloy with only 0·5 per cent. phosphorus and 0·3 per cent. carbon is melted, on slow cooling the greater amount of phosphide is found entirely in solid solution in rich segregations surrounding the primary crystallites, but they are quite free from carbon. On forging, these concentrations are drawn out into lenticular shaped bodies and are free from carbon. They resemble the "ghost lines" in large forgings, which it is shown have their origin in segregations of phosphorus. If steel must be free from these, it is necessary to have as little phosphorus in the steel as possible.

8. The order of crystallisation, when white and grey phosphoretted pig-irons solidify and cool down, has been traced, and it has been shown that the fir-tree type of crystallites are the first to form; following this the carbide or the silicocarbide of iron crystallises, while the ternary eutectic of iron-carbon-phosphorus is imprisoned in the spaces between the pre-formed solid crystallites, and is the last to solidify at 945° C.

In white iron the carbide or silicocarbide crystals remain as such in the cold alloy. In grey irons, however, the carbides decompose into graphite and austenite almost immediately they have become solid. When cold in the case when the carbides are completely decomposed the decomposition product consists of about one-fifth of graphite and four-fifths of iron by volume and the iron is almost always deposited on each side of the graphite plates. The broad bands of phosphorus-free material on each side of the graphite plates in grey pig-iron are a proof that the carbides crystallise and are solid and afterwards are decomposed and not, as some have suggested, that the graphite simply falls out of liquid solution, for, if this were so, the graphite plates would be heterogeneously arranged and not in the positions they are found surrounded by phosphorus-free layers of pearlite or ferrite.

9. An interesting mass of metal found in the hearth of a blast furnace at Skinningrove has been described, which, owing to the enormous amount of circumferential pressure during the time it was solidifying, had practically the whole of the ternary eutectic squeezed out of it, leaving the cold metal arranged in columnar form resembling the basaltic formation of the Giant's Causeway and early free from phosphorus.

In conclusion, I must acknowledge the valuable co-opera-on of Mr. J. L. Potts and his steel melter—Mr. Duckin-ld; of Messrs. J. H. Andrew and Co., Ltd., Sheffield; essrs. Hobson, Houghton and Co., Ltd., Sheffield; essrs. Wm. Shaw and Co., Ltd., Middlesbrough; Messrs. hos. Sorby and Sons, Sheffield; Messrs. Bolckow Vaughan ad Co., Ltd., Middlesbrough, and Mr. F. Outhwaite, their sistant furnace manager; Mr. T. C. Hutchinson, of essrs. The Skinningrove Iron Co., Ltd., Carlin How; d my own assistants—Messrs. E. W. Jackson, A. Scholes, H. Bellwood, and T. E. Towers.

APPENDIX I.

tectics.

A eutectic is a definite mixture of two or more con-uents which melt and solidify at a fixed point, a point ch is lower than the average melting or freezing points the component substances.

A eutectiferous alloy is a mixture of two or more metals or non-metals which are capable of forming a eutectic and which may or may not be in definite eutectic proportion. During solidification, when not in such proportion, the excess of one or the other of the substances first crystallises out leaving a liquid of definite eutectic proportion. This last portion, when liquid, resembles a "mother liquor," and, after solidification, is sometimes called a "solidified mother liquor." Guthrie coined the term eutectic.

Certain substances when mixed together have the peculiar physical effect of making very fusible mixtures. For instance, a mixture of iron saturated with phosphide which freezes at 1400° C. and iron phosphide which freezes at 1100° C. when melted together in the proportion of 61 per cent. phosphide and 39 per cent. iron does not solidify at the average temperature of these two substances, 1230° C. but at 1000° C., or 230° C. below the average.

Salt, which solidifies at 800° C. and water freezing at 0° C., when mixed together in the proportion of 23 per cent. salt and 77 per cent. water freeze at minus 22° C., or 422° C. below the average. Both these mixtures are eutectics.

The fusible alloys consisting of mixtures of two or more metals are essentially eutectics.

Eutectics are not definite chemical compounds. On solidification they usually split up into their constituents and are found in the solid binary alloys as honeycombed masses containing cells filled with one of the substances, and in the ternary alloys independent portions of three constituents.

In many cases the mixtures on freezing do not separate into the pure simple substances. The iron phosphide eutectic is an example, for a portion of the phosphide is retained in solid solution in the iron and it is this which separates at 1000° C. along with and at the same time as the iron phosphide.

Solid solution.—Glass and obsidian are types of non-crystalline solid solutions; they contain several substances homogeneously solidified together. On heating them, however, to certain temperatures some of the substances crystallise out and they become opaque and then are no longer simple solid solutions.

Many substances crystallise together into homogeneous crystals, and only one substance can be detected under the highest power of the microscope; they have all the properties of simple crystals as indicated by crystalline cleavage, crystalline orientation and crystalline habit. For instance, iron crystallises in the cubic system, and in freezing assumes the form of octahedral crystallites and the complete crystals cleave readily in three directions at right angles corresponding to the cleavages of the cube. Iron alloyed with traces up to about 10·9 per cent. phosphide of iron crystallises in exactly the same way, and the crystals have the same cubic cleavages as pure iron; the two substances are in solid solution. On heating the homogeneous alloys of iron and phosphide under certain temperature conditions a portion of the phosphide separates from solid solution and appears as ill-formed plates in the cleavage planes of the crystals.

The conception of solid solution, however, cannot be considered as beyond doubt excepting in the cases where they are non-crystalline. Some authorities hold the view that what are called solutions are mixtures crystallised together in chemical molecular groupings. Until, however, chemical combinations are proved the solution theory may be tentatively accepted.

APPENDIX II.

Method for the separation of free phosphide of iron from alloys.

In 1900 I described a crude method for approximately determining the free phosphide of iron in pig irons, etc. It was based on the relative insolubility in cold nitric acid, 1·20 sp. gr. Many approximate results were given, but no claim for accuracy was possible. Further study of the subject has led to the conclusion that analytical methods must fail on account of the complex character of the eutectics and the fact that the cell substance in them is enclosed more or less completely with solid Fe_3P

which prevents the more soluble part of the eutectics being attacked by chemical solvents. One is therefore obliged to study the structure and base one's conclusions on that and on other evidence obtained by systematic experiment, such as has been described in this paper.

MR. E. F. HOOPER IN THE CHAIR.

EXTRACTION APPARATUS, SPECIALLY DESIGNED FOR SOLVENTS OF HIGH SPECIFIC GRAVITY.

BY DR. C. BUDDE.

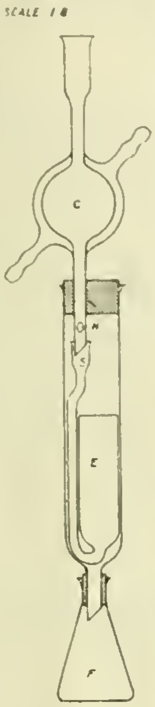
When a couple of years ago I had to make a larg number of extractions of wax from some vegetable sub stances I failed to find an apparatus specially suite for my purpose, in spite of the large number of suc apparatus already in existence.

As a solvent I had to use chloroform or carbon tetra chloride, as these were apparently the only solvent in which the wax in question was completely soluble—and that only at the boiling point of the solvent.

The point I wish to draw special attention to is this When an ordinary fat or wax is dissolved in one of thes heavy solvents, then the solution has a lower specif gravity than the pure solvent itself—in contradistinctio to what occurs when ether or benzine or any other solve of low specific gravity is used. The obvious consequen is that in my case the solution had a tendency to ri to the surface, and should be removed from there, whi fresh solvent should be supplied from the bottom, speedy and efficient extraction should be attained.

It seemed to me that previous designers of extracti apparatus had had no occasion to consider the importan of this fact, so I constructed the apparatus shown the drawing with this point in view and also keeping mind that the extraction should be performed all t time at the boiling point of the solvent.

The drawing hardly needs any explanation. T material to be extracted is placed in the extractor, either loose (with a plug of cotton wool on top prevent small particles from getting down in the fla or in a thimble or otherwise, according to the natur substance. The vapours of the solvent the pass out the extractor, E (keeping this at the boiling temperature), through the hole, H, in the condenser tube into the condenser, from where the condensed solvent flows through the side tube, S, into the bottom of the extractor. The solution of wax or fat overflows from the top of the extractor down into the flask, F. After the extraction is finished the extractor may be taken out, dried and weighed to corroborate the result obtained by weighing the flask.



I found that I was able to do the extractions not only more quickly but also more completely with this apparatus than than with an ordinary Soxhlet. It may, perhaps, also be mentioned that very little more solvent is required than is needed to fill the extractor, E, and that the bulk of it remains there when the extraction is finished.

In my case I gained yet another point by this apparatus, because I had to perform the extraction in the presence of water. This, of course, rose gradually to the surface of the solvent in the extractor and trickled down into the flask below, while in a Soxhlet it had a tendency to remain behind when the solvent emptied itself out through the syphon tube. The *modus operandi* in such cases was generally to put some water into the flask from the beginning together with the solvent. After the extraction was finished the rest of the solvent was removed by boiling the water, and on then cooling it was fairly easy to take out quantitatively the hard cake of wax floating on the surface of the water, dry it and weigh it.

It is obvious that the length of the side tube, S, should suit the purpose in view, if more than one volatile liquid be involved in the process. Supposing, for instance, that water is present and the specific gravity of the solvent is 1·5, then, if the height of the side tube be less than 1·5 times that of the extractor, the condensed water coming down from the condenser will overflow from the side tube and never enter the extractor, while if the height of the side tube be more than 1·5 times that of the extractor, the water will force its way through the solvent and overflow from the extractor.

Possibly the apparatus may be found useful for other purposes than the one mentioned. I have been able to use it with advantage for the extraction of liquids such as aqueous solutions or emulsions with solvents of lower specific gravity such as ether. It goes without saying that in such cases the side tube, S, must be high enough to allow the ether to force its way through the water into the extractor.

My apparatus have been made by Messrs. Brady and Martin, Northumberland Road, Newcastle-on-Tyne.

Yorkshire Section.

Meeting held at The University, Leeds, on Monday, January 26th, 1914.

MR. GEORGE WARD IN THE CHAIR.

FIELD METHOD FOR DETERMINING DISSOLVED OXYGEN IN WATER.

BY JAMES MILLER, F.I.C.

As the pollution of a water by organic matter increases. e amount of oxygen held in solution decreases until a int may be reached where the latter is nil.

Given free contact with air a polluted water will absorb oxygen and eventually become purified so far as readily oxidisable matter is concerned. Therefore a determination of the amount of dissolved oxygen becomes an important factor in judging the character say, of a stream into which effluent of a polluting character is discharged. This is borne out by the prominence which is given to dissolved oxygen in the Eighth Report of the Royal Commission on Sewage Disposal. Many methods have been suggested for determining dissolved oxygen in water but these have been designed mainly for laboratory use. A field method was proposed by Ramsay and Homfray (this J., 1901, 1072); this, however, requires special apparatus. Also the results are said to be modified by the presence of nitrites.

Mackey and Middleton published a method based on the use of pyrogallol and caustic potash (this J., 1898, 1127), and, working in Mr. Mackey's laboratory, my attention was drawn to the method with a view to adapting it to field work. It was found that the colour produced by the action of alkaline pyrogallate on the dissolved oxygen changed rather quickly and at times erratically, also that the colour produced was not exactly proportional to the quantity of oxygen present.

Pyrogallol with ammonia was tried but found useless. Various substances analogous to pyrogallol were tried in conjunction with caustic potash, *i.e.*, gallic acid, resorcinol, catechol, and quinol (hydroquinone), but none of these was of use.

It occurred to me that advantage might be taken of the colour produced by the action of potassium thiocyanate on ferric salts. Ferrous sulphate and caustic soda were added to a water under a layer of toluol, then acidified with hydrochloric acid and potassium thiocyanate added. The colour produced was matched with a standard ferric chloride solution. Good results were obtained when the oxygen was under 5 c.c. per litre, but over that amount the colour became too deep to match accurately. Also nitrites had a disturbing effect. The method was therefore discarded.

To overcome the detrimental effect of nitrites it seemed that the most likely line to work on would be one in which the ferrous iron could react, and any excess be detected, in an alkaline solution. Potassium ferrocyanide, the usual reagent for ferrous iron, is of no use in alkaline solutions, so another indicator was sought for without success until I saw a paper by Linossier (this J., 1891, 726) in which phenosafranine is used as an indicator for ferrous iron in presence of alkaline tartrate for the determination of dissolved oxygen in water. So the method I have now to describe becomes Linossier's adapted to field conditions.

Linossier's original process is essentially for the laboratory, involving the use of 400 c.c. of mercury, the water under examination being completely isolated from contact with the air, and is designed to give accurate results. I have found though that with very little apparatus it gives sufficiently accurate results, and, as a field method, may be used so as to give a determination in a minute or two, thus enabling one to make a large number of determinations and decide as to the condition, say, of a stream at different points, and to follow up at once any clue as to pollution.

The method I adopt is as follows:—

To 50 c.c. of the water contained in a 100 c.c. Nessler cylinder are added 5 c.c. of alkaline tartrate such as is used for Fehling's solution and one drop of phenosafranine solution (1 in 2000 of water), then from a 10 c.c. graduated pipette a solution of ferrous sulphate (0·22 grm. of pure $FeSO_4$ and 1 c.c. of conc. sulphuric acid in 100 c.c.) is run in just below the surface of the liquid stirring gently with the pipette until the colour is discharged, looking through the cylinder horizontally. The ferrous sulphate is added 1 c.c. at a time until the colour begins to fade then in additions of 0·5 c.c. to the end. There is a slight colouration at the surface of the liquid, but if the stirring is not too vigorous this does not interfere. The outlet hole of the pipette should not be more than 1 mm. in diameter to minimise diffusion.

The pipette reading gives the cubic centimetres of oxygen per litre. Theoretically 1 c.c. ferrous sulphate of above strength does not equal 1 c.c. oxygen per litre working on 50 c.c. of sample (0·25 per cent. $FeSO_4$ is theoretical strength) but under the conditions stated I have found that the above strength gives correct results.

Each experimenter should standardise his ferrous sulphate against water of known oxygen content, say distilled water shaken with air until saturated, taking the temperature and referring to Roscoe and Lunt's table (Sutton's Volumetric Analysis, page 260) for the amount of dissolved oxygen present.

In the following table are given some results by this (the field) method, compared with results obtained by the Winkler method :—

	Winkler.	Field method.
	c.c.	c.c.
Leeds supply	7·8	8·0
River Aire	7·0	7·5
River Aire	4·9	5·2
Effluent	2·0	2·5

Normal, 2-normal, and 3-normal solutions of sodium chloride contain, according to Winkler (this J., 1911, 382 and 644) at 16° C., 4·7 c.c., 3·4 c.c., and 2·4 c.c. of oxygen per litre respectively. By the field method, 5·0 c.c., 3·5 c.c., and 2·5 c.c. were obtained.

The ferrous sulphate keeps well. After keeping in a bottle repeatedly opened, and nearly empty, for four weeks, only 0·67 per cent. of the total iron had become oxidised. Experiments on samples containing up to 60 parts of sodium nitrite per 100,000 showed that nitrites had no effect on the method.

As dissolved oxygen plays an important part in the extraction of gold from gold ores by cyanide solutions, the method was tried on a 0·5 per cent. solution of potassium cyanide, but no end reaction could be obtained ; evidently the ferrous sulphate combines with the cyanide.

Discussion.

Mr. W. McD. Mackey wrote that he had used the method for practical work in the field, for determining the extent and persistence of pollution of a stream from a known source. He had found the manipulation was easy, and the time required for a test to be only about two minutes.

Dr. H. T. Calvert said that he had worked the process on the River Calder, and he could bear out all that Mr. Miller said. The methods at present in use would be divided into two classes, those suitable for very clean waters, and those suitable for dirty ones. Ramsay's method was only of use for very clean waters. Winkler's method was of almost universal application. The method advocated by Mr. Miller generally gave results rather lower than Winkler's method. They had adopted Winkler's method because it was accurate and easily carried out. The apparatus only weighed five or six pounds, and in order to simplify the operations in the field, they could proceed as far as the precipitation of the manganese hydroxide, and then finish the estimation in the laboratory.

Mr. Ward asked how the colour of the water would affect the results.

Mr. Miller replied that a pale colour of the water had no effect whatever on the results. Any water could be tested so long as it was not pink. He had determined the dissolved oxygen in an effluent which had a distinct pale blue colour, and the end point was quite sharp.

Journal and Patent Literature.

Patent Specifications may be obtained by post by remitting as follows :—

English.—8*d*. each, to the Comptroller of the Patent Office, W. Temple Franks, Esq., Southampton Buildings, Chancery Lane, London, W.C.

United States.—1*s*. each, to the Secretary of the Society.

French.—1 fr. 05 c. each, as follows : Patents dated 1902 to 1907 inclusive, Belin et Cie., 56, Rue des Francs Bourgeois, Paris (3e.) ; Patents from 1908 to date, L'Imprimerie Nationale, 87, Rue Vieille du Temple, Paris.

German.—1 mark each (with full particulars) to Kaiserlich Patentamt, Berlin, Germany.

I.—GENERAL PLANT ; MACHINERY.

Patents.

Extraction of liquids or solids held in suspension or combined in gases or fumes. J. Armstrong, London. Eng. Pat. 569, Jan. 8, 1913. Addition to Eng. Pat. 821, Jan. 10, 1912 (this J., 1913, 184).

The apparatus described in the principal patent is improved in that the compressed gases are passed in succession through a number of nozzles immersed in different liquids, each adapted to separate out a particular impurity ; the nozzles are carried on frameworks fixed to detachable lids, so that they can be removed for cleaning ; the chambers may be of cylindrical form with radial or tangential nozzles for the gas and conical collecting chambers for the impurities beneath.—H. H.

Distillation of liquids ; Process for the ——. Naamlooze Vennootschap Maatschappij Destillator. Fr. Pat. 461,822, June 25, 1913. Under Int. Conv., June 26, 1912.

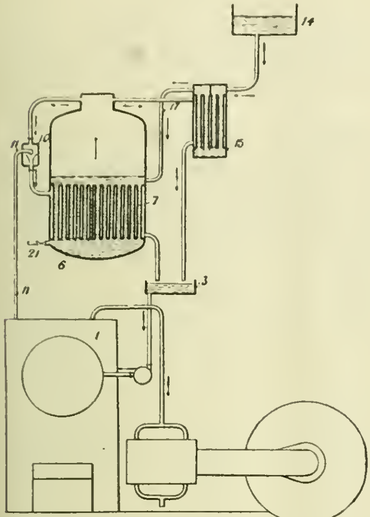
Heated water from engine or other condensers is fed into an evaporator in a finely divided condition and is exposed to a vacuum so that part of the water is evaporated by its own heat, the vapour passing to a condenser also under vacuum.—W. H. C.

Measuring the flow of fluid through a conduit ; Instruments for ——. The British Thomson-Houston Co., Ltd., London. From General Electric Co., Schenectady, New York, U.S.A. Eng. Pat. 2417, Jan. 29, 1913.

The pressure difference in a Venturi tube, Pitot tube, or similar measuring device is indicated by means of a mercury gauge supporting a short column of an " opaque substance such as carbon tetrachloride " contained in a narrow glass tube. The upper end of this tube is connected with the low-pressure side of the Venturi tube, while the lower end, which is enlarged, dips into a vessel of mercury connected with the high-pressure side. A permanent record of the pressure differences is made by a marking point carried by a lever attached to a U-shaped magnet, which encloses the vessel of mercury and moves in conjunction with a magnetic body floating on the surface thereof.—H. H.

Distilling feed water for boilers ; Process and apparatus for ——. Soc. d'Exploitation des Procédés Evaporatoires, Systéme Prache et Bouillon, Paris. Eng. Pat. 1583, Jan. 20, 1913. Under Int. Conv., Jan. 19, 1912.

Steam from the boiler, 1, enters the injector, 10, by the pipe, 11, and withdraws steam from the evaporator, 6, compresses it and injects it into the heating arrangement, 7, of the evaporator ; the steam is condensed and the condensed water flows into the tank, 3. The impure water flows from the tank, 14, through the heater, 15, where it is heated by a portion of the steam from the evaporator, 6, which is also condensed and flows into the tank, 3.



The heated water enters the evaporator, 6, by the pipe, 17, and is evaporated. The boiler is fed with the pure condensed water from the tank, 3, which has a temperature of about 100° C. and as only a small portion of the steam produced is required to actuate the compressor, 10, and the remainder can be utilised in any desired way, only a small increased fuel consumption is required to enable the boiler to be fed with pure hot condensed water. The impurities become concentrated in the evaporator, 6, and are got rid of by blowing off at intervals a portion of the liquor in the evaporator through the cock, 21.—W. H. C.

Air; Method of heating a current of ——. A. G. Bloxam, London. From Bergmann Elektricitäts-Werke A.-G., Berlin. Eng. Pat. 11,874, May 21, 1913.

An electrical heating apparatus is inserted in the suction pipe or receiving chamber of a dust suction plant or a vacuum cleaner.—W. H. C.

Dryers with rotary agitators. F. E. Otto and Phönixwerk G. m. b H., Meerane, Germany. Eng. Pat. 14,502, June 23, 1913.

The material is carried slowly through a drum by a set of rotary spiral heating coils arranged in the manner of a screw conveyer, the pitch of the spirals decreasing from the intake side of the dryer to the discharge side in order to make allowance for the decreasing bulk of the material as it becomes dry. Agitator blades mounted outside the spirals scrape material from the lower walls of the drum, lift it above the heating coils, and drop it thereon as the rotation proceeds. An additional heating coil may also be arranged in close proximity to the wall of the drum. —H. H.

Drying installations for all kinds of materials. A. Huillard. Fr. Pat. 461,611, July 31, 1913.

An improvement in the apparatus described in Fr. Pat. 318,562 of 1902 (see Eng. Pat. 17,663 of 1902; this J. 1902, 1386), whereby the material is passed over a sieve before it enters the drying tower. The coarser particles are fed into the upper part of the tower and the finer material enters lower down along with a supplementary supply of air which also assists in the sifting.—W. H. C.

Dryers; Stage ——. A. Huillard. Fr. Pat. 461,612, July 31, 1913.

The material is fed into the top of a tower provided with a number of horizontal perforated shelves. It is swept from the periphery to the centre of each shelf by agitators driven from a central shaft and is dried by a current of hot air which passes up the tower. When the material reaches the centre of each shelf it falls into a box provided with sliding baffles which allow the material to pass downwards but prevent the air passing upward so that the latter is forced to pass through the perforations in the shelves. The material falls from the box on to a conical spreader which guides it to the periphery of the shelf below.—W. H. C.

Filter [for slimes]. H. Alinder, Milwaukee, Wis., Assignor to Allis-Chalmers Manufacturing Co. U.S. Pat. 1,084,383, Jan. 13, 1914.

A number of wedge-shaped filter cells are arranged round a horizontal shaft which is rotated above a tank so that the cells are partially immersed in the tank. The cells have openings on the outer side for the supply of the "slimes" and inward openings for the discharge of the cake over the edge of the tank.—W. H. C.

Filters; Vacuum drum —— for the concentration of precious metals and other applications. G. Spence. Fr. Pat. 461,346, Aug. 12, 1913. Under Int. Conv., Aug. 31, 1912.

The periphery of the drum is divided by projecting ⊥-shaped bars into sections, in each of which is fixed a removable arc-shaped filter-element consisting of a shallow metal box covered with suitable filtering material supported on metallic gauze or on a perforated plate. The periphery of the drum is supported from the axis by a double series of radial tubes; one of each series is attached to each filter element and serves to connect it, through sleeves on the axis, in the one case with a vacuum pump and in the other with a supply of compressed air. The drum is rotated, partly immersed in a tank containing the liquid or mud to be filtered and the elements immersed are in connection with the vacuum pump. As each element comes to the discharge position, the vacuum is automatically cut off and compressed air is admitted which forces the cake off the surface. It is claimed that the action of the vacuum and compressed air is localised where it is required and that the filter elements can be easily and quickly replaced or repaired.—W. H. C.

Filter; Rotary drum ——. C. C. Bohm. Ger. Pat. 268,620, Jan. 30, 1913.

A curved, non-perforated, fixed plate extends across the lower part of the perforated drum which dips into the liquid to be filtered, and is provided with two pipes which extend upwards and then axially through the drum to opposite ends thereof. One pipe serves for suction of the liquid through the filter-drum, whilst the other serves for passing air either by suction or pressure through the filter-cake on the outer surface of the drum in order to dry it. —A. S.

Filtering material of high efficiency; Process of obtaining a ——. F. Pott. Fr. Pat. 461,386, Aug. 14, 1913.

Porous minerals are impregnated with an albuminous substance (blood, etc.) dissolved in alkali solution, then dried, and heated to redness out of contact with air. The carbonised mass is washed to remove soluble salts, and, if desired, may then be impregnated with iron, aluminium, manganese, nickel or cobalt hydroxides mixed with calcium carbonate.—W. P. S.

Evaporation of liquids, particularly saccharine juices; Process and apparatus for the ——. J. C. Grière. Fr. Pat. 461,208, Aug. 8, 1913. Under Int. Conv., Aug. 23, 1912.

The evaporator is divided, except in the vapour space above the liquid, into a number of separate compartments (*e.g.*, six) each comprising an upper and a lower chamber connected by a bundle of vertical tubes. In each compartment the heated liquid rises from the lower to the upper chamber and then passes from this to the lower chamber of the next compartment by a tube which is not heated and which may be external to the apparatus or may pass down a central duct. The liquid thus passes through each of the compartments in turn; its rate of flow, and therewith the degree of concentration attained, may be regulated by valves in the inlet pipe.—J. H. L.

Evaporating apparatus for all kinds of liquids. E. A. Barbet. Fr. Pat. 461,890, Nov. 8, 1912.

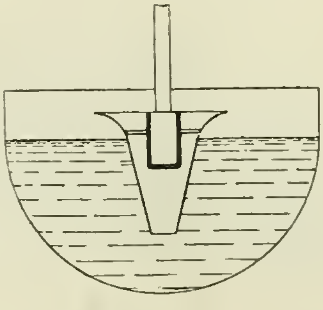
The tubes of a vacuum evaporator are arranged in two sets at an angle to each other, the liquid passing first through the lower set to a junction-box and back through the upper set to the main chamber of the apparatus where separation into vapour and liquid takes place. In this way the tubes may be short, easily cleaned, and yet at the same time afford a long distance through which the liquid must travel.—W. H. C.

Chemical reactions and thermal processes; Process and apparatus for the execution of —— *the materials treated being in a finely divided condition in solution or suspension.* A. Pollak. Fr. Pat. 461,446, Aug. 18, 1913. Under Int. Conv., Oct. 18, 1912.

The material (*e.g.*, a solution to be evaporated) is introduced in a finely-divided condition into the narrow upper part of a chamber along with a supply of heated air or gas and they pass downwards into the larger conical part of the chamber which is provided with baffles to assist the separation of solid particles produced by evaporation of the liquid. The gas is withdrawn from the top of the lower part of the chamber and is caused to pass through two condensers placed in series. In the first the separation of the solid particles is completed and in the second the vapour is condensed. The gas next passes through a fan which maintains a slight vacuum in the chamber and thence through a heater back to the main chamber to be used over again.—W. H. C.

Spraying liquids and intimately mixing them with gases or vapours; Device for ——. Salzbergwerk Neustassfurt und Teilnehmer. Ger. Pat. 267,939, March 12, 1912.

The device (see fig.) is hollow and is rapidly rotated whilst partly immersed in the liquid. Owing to the conical shape of the device, the liquid is drawn in at the lower edge, then forced upwards and delivered from the upper edge in the form of a fine spray.—A. S.



Purification, clarification and decolourisation of liquids and gases; Process for the ——. R. Marcus. Ger. Pat. 268,057, March 26, 1912.

The liquid or gas is treated with finely divided, artificial silicic acid, which has been freed from foreign adsorbed substances, and is subsequently filtered; the impurities are retained on the filter by the silicic acid.—A. S.

Crystals; Apparatus for separating large —— *from hot solutions by artificial cooling.* Gewerkschaft Carlsfund. Ger. Pat. 268,328, March 16, 1911.

Cooling is effected in a number of separate receptacles, through which the cooling medium is led successively, in such wise that the difference in temperature between the hot solution and the cooling medium is kept as small as possible. The cooling tubes may be helical and the cooling medium may be led in one direction through one tube or group of tubes and in the opposite direction through others.—A. S.

Crystallisation in motion; Apparatus for ——. F. A. Bühler. Ger. Pat. 268,409, Aug. 17, 1912.

Crystallisation is preferably effected in a double-walled tubular vessel, the jacket being formed as a helical channel. The agitator is rotated alternately to the right and left, and the agitating arms are so mounted that during rotation in one direction they glide over the material, whilst during rotation in the other direction they lift the material and move it forwards.—A. S.

Drying machines; Application of liquids to cylindrical ——. F. F. W. Stieler, Berlin. Eng. Pat. 4085, Feb. 17, 1913.

See Fr. Pat. 454,468 of 1913; this J., 1913, 858.—T. F. B.

Drying granular substances: Process and apparatus for ——. J. A. Topf und Söhne. Fr. Pat. 461,679, Aug. 21, 1913.

See Eng. Pat. 29,835 of 1912; this J., 1913, 1147.—T. F. B.

Drying solid substances held in suspension or solution; Method and apparatus for ——. F. E. Beeton. Fr. Pat. 462,212, Sept. 5, 1913.

See Eng. Pat. 13,505 of 1912; this J., 1913, 968.—T. F. B.

Extraction of various materials by means of volatile liquids; Apparatus for the ——. L. C. Bonneau, Paris. Eng. Pat. 12,138, May 24, 1913. Under Int. Conv., May 24, 1912.

See Fr. Pat. 457,905 of 1913; this J., 1913, 999.—T. F. B.

Filter-press. G. Pistor, J. Dion, and H. Reitz, Griesheim, Assignors to Chem. Fabr. Griesheim-Elektron, Frankfort, Germany. U.S. Pat. 1,084,659, Jan. 20, 1914.

See Ger. Pat. 252,577 of 1911; this J., 1913, 75.—T. F. B.

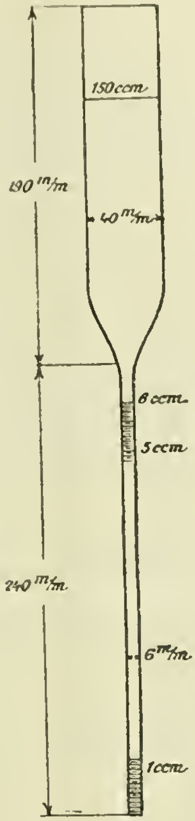
IIa.—FUEL; GAS; MINERAL OILS AND WAXES.

Coke ovens; Different methods of measuring the energy consumed by regenerative ——. *A new method for the exact determination of this quantity of heat.* E. Lecocq and J. Pieters. Rev. Mét., 1914, 11, 95—126.

The methods depending on the measurement in gasometers of the excess gas not utilised for heating the ovens and on measurement of the gas supplied to the ovens by means of Pitot tubes, are subjected to a detailed criticism. The method proposed is to calculate the volume of gas supplied, after obtaining by direct measurement the volume, temperature and pressure of the air supplied to the ovens, the composition of the ga supplied, the composition of the burnt gases passing up the chimney. The volume of air may be measured by a Pitot tube or preferably by means of an anemometer The calorific value of the gas supplied having been deter mined, the heat supplied to the ovens can be calculated The method of making the necessary calculation is illus trated by an example. The methods of making th required measurements are discussed, and the actua operations described. The probable error is stated to b under 2 per cent. The method used by the authors t measure the total volume of distilled gas is also describe

—T. St.

Fuels; Determination of water in solid and liquid —— by distillation with xylene. P. Schläpfer. Z. angew. Chem., 1914, 27, 52—56.



The author describes in greater detail his method of determining water which has been outlined by Huntley and Coste (this J., 1913, 63). A suitable quantity (30—100 grms.) of the fuel is brought into an Erlenmeyer flask of 500 c.c. capacity with 200 c.c. of xylene. The flask is connected by means of a tube, 0·8 to 1 cm. diam., with a vertical condenser which leads to the measuring vessel, shown in the figure. The distillation is conducted slowly whilst the first 30 c.c. are being collected, and then more rapidly, the total 150 c.c. being obtained in about 30 mins. For larger quantities of water a tube of 12 mm. diameter in its narrowest part is used, the other dimensions being approximately the same. The cylinder is carefully cleaned by steam and chromic acid after each determination. The volume of water observed must be corrected for errors in the graduation of the tube, for change in the shape of the meniscus by the pressure of the xylene (about 0·02 c.c. for the narrow tube) and finally for water lost in the distillation which depends on the quantity present and the form of the apparatus. When once the last correction has been determined under known conditions, it is possible to make accurate corrections and to obtain results which are very reliable, except in the case of certain anthracites. For material such as briquettes with a volatile binding agent, this appears to be the only reliable method of determining moisture, and it is also very convenient and rapid compared with other methods for liquids such as tar and viscous mineral oils.
—W. H. P.

Vertical [gas] retorts; American ——. J. H. Taussig. J. Gas Lighting, 1914, **125**, 232—233.

In new plant in course of erection by the United Gas Improvement Co. of Philadelphia, the size of the retorts is greater than heretofore, the object being to obtain complete carbonisation simultaneously at all heights, uniform discharge and larger size of coke, and economy of labour. The new retorts are 18 × 30 in. at the bottom, 12 × 22 in. at the top and 18 ft. 6 in. high, holding 1650 lb. of coal, and the carbonising period is 12 hours. The hot coke is discharged into a cast-iron shoot and fed by an electrically-operated drum on to a conveyor which elevates and delivers it to a shaking screen. The hot coke passes either into a brick-lined hot-coke bin, or on to a shaking table where it is quenched. The hot coke is also used in the water-gas generators. The breeze is passed dry from the bin into the conveyor and elevated to overhead bins for use as stoppers. The primary and secondary air is supplied through meters by blowers.
—A. T. L.

Oil-field; The Taranaki ——. A. E. Watkins. Trans. Australasian Inst. Min. Eng., 1912, **16**, 197—209.

THE author describes the geological formation of the Taranaki oil-field, which is situated on the western side f the North Island of New Zealand, and enumerates the urface indications of petroleum as indicating the extent f oil-bearing rocks. At present there are two flowing ells producing 6720 gallons per week. The oil, which esembles Pennsylvanian petroleum very closely, contains only a very small proportion of unsaturated hydrocarbons, and is free from sulphur. It yields about 14 per cent. of motor spirit (sp. gr. 0·756), about 38 per cent. of burning oil, and 10 per cent. of refined wax. It would be possible to distil it so as to leave a large percentage of fuel oil.
—T. St.

Petroleum pitch; Detection of —— in asphaltum and "liquid bitumens." G. Halphen and J. Spiess. Les Matières Grasses, 1914, 7, 3369.

The method of detecting pitch in asphaltum (this J., 1913, 1096) may also be used for its detection in "liquid bitumens." About 10 grms. of the sample are dissolved in carbon bisulphide, and the solution filtered and concentrated *in vacuo*, to eliminate the solvent and more volatile constituents. The residue is then dissolved in carbon bisulphide and the solution allowed to evaporate spontaneously as described (*loc. cit.*). A viscous bitumen from the Ivory Coast contained:—Water, 10·61; "cracking" oils (of sp. gr. 0·896) 30·56; coke and sand, 54·64; and gas (H_2S, NH_3) and loss, 4·19 per cent. When tested as described a glossy black residue was obtained. On the other hand, a fluid petroleum pitch left a dull black residue with a corrugated centre similar to that given by ordinary petroleum pitch.—C. A. M.

Motor fuels, with special reference to alcohol. W. R. Ormandy. J. Roy. Soc. Arts, 1914, 62, 234—245.

After referring to the enormous increase in the consumption of motor spirit in the past few years, the author discusses in turn the different sources of supply of petrol and its substitutes (see this J., 1913, 416, 819; 1914, 66). With regard to the suggestion that if the illuminating power standard for coal gas were replaced entirely by a calorific power standard, it would be possible to recover 20,000,000 gallons of benzene from the gas per annum in the United Kingdom, it is pointed out that if such change of standard took place, in all probability gas of a different type would be produced by carbonisation at higher temperatures and increased use of water-gas, and that it would be necessary then to leave in all the benzene and paraffin-like substances for such lower-grade gas to attain the required standard of calorific power. Of the petrol substitutes which have been suggested, alcohol alone seems to offer satisfactory possibilities, and tests have shown that with two types of modern petrol engines, mixtures of alcohol and benzene (1 : 1 and 2 : 1) will yield as much power as can be obtained from the same engines running on petrol (see this J., 1913, 1096). According to official statements in certain British Colonies, raw materials for the manufacture of alcohol can be produced in practically limitless quantities at a price equivalent to 3d. per gallon for 95 per cent. alcohol.—A. S.

Tars and heavy oils. Their use as fuels. See III.

Patents.

Coke-oven. Dr. C. Otto und Co. Ges. m. b. H. Ger. Pat. 268,399, Nov. 24, 1911.

The oven is heated from below and in order that heating may be effected alternately with high-grade gas and with low-grade (producer) gas, one of the two chambers alongside the block carrying the burner nozzles is provided with a means of communication with the supply pipe for the low-grade gas. When high-grade gas is being used, both of these chambers are utilised for preheating the air, but when low-grade gas is used, one chamber serves for preheating the air and the other for preheating the gas.—A. S.

Coke; Apparatus for quenching and loading ——. F. Méguin und Co. A.-G. and W. Muller, Dillingen-Saar, Germany. Eng. Pat. 1430, Jan. 17, 1913.

The red-hot coke is discharged into an open, water-jacketed hopper supported by a travelling framework. Short open pipes pass through the bottom of the hopper and through the bottom jacket and may be closed or opened at their lower ends by a sliding perforated plate. The hopper containing the hot coke is moved above a water tank, the sliding plate drawn back and the hopper lowered vertically into the water, which rises through the tubes and quenches the coke. The hopper is then again raised and tilted sideways so that the coke slides over the sloping side into a truck or store.—W. H. C.

Gas producers. C. Whitfield, London. Eng. Pat. 1117, Jan. 15, 1913.

In a suction gas producer, intended for light fuels of a bituminous or tarry nature, the gas is caused to pass through a restricted orifice formed by a conical nozzle, at any point between the producer and the tar extractor, in order to reduce the pulsations in the producer caused by the suction of the engine piston. The producer outlet converges inwards towards a junction box, whence the gas passes downwards through the conical nozzle which is arranged in a vertical pipe sealed in water. A branch near the lower end of this pipe leads to the scrubber and tar extractor, the latter preferably of the kind described in Eng. Pat. 1118 of 1913 (see following abstract). Water is admitted tangentially into the downpipe above the nozzle in order to keep the surfaces free from tar and dust. —A. T. L.

Gas washers or tar extractors. C. Whitfield, London. Eng. Pat. 1118, Jan. 15, 1913.

In a centrifugal tar extractor suitable for use with gas producers the rotating element comprises a central disc having radial blades on both sides, and annular discs attached to the outer edges of the blades. Additional blades are provided on the outer side of one of these discs, in the outlet compartment of the casing, in order to draw gas through the scrubber. The gas passes radially outwards between one set of blades to an annular channel in the casing, and thence radially inwards between the blades on the other side of the central disc and finally radially outwards in the outlet compartment. Water may be sprayed into the scrubber, and a settling tank may be provided.—A. T. L.

Producer gas; Cooling ——, and simultaneously manufacturing salt by the evaporation of brine. A. Burrows, Urmston, and J. Charlton, Heaton Moor, Lancs. Eng. Pat. 2728, Feb. 3, 1913.

An evaporating pan for brine has the central portion of the bottom raised throughout the length of the pan so as to form a flue beneath for the hot gases leaving a producer. In this way, the gases are cooled, and the raised part of the pan provides a large heating surface covered by a shallow depth of brine, whilst leaving the full depth of the pan near each side, where the brine is fed in and the salt accumulates.—A. T. L.

Wood gas and by-products; Apparatus for and mode of manufacturing ——. R. M. Poole, Mount Gambier, S. Australia. Eng. Pat. 13,929, June 16, 1913. Under Int. Conv., July 9, 1912.

Waste wood is carbonised in a horizontal retort set in a furnace and after separating the heavy tar which settles in the gas main the gas is passed through a water-cooled condenser where heavy and light liquids are condensed. The gas (poor gas or gas "y") then passes on through a train of purifying apparatus into a holder. The heavy liquid is withdrawn from the condenser and the light liquid which floats on the surface flows back through a store tank into a horizontal still placed above the retort and heated by the waste heat from the furnace. The liquid is distilled, the lighter portions pass through a condenser into a storage tank and the heavy residual oil is withdrawn from time to time. The light condensed liquid flows first into a vaporiser and thence into one or more retorts which are maintained at a high temperature to convert the vapours into permanent gas. This rich gas or gas "z," is passed through a separate train of purifying apparatus into a separate holder. The two gases are then mixed in suitable proportions in a third holder. The mixed gas burns with a blue flame and is said to give with an incandescence burner a light very similar in its properties to daylight.—W. H. C.

Gas-producers; Steam generators for ——. O. G. Pierson and La Soc. J. and O. G. Pierson, Paris. Eng. Pat. 21,553, Sept. 24, 1913. Under Int. Conv., Sept. 24, 1912. Addition to Eng. Pat. 14,531, June 24, 1907.

The cylindrical portion of the boiler described in the chief patent is made integral with the body of the producer and the inner cylinder is made of steel or other material more highly resistant than cast iron.—W. H. C.

Gas; Manufacture of lighting or heating ——, or hydrogen, by decomposition of the vapours of oil, tar, or liquid hydrocarbons. Berlin Anhaltische Maschinenbau A.-G. Ger. Pat. 267,944, Jan. 28, 1913.

The oil or the like is vaporised in a chamber packed with refractory material, so disposed that its permeability increases from the bottom of the chamber upwards. The vapours are then passed through a column of incandescent coke in a producer chamber, whereby carbon is deposited and a gas suitable for heating or lighting, or, under suitable conditions, hydrogen, is produced. After a certain period the oil supply is cut off, and the producer is "blown" with air, the exit-gases being led into the vaporising chamber, where they are mixed with air and burnt, and thus serve to heat the refractory packing preparatory to the vaporisation of a further quantity of oil. The oil vapours are preferably passed through the producer alternately in an upward and a downward direction.—A. S.

Methane or other inflammable gases in the air; Apparatus for measuring the content of ——. Akkumulatorenfabrik A.-G. Ger. Pat. 268,844, April 16, 1913.

Several heated conducting wires (*e.g.*, of platinum) capable of acting catalytically are introduced into the air to be tested. According to the content of inflammable gases a smaller or larger number of the wires is brought to incandescence.—A. S.

Methane or other inflammable gases in the air; Process and apparatus for detecting ——. Akkumulatorenfabrik A.-G. Ger. Pat. 268,845, April 16, 1913.

The apparatus is of the type in which an electrically heated wire, capable of acting as a catalyst, is brought to incandescence when the air contains inflammable gases. A variable resistance is inserted in the heating current circuit, and the content of inflammable gases in the air is estimated from the intensity of the current (varied by means of the resistance) needed to heat the wire to a degree sufficient for it to exert and maintain its catalytic activity. The apparatus is calibrated by means of gaseous mixtures of known composition.—A. S.

Inflammable gases in the air; Apparatus for detecting and measuring the content of ——. W. Kraushaar. Ger. Pat. 268,898, Jan. 14, 1913.

An electrically heated wire, preferably in the form of a spiral, is enclosed in a casing of incombustible, opaque material, having an opening below or at the side for the introduction of the air to be tested, and an opening above at which a flame with an aureole or cap appears in presence of a certain quantity of inflammable gases. The device can be applied to existing electric mine lamps.—A. S.

Petroleum; Apparatus for distilling ——. C. R. Ewing, Baltimore, Md., Assignor to Standard Oil Co., Bayonne, N.J. U.S. Pat. 1,083,998, Jan. 13, 1914.

The petroleum vapours pass upwards through a tower containing baffles or mixing devices at the bottom, a reflux condenser at the top, and an adjustable intercepting device in the middle adapted either to collect all the condensed liquid falling from the condenser and lead it to a liquid outlet, or to allow a free passage for the condensed liquid to fall on to the mixing device beneath. In either position of the intercepting device, there is a free passag for the upward flow of the vapours. A liquid outlet is provided at the bottom of the tower, and the vapours pass from the top into a condenser.—H. H.

Petroleum ; Distilling ——. W. C. Koehler and L. Link, Elizabeth, N.J., Assignors to Standard Oil Co., Bayonne, N.J. U.S. Pat. 1,084,016, Jan. 13, 1914.

The fraction of crude petroleum containing the wax and lubricating oils is heated to 650° F. (332° C.) and the vapours evolved are conducted at this temperature into a tower containing a large number of tubes acting as reflux condensers, whereby the gummy or asphaltic portions are removed while the lubricant and wax yielding hydrocarbons pass over and are separately condensed.—H. H.

Oil refining mechanism. G. H. Gillons, Assignor to Richfield Oil Co., Los Angeles, Cal. U.S. Pat. 1,084,080, Jan. 13, 1914.

The oil is pumped under uniform pressure through a series of alternate heating coils and vapour-separating devices, from which the vapours are led to condensers. Each separating device comprises a chamber having a number of nozzles and baffle-plates for thoroughly breaking up the oil, and a perforated plate adapted to distribute the oil and permit vapours to escape therefrom, suitable overflow pipes being provided to maintain a constant depth of oil in the separator.—H. H.

Petroleum soluble [emulsifiable] in water ; Manufacture of ——. P. H. Crochepeyre. Fr. Pat. 461,538, May 10, 1913.

Petroleum, 2 parts, is stirred into molten rosin, 1 part, and soda lye, 1 part, is then mixed in. The product will make an emulsion with water without any oil coming to the surface.—A. T. L.

Esters of fatty acids ; Utilisation of —— *[for carburetting, etc.].* Soc. d'Etude du Carburol. Fr. Pat. 461,520, Aug. 20, 1913.

The following esters are used, with or without the corresponding alcohols, for carburetting, for heating, and for lighting, in place of mineral oils :—the acetic, propionic, butyric, valeric and caproic esters of methyl, ethyl, propyl, butyl and amyl alcohols.—A. T. L.

Aliphatic hydrocarbons from polymethylenes or mixtures containing polymethylenes [petroleum products] ; Process for preparing ——. Steaua Romana Petroleum-Ges. m. b. H. Fr. Pat. 462,073, Sept. 2, 1913. Under Int. Conv., Sept. 24, 1912.

Polymethylenes or mixtures containing polymethylenes, especially petroleum residuum or mineral oils of high boiling point, are subjected to destructive distillation, and the products are converted into saturated hydrocarbons by treatment with hydrogen. For example, 10 kilos. of a mineral oil fraction of sp. gr. 0·850 are subjected to destructive distillation, at a temperature not exceeding 230° C. ; in addition to the coke and gas, to 9·5 kilos. of distillate of sp. gr. 0·750—0·780 are obtained ; this is now saturated with hydrogen in presence of a suitable catalytic agent, until a sample treated with oncentrated sulphuric acid diminishes in volume by less han 2 per cent. The product consists of 9·2 to 9·8 kilos. f saturated hydrocarbons of sp. gr. 0·740 to 0·770. The esulting liquids may be used as motor fuels.—T. F. B.

riquetting fuel by adding dry paper pulp flakes ; Process of ——. F. Reinold, Charlottenburg, Germany. Eng. Pat. 15,439, July 4, 1913.

Bituminous composition [for roads]. Eng. Pat. 1458. *See* IX.

IIb.—DESTRUCTIVE DISTILLATION ; HEATING ; LIGHTING.

Coal ; Distillation of —— *in a vacuum.* M. J. Burgess and R. V. Wheeler. Chem. Soc. Trans., 1914, **105**, 131—140.

The apparatus, after introduction of the coal (200 grms. of fine dust) was rapidly exhausted by means of a Geryk oil pump, and the last traces of air removed by a mercury pump fitted with two Sprengel tubes. In order to prevent reflux condensation and consequent decomposition of liquid distillation products, the neck of the glass retort was directed vertically downwards into the first condenser. When all occluded gases capable of being extracted at the ordinary temperature had been removed, the temperature was raised to 100° C., and exhaustion continued at that temperature until no more gases could be pumped off. The temperature was then raised gradually in successive stages of 50° or 100° C., and the gases removed at each stage. The pressure at no time exceeeded 20 mm. Small quantities of occluded gases (mainly carbon dioxide and monoxide) were obtained at the ordinary temperature from coal dust which had been dried in the air at 107° C. At about 200° C. there was a copious evolution of water, and water was also evolved at successive stages up to 450° C. ; during the period of most rapid evolution of water, the gases contained a high percentage of oxides of carbon. Decomposition of some sulphur-containing substance occurred at 270°—300° C. A thin reddish-brown oil began to distil at 310° C., but there was no marked evolution of gas at this temperature. At 350° C. there was a rapid evolution of gas and much viscid oil distilled over, and from this point decomposition continued with increasing rapidity as the temperature was raised (up to 450° C.). The gases were probably free from benzene (neither this compound nor its homologues were present in the liquid distillation products) but contained ethylene and higher olefines, and paraffin hydrocarbons up to and including pentane. For giving some indication of the nature of mixtures of paraffin hydrocarbons, instead of the commonly used ratio C/A (contraction on explosion : absorption by potassium hydroxide, or carbon dioxide formed), the authors recommend regarding the mixture of paraffins as consisting of *m* CH_4 groups and *n* CH_2 groups and determining the ratio n/V (number of CH_2 groups per unit volume of the paraffins). This ratio $\frac{n}{V} = \frac{2(2A—C)}{2C—A}$ is 0 for methane, 1 for ethane, 2 for propane, and so on. The composition and volume (per 100 grms. of Silkstone bituminous coal) of the gases evolved at different temperatures are shown in the following table :—

	100° C.	200° C.	300° C.	350° C.	400° C.

Coal ; Composition of ——. [*Tar obtained by distillation in a vacuum at low temperatures.*] D. T. Jones and R. V. Wheeler. Chem. Soc. Trans., 1914, **105**, 140—151.

Two bituminous coals (one from Scotland and one from Durham) were employed in the experiments, the crushed coal being sifted through a 10-mesh and on a 65-mesh sieve, and then dried at 105° C. for 1 hour. The temperature of the glass retort was raised gradually to 430° C. and distillation continued at this temperature at a pressure of 5—40 mm. It has been shown previously (this J., 1910, 1291; 1911, 606) that at temperatures below 500° C. only the "resinous substances" in bituminous coals are decomposed to any great extent. Besides gaseous products (see preceding abstract) and water, the coals yielded about 6·5 per cent. of their weight of a thin, brown, pleasant smelling tar (sp. gr. 0·999 at 15°/15° C.) covered with a layer of paraffins. The tar was distilled up to 300° C., leaving as residue about half its weight of pitch. The oils boiling below 300° C. contained 40—45 per cent. of unsaturated (ethylenic) hydrocarbons (mostly richer in carbon than the mono-olefines, C_nH_{2n}), about 40 per cent. of naphthenes (C_nH_{2n}), and liquid paraffins, the former greatly predominating, 12—15 per cent. of phenols, chiefly cresols and xylenols, about 7 per cent. of aromatic compounds, apparently homologues of naphthalene, a small quantity of a solid paraffin of m. pt. 52·5°—54° C. and mol. wt. 373·7 (intermediate between $C_{26}H_{54}$ and $C_{27}H_{56}$), and traces of pyridine bases. Benzene, naphthalene, anthracene, carbon bisulphide, and solid aromatic hydrocarbons were absent, as also were toluene and other homologues of benzene, except possibly in traces. The aqueous distillate from the coal contained hydrochloric acid and traces of ammonium chloride. The authors' results differ in many respects from those of Pictet and Bouvier (this J., 1913, 1098; 1914, 70), notably in the absence of phenols and solid paraffins from the tar obtained by the French authors. In the authors' experiments the mouth of the retort projected vertically downwards into the first condenser, so as to avoid thermal decomposition of the distillation products, and distillation was effected slowly during about 5 weeks, whereas Pictet and Bouvier completed a distillation in 5 hours. The authors have isolated paraffin wax (m. pt. 55°—59° C.) from several British coals by treating the extract obtained by the solvent action of pyridine and chloroform (this J., 1913, 969) with pentane. The possible ways in which the various distillation products are formed from the "resinous substances" of the coals are discussed.—A. S.

Lighting gas from coke ovens (*Westphalia*). L. D. Ford. North of England Institute of Mining and Mechanical Eng. Through Times Eng. Suppl., 1914, Feb. 18.

The plant erected in 1909, in addition to its other duties, such as feeding the boilers and gas-engines and making the usual by-products, supplies a Westphalian town of about 146,000 inhabitants with illuminating gas. A feature of interest is that the gas and ammonia are extracted from the gases whilst these are, comparatively speaking, still hot, by means of the Otto "direct" process. The coke ovens consist of two batteries of 50 ovens each, of the Otto-Hilgenstock under-burning regenerative type. The charge per oven is eight tons of uncompressed small coal. For heating the ovens the gas from the by-product plant is conveyed through a central main running underneath the entire battery, two small branch pipes being taken off the main directly under the walls of each oven and connected to nine Bunsen burners, which burn in vertical flues in each wall. The time taken for coking varies from 28 to 29 hours, each oven giving a 75 per cent. yield, or six tons of coke. Of the 50 ovens in each battery, 42 are discharged in 24 hours, and give an output of about 500 tons of coke per day. The yield of gas may be reckoned as 11,300 cb. ft. per ton of dry coke, or some 5,651,000 cb. ft. per 24 hours. Of the total gas, 50 per cent. is burned under the coke ovens, the surplus being divided in the following rough proportion :—Illuminating gas, 12 to 20 per cent.; power gas, 12 to 18 per cent.; and gas for heating boilers, 15 to 25 per cent. The town gas is supplied from one battery only, and in order to ensure good quality the following arrangement has been adopted :—When an oven has been filled, it is first coupled to the working-gas collecting main, which takes the products of distillation until the end of the second or third hour, after which the gas is switched over into the town gas collecting main, which draws the gas until the end of the 22nd or 23rd hour, when it is again taken by the working-gas collecting main until the coking is complete. Generally speaking, there are 20 to 25 ovens giving town gas at one time. With the present arrangement the largest number of ovens capable of yielding illuminating gas at one time, would be 30. The gas from the second battery is used entirely for working purposes—that is, for the by-product plant—for burning under the ovens and in the boilers, and for driving gas-engines, and needs only one collecting main. The town gas and working gas are thus entirely separate and require separate apparatus.

Patents.

Grape marc from the manufacture of wine ; Dry distillation of ——. M. Daza. Fr. Pat. 461,443, Aug. 18, 1913.

The marc is distilled in a closed vessel in order to obtain useful products such as charcoal, oils, ammonia and alcohol.—A. T. L.

Coal or other products ; Dry distillation of ——. B. Ludwig. Fr. Pat. 462,024, Aug. 30, 1913. Under Int. Conv., Sept. 2, 1912.

The coal is heated in small inclined retorts in thin layers which are renewed at frequent intervals. The coal is fed in through a vertical conduit near the upper end of the retort. After carbonisation, the coke is moved down the retort by a ram to a zone which is cooled by the circulation of air in flues around it, this air serving afterwards for combustion. From the cooling zone, the coke is discharged over a sill into a chamber common to a series of retorts, whence it can be removed in bulk. Gas outlets are provided both at the lower end and at the upper end of the distillation zone. The upper wall of the retort adjacent to the distillation zone is removable.—A. T. L.

Charcoal of great absorptive power ; Manufacture of active ——. J. von Kruszewski. Ger. Pat. 267,346, Oct. 13, 1912.

Wet peat is subjected for a long time to the action of alkaline substances (hydroxides or carbonates of potassium or sodium, or lime or baryta), and the mass, after further drying, is heated, with exclusion of air, until evolution of gas ceases. The resulting finely divided black powder is stated to be specially suitable for purifying and deodourising liquids and gases.—A. S.

Electric lamp filament containing cobalt ; Process of manufacturing an ——. C. Kanazawa, Tokyo, Japan. Eng Pat. 16,481, July 17, 1913. Under Int. Conv., July 17 1912.

See Fr. Pat. 460,093 of 1913 ; this J., 1914, 69.—T. F. B.

Zirconium lamp-filament. C. A. Hansen, Schenectady, N.Y., Assgnor to General Electric Co., New York. U.S. Pat. 1,084,629, Jan. 20, 1914.

See Eng. Pat. 5415 of 1908 ; this J., 1909, 83.—T. F. B.

Manufacturing wood gas and by-products. Eng. Pat. 13,929. *See* IIa.

Utilisation of esters of fatty acids [for carburetting, heating, lighting]. Fr. Pat. 461,520. *See* IIa.

Manufacture of active powdered charcoal [from refuse] for purifying and filtering purposes. Ger. Pat. 267,443. *See* XIXb.

III.—TAR AND TAR PRODUCTS.

Tars and heavy oils. Their use as fuels. Times Eng. Suppl., Feb. 4, 1914.

With the gradually increasing use of tar and the like as fuels, the necessary apparatus has been improved and burners can now be obtained capable of dealing not only with ordinary gas tar but also with lower-grade products such as Mond gas tar and carburetted water-gas tar. The burners work on the "air jet" or "steam jet" principle, the air or steam being delivered under pressure, whilst the fuel is subjected only to the hydrostatic pressure corresponding to the height of the overhead supply tank. When burners of the air jet type are used, the tar is preheated by means of a steam coil fitted to the supply tank and small steam pipes placed in the fuel services: any water which separates from the heated tar is run off. In an installation in a Liverpool gasworks in which three 500 h.p. boilers are fired by means of tar from air jet burners, the flow of tar is controlled by an ordinary wheel valve, and preheating is effected by a superheater in the waste-gas flue. The air, supplied at a pressure of about 3 lb. per sq. in., is divided into two currents. The primary air meets the preheated tar as it issues through the main control valve, and the two pass together down the central passage and around a helix which ensures thorough admixture and atomisation. The secondary air circulates through an annular chamber around the central passage and is discharged at the point where combustion takes place, whilst there is a third supply of air through the fire-bars or the hollow front of the furnace. The air supply is adjusted at the different points by sleeves operated by a rack and pinion. The air compressor is said to absorb no more than 3 per cent. of the steam raised. In the trials it is stated that the evaporative power of the tar was 14·65 lb. of water from and at 212° F. (100° C.), 84 per cent. of the heat being utilised. In burners of the steam jet type, the tar is superheated by the steam, and there is only one air supply, corresponding to the secondary air in the air-jet burners. The proper quantity of air can be easily judged from the "roar" of the fire and the character of the flame: the latter should be almost transparent and of an intense white colour ; with light oils the colour should approach a vivid pink. With the newer types of liquid-fuel burners, a change to ordinary coal firing can be carried out in a few minutes, with little or no loss in steam pressure, practically no alteration of the original grate being necessary. The chief difficulty in connection with Mond gas tar and carburetted water-gas tar is the high percentage of water they contain (60—70 per cent. in the case of Mond gas tar) : it may be overcome to some extent by burning the tar over a coke or coal fire sed for raising the steam in the first instance.—A. S.

Dimethyl-o-toluidine ; Preparation of pure ——. J. v. Braun and E. Aust. Ber., 1914, 47, 260—262.

MPURITIES which cannot be removed from dimethyl-o-toluidine by distillation are very easily got rid of by eating with formaldehyde and hydrochloric acid on he water-bath, making alkaline, washing, and fractionating *vacuo.* The dimethyl-*o*-toluidine is almost entirely unacted upon, whereas the para-isomeride is converted into a benzyl alcohol derivative and a carboxylic acid, the other impurities—dimethyl-*m*-toluidine and dimethylaniline—being converted into the corresponding benzyl alcohol or diphenylmethane derivatives, all products of very high boiling points.—J. B.

Composition of coal. [Tar obtained by distillation in a vacuum at low temperatures.] Jones and Wheeler. *See* IIb.

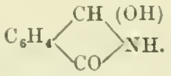
Patents.

Nitro compounds ; Process for the continuous reduction of ——. Chem. Fabr. vorm. Weiler-ter Meer. Fr. Pat. 462,006, Aug. 29, 1913. Under Int. Conv., Sept. 23, 1912.

Ferrous oxide and magnetic iron oxide are found to be excellent hydrogen-carriers when applied to the reduction of nitro-compounds, especially nitrobenzene. The process in question consists in mixing the nitro-compound in a state of vapour with hydrogen or a gas containing hydrogen, and passing the mixture over finely divided and heated ferrous oxide or magnetic oxide ; it is advisable to mix the iron oxide with an indifferent substance, such as asbestos or kieselguhr. The iron oxides are not reduced during the process.—T. F. B.

Phthalimide ; Process for preparing reduction products of ——. Kalle und Co. A.-G. Ger. Pat. 267,596, May 31, 1912.

Reduction of phthalimide by means of zinc dust and alkali hydroxide solution at the ordinary temperature gives rise to hydroxyphthalimidine,



$$C_6H_4\langle\begin{matrix}CH(OH)\\CO\end{matrix}\rangle NH.$$

When heat is applied to the reaction, the imino group is replaced by oxygen and the hydroxyl group by hydrogen, phthalide being produced.—T. F. B.

Polynitrocarbazoles and their N-alkyl derivatives ; Process for preparing ——. L. Cassella und Co. Ger. Pat. 268,173, Dec. 15, 1912.

Carbazole or an N-alkylcarbazole is sulphonated until products soluble in water are obtained ; the resulting polysulphonic acids are then treated with vigorous nitrating agents, whereupon the sulphonic groups are replaced by nitro groups. The products are suitable for use in the preparation of developers and of dyestuffs. —T. F. B.

Dianthraquinonylaminecarboxylic acids ; Process for preparing ——. Badische Anilin und Soda Fabrik. Ger. Pat. 268,219, Oct. 31, 1912.

A halogen-anthraquinonecarboxylic acid is heated with an aminoanthraquinone or an aminoanthraquinone-carboxylic acid with a halogen-anthraquinone in a solvent of high boiling-point, in presence of copper or a copper compound, or similar catalyst : an oxide or salt of an alkaline-earth metal is also added to combine with the hydrohalogen acid.—T. F. B.

Nitrogenous condensation products of the anthraquinone series ; Process for preparing ——. Farbwerke vorm. Meister, Lucius, und Brüning. Ger. Pat. 268,454, April 23, 1912.

1-Monoanthraquinonylamino-8-aminonaphthalene or one of its derivatives substituted in the anthraquinonyl nucleus, is heated either alone or in a high-boiling solvent. Similar products are obtained by heating 1-chloro-anthraquinone or its derivatives with 1.8-diaminonaphthalene in presence of a copper compound and a substance which combines with acid, in a high-boiling solvent.—T. F. B.

1.4-*Diaminoanthraquinone and its nucleus substitution products; Process for preparing sulphuric acid compounds of* ——. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 268,592, Oct. 3, 1912.

1.4-Diaminoanthraquinone or a nucleus-substitution product thereof is treated with fuming sulphuric acid until compounds insoluble in water but soluble in alkali are produced. The products are neither sulphates nor sulphonic acids, but have the characteristics of an acidyl derivative. They are probably of the formula, $C_{14}H_6O_2(N:SO_2)_2$. On heating with aqueous sulphuric acid the original diaminoanthraquinone is formed, whilst treatment with nitric acid and saponification gives 5-nitro-1.4-diaminoanthraquinone, and heating with caustic soda solution produces 4-amino-1.2-dihydroxyanthraquinone. —T. F. B.

2-*Dimethylamino-5-methylbenzyl alcohol; Process for preparing* ——. L. Cassella und Co. Ger. Pat. 268,486, Aug. 21, 1912.

Dimethyl-*p*-toluidine is converted into 2-dimethylamino-5-methylbenzyl alcohol by treatment with a considerable excess of formaldehyde in presence of a mineral acid. The product can be condensed to diphenylmethane derivatives by heating with a further quantity of dimethyl-*p*-toluidine or other tertiary aromatic base, to a high temperature in presence of zinc chloride.—T. F. B.

Sulphochlorides of phenolcarboxylic acids and of their derivatives; Process for producing ——. Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. Eng. Pat. 18,430, Aug. 13, 1913. Under Int. Conv., Aug. 13, 1912.

See Ger. Pat. 264,786 of 1912; this J., 1913, 1003.—T.F.B.

IV.—COLOURING MATTERS AND DYES.

p-Nitroso-N-phenylglycin and p-nitroso-N-phenylglycin-o-carboxylic acid. J. Houben. Ber., 1913, **46**, 3984—4000.

The author has obtained an 80 per cent. yield of nitrosophenylglycin by acting on phenylglycin directly with fuming hydrochloric acid and sodium nitrite. The *p*-nitrosophenylglycin forms a sparingly soluble brown powder, unstable, exploding when heated. The ammonium salt is green and more stable than the free acid. Condensation products (dyestuffs) are formed with α-naphthol (red-violet), *m*-toluylenediamine (blue), gallic acid (red violet), etc. By the new method N-methylphenylglycin gives no nitroso compound, nor does dimethylanthranilic ester; phenylglycin-*o*-carboxylic acid and its esters, however, give good yields. *p*-Nitrosophenylglycin-*o*-carboxylic acid is green; it gives a blue indophenol with β-naphthol and a blue-violet azine with *m*-toluylenediamine. (Compare Eng. Pat. 22,694 of 1913; this J., 1914, 70.)—J. B.

Methylethylaniline and p-nitrosomethylethylaniline and colouring matters therefrom. J. C. Cain and A. Coulthard. J. Soc. Dyers and Col., 1914, **30**, 48—50.

p-Nitrosomethylethylaniline behaves just like *p*-nitrosodimethylaniline in the synthesis of colouring matters. The analogues of Methyl Orange, Malachite Green, Crystal Violet, Auramine, Toluylene Blue, Neutral Red, α-Naphthol Blue, Gallocyanine, Meldola's Blue, Methylene Blue and Methylene Grey have been prepared. They approximate in shade to the ordinary products from dimethylaniline but generally the shade is moved nearer to the red end of the spectrum (*i.e.* the blues are greener, the oranges redder).—J. B.

Naphthoflavones and naphthothioflavones. S. Ruhemann. Ber., 1914, **47**, 119—125.

The naphthols and thionaphthols, in the form of their sodium compounds, react with phenylpropiolic ester to form cinnamic esters, just as do the phenols and thiophenols, although not so easily. These esters are very readily converted into the corresponding flavones and thioflavones. The naphthoflavones give fluorescent solutions in sulphuric acid like the benzene homologues; the naphthothioflavones also give weakly fluorescent solutions, a property which is lacking in the thioflavones of the benzene series.—J. B.

Patents.

Colouring matters of the benzanthrone series; Manufacture of —— *and dyeing and printing therewith.* J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. Eng. Pat. 5248, March 1, 1913. Addition to Eng. Pat. 26,551, Nov. 19, 1912 (see this J., 1913, 1004).

The introduction of aldehyde groups into aminodibenzanthrones can be effected by treating a leuco compound of the aminodibenzanthrone with the aldehyde, or by the action of the aldehyde on an amino- or nitro-dibenzanthrone in presence of a reducing agent. Aldehyde hydrosulphites or sulphoxylates are especially suitable for use in this process, and if alkali is used during the reaction, the solution or mixture produced can be used directly in dyeing and printing. The process can also be carried out on nitro- or amino-dibenzanthrone compounds which have already been applied to the fibre. Fast maroon dyestuffs are obtained from nitrodibenzanthrone and sodium formaldehyde-sulphoxylate.—T. F. B.

Colouring matters of the anthracene series; Manufacture of compounds and ——. Badische Anilin und Soda Fabrik, Ludwigshafen-on-Rhine, Germany. Eng. Pat. 22,836, Oct. 9. 1913. Under Int. Conv., Nov. 1, 1912.

Carbazole, or a homologue or a halogen derivative thereof, is treated with phthalic anhydride or a halogen derivative thereof in the presence of sulphuric acid. A mono- or diphthaloylcarbazole is probably formed. If a sulphonic acid group is present the product is an acid dyestuff; if no acid groups are present a vat dye. The shades obtained are generally yellow. (Compare this J., 1911, 738).—J. B.

Indigo and thioindigo dyestuffs in the colloidal condition. Badische Anilin und Soda Fabrik. Fr. Pat. 462,079, Sept. 2, 1913. Under Int. Conv., Nov. 2, 1912, and March 28, 1913.

See Ger. Pat. 265,536 of 1912; this J., 1913, 1101. Instead of the sulphite-cellulose lyes, there may be used aromatic sulphonic or carboxylic acids, especially benzylamine-sulphonic acids, or phenolsulphonic acids or their condensation products with formaldehyde, etc., or amorphous non-hydroxylated aromatic sulphonic acids soluble in water.—T. F. B.

3.6-*Diaminoacridine and its alkyl derivatives; Process for producing* ——. L. Cassella und Co. G. m. b. H First Addition, dated July 10, 1913, to Fr. Pat. 433,079, Oct. 18, 1910.

This addition is for the purpose of indicating severa typographical errors in the chief patent (see this J., 1912 120).—T. F. B.

Half-wool and half-silk dyestuffs; Manufacture of —— O. Imray, London. From Farbwerke vorm. Meiste Lucius, und Brüning, Hoechst a/M., Germany. Eng Pat. 13,236, June 7, 1913.

A tetrazo compound from *p*-phenylenediamine, benzidin tolidine or dianisidine, or a derivative or homolog thereof, is combined with 1 mol. of a mono- or di-sulphon acid of a naphthol, aminonaphthol or dihydroxynaphth lene, and with 1 mol. of an acidyl derivative of 1.5. or 2.5.7-aminonaphtholsulphonic acid. The dyestuffs a generally blue and dye only the cotton in mixed fabri —J. B.

o-Hydroxymonoazo dyestuffs; Process for making ——. Farbwerke vorm. Meister, Lucius, und Brüning. Third Addition, dated July 25, 1913, to Fr. Pat. 361,649, July 26, 1905. Under Int. Conv., Oct. 16, 1912 (see U.S. Pat. 827,468 of 1906; this J., 1906, 922).

THE diazo derivative of picramic acid (2-amino-4.6-dinitrophenol) is combined with a monoalkyl ester of 1.8-dihydroxynaphthalene-4-sulphonic acid. The products dye unmordanted wool, in presence of bichromate and an acid, green shades fast to fulling and to light (see also Second Addition to this Patent; this J., 1913, 650).—T. F. B.

[Indigo] dyestuffs for wool; Process for preparing yellow ——. Farbwerke vorm. Meister, Lucius, und Brüning. Ger. Pat. 267,384, Feb. 26, 1911.

THE yellow compounds obtained from indigo or 5.5′-dimethylindigo by treatment with benzoyl chloride, benzyl chloride, or benzotrichloride, are converted into yellow acid wool dyestuffs by heating with fuming sulphuric acid.—T. F. B.

Vat dyestuffs of the anthracene series; Process for preparing ——. Farbwerke vorm. Meister, Lucius, und Brüning. Ger. Pat. 267,522, Aug. 23, 1912.

o-HALOGEN-DIANTHRIMIDES are converted into vat dyestuffs by treating with substances which eliminate hydrohalogen acids. For example, 2-bromo-1.1′-dianthrimide (obtained by boiling 2-bromo-1′-aminoanthraquinone with 1-chloroanthraquinone in amyl alcohol in presence of copper acetate and calcium acetate) gives an orange-yellow vat dyestuff.—T. F. B.

Vat dyestuff of the anthracene series; Process for preparing a ——. Farbwerke vorm. Meister, Lucius, und Brüning. Ger. Pat. 267,833, Sept. 26, 1912.

1.1′-DIAMINO-2.2′-dianthraquinonyl is treated with an acid or neutral condensing agent. The product appears to be identical with that obtained from bromo-1.1′-dianthrimide according to Ger. Pat. 267,522 (see preceding abstract).—T. F. B.

Dyestuff of the anthracene series; Process for preparing a yellow ——. Farbwerke vorm. Meister, Lucius, und Brüning. Ger. Pat. 267,546, Nov. 3, 1909.

A YELLOW vat dyestuff, which is applied in the same way as Flavanthrene, but dyes richer shades, is obtained by heating an ω-dihalogen-2-methylanthraquinone with copper.—T. F. B.

Disazo dyestuffs especially suitable for making lakes; Process for producing ——. Chem. Fabr. Griesheim-Elektron. Fr. Pat. 461,644, Aug. 13, 1913. Under Int. Conv., Jan. 9, 1913.

THE tetrazo derivative of tetrachlorobenzidine $NH_2 : Cl : Cl = 1 : 2 : 5$) is combined with two mols. of 1-aryl-3-methyl-5-pyrazolone. The dyestuffs produce ellow to orange lakes, fast to light and insoluble in oil, nd yellower than those obtained from *o*-dichlorobenzidine. —T. F. B.

riphenylmethane dyestuffs; Process for producing ——. Farbenfabr. vorm. F. Bayer und Co. Fr. Pat. 461,810, Aug. 26, 1913. Under Int. Conv., Aug. 30, 1912.

SULPHONIC acid of alkylated or arylated *m*-toluidine, or mixture of such sulphonic acids, is condensed with an omatic aldehyde which does not contain an alkylamino oup in the *p*-position to the aldehydic group, and the ico compounds are oxidised. Similarly, the unsulphoted amines may be condensed with the aldehydes, and products sulphonated before or after oxidation. llowish-green dyestuffs are produced which are much ter to fulling and to alkalis than the corresponding stuff from ethylbenzylanilinesulphonic acid.—T. F. B.

Disazo dyestuffs for wool; Process for preparing red ——. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 268,067, July 20, 1912.

A TETRAZO compound is combined on the one hand with one mol. of a monoalkyl-1.8-dihydroxynaphthalene-3.6-disulphonic acid, and on the other hand with a derivative of a β-ketone-aldehyde in which the aldehyde-hydrogen is replaced by an alkyl, aryl, alkoxy, or arylamino group, or with methylketol or its sulphonic acids, or with phenylmethylpyrazolone or its sulphonic, carboxylic, halogen, or nitro derivatives. The products dye red shades on wool fast to sulphuring.—T. F. B.

[Azo] dyestuffs capable of being developed; Process for preparing ——. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 268,792, Dec. 28, 1912.

A DIAZO or diazo-azo compound is combined with 1.5-aminonaphthol or with its 6- or 7-sulphonic acid, and the product is diazotised and combined with a derivative of 2·5-aminonaphthol-7-sulphonic acid or its 1-substitution products which contain a diazotisable amino-group in a heteronuclear side-chain; as examples of these derivatives may be mentioned aminobenzoyl-2-amino-5-naphthol-7-sulphonic acid, aminophenyl-1.2 naphthiminazole-5-hydroxy-7-sulphonic acid, aminophenyl-1·2-naphthothiazole-5-hydroxy-7-sulphonic acid, etc. The products dye cotton blue-black to greenish-black shades, and can be diazotised on the fibre and developed with phenylmethylpyrazolone, acetoacetanilide, etc., to produce pure green shades very fast to light.—T. F. B.

Vat dyestuffs of the anthracene series; Process for preparing ——. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 268,505, Jan. 22, 1913.

THE indazoles, obtained by eliminating the elements of water from *o*-diazo-methylanthraquinones, are treated with halogens or mixtures which evolve halogens. Vat dyestuffs are produced.—T. F. B.

Leucogallocyanines; Process for preparing blue to green ——. Farbwerke vorm. Durand, Huguenin und Co. Ger. Pat. 266,599, March 23, 1913. Addition to Ger. Pat. 167,805.

LEUCO-COMPOUNDS of gallocyanine dyestuffs are condensed with aromatic aldehydes to produce substances which dye blue to green shades on a chrome mordant.—T. F. B.

Vat [anthracene] dyestuffs; Process for preparing red-brown to brown ——. L. Cassella und Co. Ger. Pat. 267,416, Aug. 15, 1912. Addition to Ger. Pat. 267,414.

1.5-DIAMINOANTHRAQUINONE is condensed with benzoquinone and the product is treated with α- or β-chloroanthraquinone. The red-brown to brown dyestuffs thus produced give very fast, full shades in dyeing.—T. F. B.

[Azo] colouring matters capable of being further developed; Process of producing ——. Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. Eng. Pat. 16,386, July 16, 1913. Under Int. Conv., Dec. 27, 1912.

SEE Ger. Pat. 268,792 of 1912; preceding.—T. F. B.

Disazo dyestuffs for cotton; Manufacture of yellow ——. A. G. Bloxam, London. From Chem. Fabr. Griesheim-Elektron, Frankfort on Maine, Germany. Eng. Pat. 17,878, Aug. 5, 1913.

SEE Fr. Pat. 461,039 of 1913; this J., 1914, 19.—T. F. B.

Disazo dyestuffs; Manufacture of ——. A. G. Bloxam, London. From Chem. Fabr. Griesheim-Elektron, Frankfort on Maine, Germany. Eng. Pat. 18,096, Aug. 8, 1913. Addition to Eng. Pat. 1730, Jan. 23, 1911.

SEE Fr. Pat. 461,644 of 1913; preceding.—T. F. B.

Monoazo dyestuffs especially suitable for making lakes [and for producing ice-colours]; Process for preparing ——. Chem. Fabr. Griesheim-Elektron. First Addition, dated July 28, 1913, to Fr. Pat. 441,333, March 13, 1912. Under Int. Conv., March 10, 1913.

See Eng. Pat. 17,279 of 1913; this J., 1914, 73.—T. F. B.

Production of fast shades on vegetable fibres and dyestuffs therefor. Eng. Pat. 1436. *See* VI.

V.—FIBRES; TEXTILES; CELLULOSE; PAPER.

Manufacture of ethyl alcohol from sawdust. Junien. *See* XVIII.

Manufacture of nitrocellulose for collodion. Viscosity of collodions. Chandelon. *See* XXII.

Patents.

Cellulose; Bleaching of ——. F. W. Dobson, Tamworth, Staffs. Eng. Pat. 3801, Feb. 14, 1913. Addition to Eng. Pat. 3181, Feb. 8, 1911 (this J., 1912, 225).

In bleaching cellulose by the method of rotating it with concentrated bleach liquor in a closed vessel, the action may be accelerated by introducing air, chlorine or other suitable gas so that a pressure of about 10 lb. per sq. in. is attained. When chlorine gas is used the water placed in the vessel to saturate the pulp may be made alkaline and caused to absorb chlorine gas prior to bleaching under a pressure of gas.—J. F. B.

Artificial silk and the like thread; Machines for manufacturing ——. Soc. Anon. des Celluloses Planchon, Lyons, France. Eng. Pat. 13,360, June 9, 1913. Under Int. Conv., May 2, 1913.

Two sets of bobbins on parallel shafts are driven by means of friction wheels rotating on a sleeve of a central shaft; means are provided through tappets, cams and levers, whereby the central shaft is caused to rotate through an angle of 180° when the set of bobbins receiving the thread is filled up. Thus the set of empty bobbins on the other shaft takes the place of the previous one automatically and the guide levers are so arranged that the thread is gathered up by adhesion to the empty bobbins and broken off the full ones without the attention of the operator.—J. F. B.

Cellulose esters; Manufacture of products having a basis of ——. H. Dreyfus. Fr. Pat. 461,544, June 2, 1913. Under Int. Conv., May 27, 1913.

Nitrocellulose or esters of cellulose with fatty acids are combined in solution with glyceryl esters of aromatic carboxylic acids and the products are employed for all purposes where plastic cellulose derivatives are required. Example: Glyceryl monobenzoate is dissolved in acetone, tetrachloroethane or other suitable solvent of cellulose esters, together with an equal weight of cellulose acetate, and pliable films or coatings are obtained on evaporation of the solution. More rigid products are prepared by using smaller proportions of the glyceryl benzoate.—J. F. B.

Cellulose xanthate [viscose]; Manufacture of derivatives of ——. F. Petit. Fr. Pat. 461,900, Nov. 8, 1912.

For the preparation of brilliant products from viscose a coagulating bath is employed consisting of a concentrated saline solution, together with a quantity of acid regulated so as to produce at first a thread consisting of yellow xanthate, still soluble in water, which is gradually converted into cellulose by the action of the acid liquid. Examples: a solution containing 30 per cent. of sodium sulphate and 12 per cent. of commercial hydrochloric acid or a saturated solution of common salt containing 10 per cent. of acetic or formic acid.—J. F. B.

Viscose solution from wood cellulose; Manufacture of a [purified] ——. A. Bernstein. Fr. Pat. 462,147, Sept. 3, 1913. Under Int. Conv., Sept. 3, 1912.

The alkali-cellulose prepared from wood pulp is subjected to the action of carbon bisulphide in the usual manner. The product is then discharged into a vertical vessel with agitators and a conical bottom, the latter being provided with a grid and discharge-cock. In this vessel the crude xanthate is washed for a few minutes with water or with water slightly acidulated with acetic acid, and the liquid which absorbs the saline by-products and excess of carbon bisulphide, is discharged. The purified residue is then dissolved by the addition of an alkali.—J. F. B.

Cellulose formate solutions; Process for preparing ——. Internationale Celluloseester-Ges. m. b. H. Ger. Pats. 266,600 and 267,577, July 5, 1912, and Feb. 26, 1913.

(1) Solutions of the following compounds are used as solvents of cellulose formate:—Alkali iodides and bromides, calcium chloride, ammonium nitrate, alkaline-earth and metallic nitrates, cupric chloride, alkali xanthates, aniline salts, and alkali salts of aromatic mono- and polysulphonic acids. The solutions set to a jelly when cool, but become liquid again on warming. The cellulose formate can be separated from them by suitable precipitants. (2) Solutions of soluble bichromates are used as solvents; thus, 20 kilos. of cellulose formate can be completely dissolved in a solution of 30 kilos. of ammonium bichromate in 100 litres of water, preferably by aid of gentle heat. —T. F. B.

Plastic composition [from yeast and spent hops]. A. S. Quick, Assignor to M. Bartholomew, London. U.S. Pat. 1,084,900, Jan. 20, 1914.

A mass containing yeast in a condensed or semi-solid condition is thoroughly mixed with a smaller quantity of a textile fibre; the mixture is heated and the product shaped while hot. Ground spent hops may be added to the mixture; the fibres used should be sufficiently long to produce a felted mass.—J. F. B.

[Paper] Pulp; Method of preparing ——. C. Bache-Wüg, Berlin, N.H., Assignor to H. J. Chisholm, New York. U.S. Pat. 1,084,244, Jan. 13, 1914.

A stock suitable as a substitute for ground wood pulp is prepared from cellulose material such as straw or corn (maize) stalks by placing the material in a digester, withdrawing the air from it, forcing in a bleaching gas such as sulphur dioxide, then injecting a pulp-forming liquor such as sodium chloride solution and cooking the mass. —J. B.

Fibrous matter; Process for separating —— from admixtures. J. J. Werst, Delft, P. M. H. L. Collée, an J. M. Egmond, Rotterdam. U.S. Pat. 1,083,204 Dec. 30, 1913.

See Fr. Pat. 449,059 of 1912; this J., 1913, 482.—T. F. B

Cellulose and other substances of which it forms the essenti part; Process and apparatus for the electrical treatme of ——. A. L. C. Nodon, Bordeaux, France. Eng Pat. 6668, March 18, 1913. Under Int. Conv., March 2 1912.

See Fr. Pat. 453,111 of 1912; this J., 1913, 785.—T. F.

Celluloid, acetylcellulose, and analogous substances; Proce for cleaning or renovating objects of ——. A. Püsch Fr. Pat. 461,121, Aug. 5, 1913.

See Eng. Pat. 18,105 of 1913; this J., 1914, 20.—T. F.

Production of solvents [of nitrocellulose] by means of halog compounds. U.S. Pat. 1,082,543. *See* XX.

VI.—BLEACHING ; DYEING ; PRINTING ; FINISHING.

Dyeing ; The theory of ——. I. W. D. Bancroft. J. Phys. Chem., 1914, 18, 1—25.

The author discusses the experimental data available and concludes that it is sufficient to establish the outlines of a satisfactory theory of dyeing if the single postulate be accepted that a fibre tends to adsorb everything in the dye solution in amounts varying with the nature, concentration, and temperature of the solution and with the nature of the fibre. In the present paper the data available in regard to dyeing with acid dyes are discussed in relation to this postulate, and it is shown that in the case of acid dyes it may be deduced that the dye will be most readily taken up in an acid solution, but may be taken up in a neutral or alkaline solution ; also that a readily adsorbed anion will decrease and a readily adsorbed cation increase the amount of dye taken up. The paper of Hallitt on "The Theory of the Acid Dye-bath" (this J., 1899, 368) is discussed in detail in relation to the adsorption theory. —A. S.

Basic dyestuffs ; The fixation of —— by means of naphthols. J. Niagavi. Rev. Gén. Mat. Col., 1914, 18, 33.

The process consists in fixing a naphthol or naphtholsulphonic acid on vegetable fibres by steaming, a compound being produced which has a chemical affinity for basic dyestuffs like that of tannin, and which also has the property of fixing dyestuffs mechanically like albumin, casein, etc. The presence of a catalyst is necessary for the formation of the lake, a wide variety of inorganic compounds being suitable. The shades are brighter than those produced on a tannin-antimony mordant.—J. B.

Colour measurement and nomenclature ; The industrial applicability of the various systems of ——. P. Krais. Z. angew. Chem., 1914, 27, 25—37.

The author examines the possibility of establishing a standard system of colour value nomenclature, and comes to the conclusion that only a compromise can be achieved on account of such difficulties as the practical impossibility of obtaining pure spectrum standards, the variations in light from different sources, the difficulty of comparing a lithographed colour scale with textile materials, for example, if it is necessary to judge the appearance of a shade "overhand," etc. The various schemes that have been devised (by Radde, Langhein, K. Mayer, Kallab, Arons, Klemperer, Lovibond, Baumann and Rosenstiehl) are described and criticised, and the author discusses his experiences with the three main types of apparatus—the pigment colour scale, the light-filter apparatus and the rotating disc apparatus. Yellow, on account of the difficulty in measuring its strength, is always an obstacle. Baumann's scale is finally recommended as a practical basis for the measurement of colour values, in spite of its complicated nomenclature and the difficulty of securing absolute regularity in commercial pigments.—J. B.

Patents.

Lixiviating, acidifying and washing wool ; Pump worked by compressed air for machines for ——. F. Bernhardt Maschinenfabrik und Eisengiesserei. Fr. Pat. 462,166, Sept. 3, 1913. Under Int. Conv., June 11, 1913.

A reciprocating current of compressed air is used for orcing liquids from a lower to a higher level in wool washng, etc., machines, whereby metallic corrosion usually sociated with rotary and other pumps, is avoided.—J. B.

leaching, dyeing, washing, etc., hanks ; Apparatus for ——. Courtaulds Ltd., and J. Clayton, Coventry. Eng. Pat. 9067, April 17, 1913.

HE yarn rods are supported on rails which are alternately ised, moved forward, lowered and moved back to their rmer position. The yarn rods are also caused to revolve, st in one direction, then in the other, by rollers on which they rest. The working parts of the machine are enclosed in casings inside of which a pressure of air is maintained in order to prevent the entrance of the bleaching or other corrosive liquor.—J. B.

Fast shades on vegetable fibres ; Production of —— and dyestuffs therefor. H. Levinstein, J. Baddiley and Levinstein, Ltd., Manchester. Eng. Pat. 1436, Jan. 17, 1913.

Dyestuffs of the general formula, $R.N_2.D.N_2.M.N_2.R$, in which R represents resorcinol, D the residue of a diamino capable of giving substantive dyestuffs, and M the residue of an aminonaphtholsulphonic acid containing an extra-nuclear diazotisable amino-group, are claimed. Bright shades are produced on vegetable fibres which on after-treating with formaldehyde become fast to boiling soap. For example, the tetrazo-compound from *m*-azoxytoluidine combined with one mol. of *m*-aminobenzoyl-1-amino-8-naphthol-3-6-disulphonic acid, re-diazotised and combined with two mols. of resorcinol gives a red.—J. B.

Dyeing machines. W. Furness, Greetland. Eng. Pat. 1688, Jan. 21, 1913.

In order to allow of their ready removal, the rollers in hawking machines, such as are used for indigo vats, are mounted in the frame in open slots, the stripper-blades being mounted on beams parallel to the rollers and so disposed as not to prevent the removal of the latter.—J. B.

Dyeing and otherwise treating textile fibres or fabrics ; Apparatus for ——. W. and J. A. Cock, Huddersfield. Eng. Pat. 22,185, Oct. 2, 1913.

The dye-vat has a false bottom and a vertical circulating pipe, open at both ends. The circulation is effected by means of steam which enters through a pipe brought down inside the circulating pipe. On emerging from this pipe the steam impinges on a dish having a central mound, whence it is reflected up through a horizontal grating into the circulating pipe. The top of the circulating pipe is fitted with a dome-shaped deflecting plate.—J. B.

Charges for dye-vats ; Apparatus for forming and preparing ——. J. T. Psarski, Cleveland, Ohio. U.S. Pat. 1,083,410, Jan. 6, 1914.

The material is compressed by means of a weighted lid and the admission of steam in a cylinder which telescopes into the mouth of a cylindrical dye-vat, and which has for a temporary bottom the false bottom of the dye-vat. —J. B.

Dyeing on bobbins ; Apparatus for ——. Textilmaschinenfabrik B. Cohnen. Fr. Pat. 461,251, Aug. 11, 1913.

The blocks of wood on which the small bobbins are wound are displaced by perforated dyeing tubes, each tube being slightly enlarged at its lower end. The bobbins are then slipped on to the longer perforated spindles of the dyeing machine, one above another, each tube fitting into the enlarged portion of the one above it.—J. B.

Naphthazarin derivatives ; Dyeing or printing with ——. O. Imray, London. From Soc. of Chem. Industry in Basle, Switzerland. Eng. Pat. 12,790, June 2, 1913.

Certain condensation products of naphthazarin are dyed or printed on vegetable fibres in the form of their leuco-compounds, after the manner of vat dyestuffs. Greys, browns and various shades of black are produced, which are improved in fastness on after-treating with metallic salts. Suitable condensation products are obtained (1) by condensing naphthazarin or its derivatives with substances containing one or more primary, secondary or tertiary amino-groups ; or (2) by heating naphthazarin or its derivatives or the products obtained as described under (1) in solution or suspension in a diluent with or without the addition of alkali, a sulphide or the like.—J. B.

Solutions for bleaching and other like purposes; Electrolytic apparatus for making ——. C. A. M. Buckley. Fr. Pat. 461,666, Aug. 21, 1913.

See Eng. Pat. 18,600 of 1912; this J., 1913, 1007.—T. F. B.

Dyeing skins, hairs, feathers, and the like; Process for ——. Act.-Ges. f. Anilinfabr., Treptow, Germany. Eng. Pat. 10,293, May 1, 1913. Under Int. Conv., Oct. 19, 1912. Addition to Eng. Pat. 20,926, March 19, 1912.

See Ger. Pat. 262,692 of 1912; this J., 1913, 941.—T. F. B.

Fast dyeings on the fibre; Process for producing ——. L. Cassella und Co. G.m.b.H. Fr. Pat. 461,747, Nov. 5, 1912.

See Eng. Pat. 25,897 of 1912; this J., 1913, 1007.—T. F. B.

Dyeing machine. The Psarski Dyeing Machine Co. Fr. Pat. 461,857, Aug. 8, 1913.

See Eng. Pat. 18,303 of 1913; this J., 1914, 73.—T. F. B.

Manufacture of colouring matters of the benzanthrone series and dyeing and printing therewith. Eng. Pat. 5248. *See* IV.

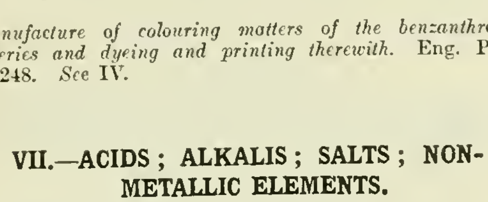
VII.—ACIDS; ALKALIS; SALTS; NON-METALLIC ELEMENTS.

Sulphuric acid free from nitric acid and oxides of nitrogen; Preparation of ——. A. Grégoire. Bull. Soc. Chim. Belg., 1914, **28**, 32—33.

The sulphuric acid to be purified is diluted in a Kjeldahl flask with its own volume of water and concentrated by boiling. If traces of nitrous compounds still remain, the process is repeated.—O. E. M.

Electrolytic chlorine at Mount Morgan, Queensland. B. Du Faur. Trans. Australasian Inst. Min. Eng., 1911, **15**, 375—389.

The installation comprises 20 cells, each of which (see fig.) is divided into three compartments by means of two perforated sheets of iron (*b*) bolted to the bottom and ends; the two asbestos diaphragms (c), upon the inside walls, extend to the bottom of the cell, the anode compartment thus formed being covered at the bottom and each end with cement 1 in. thick. The diaphragms extend upwards to (*d*) and are held in position by the earthenware cover (*e*) of the cell, the space between them and the latter being filled with cement. The upper part (*f*) of the cover is removable for the purpose of renewing the anodes, but while the cell is in use is rendered gas-tight by means of pitch. The anodes (*a*) are of Acheson graphite, the holders being composed of an alloy of Pb 80 and Sb 20 per cent. For the purpose of indicating the level of the solution in the anode compartment, the latter is connected with the glazed earthenware pot (*g*) by means of the ebonite pipe (*k*). The electrolyte is a solution of common salt from which lime and magnesia have been separated by precipitation with a mixture of sodium carbonate and hydroxide (in calculated quantities) followed by settling, decantation of the clear solution, and filtration of the sludge. The purified solution from the storage tank drips into the anode compartment of each cell, through a funnel, the chlorine evolved being drawn off by suitable means and the anode liquor returned to the dissolving tank; the cathode solution, the sodium hydroxide content of which is not allowed to exceed 8 per cent., is periodically withdrawn and either run to waste or evaporated for the recovery of sodium chloride. The cells are connected in series and a current of 350 amp. is employed, the voltage necessary being 88 when the anodes are new and 98 when fresh ones are required (6 months later). The chlorine production over a period of 6 months was 312·48 lb. per 24 hours; and the consumption of sodium chloride 3 lb., or 1·67 lb., per lb. of chlorine obtained, according as the sodium chloride was extracted from the cathode liquors or not. The mean power consumption by the cells was 2·5 electrical-horse-power-hours per lb. of chlorine produced, the electrical current efficiency being 63·72 per cent. and the energy efficiency 49·24 per cent. On the basis of salt consumption per lb. of chlorine produced, the efficiency of the plant was 55 or 98 per cent. according to the disposition of the cathode liquors.—W. E. F. P.



Polysulphides of the alkali metals. I. Polysulphides of sodium. A. Rule and J. S. Thomas. Chem. Soc. Trans., 1914, **105**, 177—189.

Sulphur reacts readily with sodium hydrosulphide in alcoholic solution with the evolution of hydrogen sulphide and formation of polysulphides. The authors have used quantities of sulphur corresponding to di-, tri-, tetra-, penta-, and hexa-sulphides, and concentrated the solution in each case to obtain a solid product. Only in the case of the tetrasulphide proportion was the product homogeneous, when it was pure anhydrous tetrasulphide crystallising in cubes and having a yellowish colour. The crystals melted at about 267° C. and were readily soluble in water, but the solution soon became cloudy. The other proportions gave mixtures of tetrasulphide with unchanged hydrosulphide or with sulphur, although there was some indication of the formation of a higher sulphide when much sulphur was used. The course of the reaction was followed in each case by measuring the amount of hydrogen sulphide evolved, which also gave an idea of the nature of the substances in solution. By reducing solutions of the tetrasulphide with metallic sodium the anhydrous disulphide was obtained as a bright yellow crystalline powder, not so soluble in alcohol as the tetrasulphide.—W. H. P.

Persulphates; Action of —— *on acetates.* M. A. Gordon. J. Phys. Chem., 1914, **18**, 55—66.

Acetic acid is decomposed in two ways by persulphate, being, on the one hand, oxidised, with formation of ethane, olefines, carbon dioxide, water, and other products, and on the other hand, decomposed into methane and carbon dioxide, the persulphate acting catalytically. That persulphate itself is the catalyst in this second mode of decomposition is shown by the facts that probable impuritie when tested had no such action and that the action ceased when the persulphate was destroyed. The oxidation of th acetic acid is promoted by conditions favouring th decomposition of persulphate (*e.g.*, high concentratio of persulphate, high temperature, moderate acidity presence of manganous sulphate or platinum foil), provide they are not carried to excess: in presence of an excessiv quantity of sulphuric acid, the persulphate is decompose at high temperatures with liberation of oxygen, and oxida tion of the acetic acid is diminished. The catalyt decomposition of acetic acid into methane and carbo dioxide is promoted by high concentration of acetic aci low acidity (obtained by addition of sodium acetate reduce the dissociation of the acetic acid) and low co centration of persulphate.—A. S.

Peroxides. S. Tanatar. Ber., 1914, **47**, 87—89.

The author controverts some results obtained by Tuba and Riedel (this J., 1911, 1210). A solution of nic peroxide in dilute sulphuric acid contains hydrogen peroxi and not merely persulphuric acid. Nickel peroxi dissolved in hydrocyanic acid in presence of potassi cyanide yields larger quantities of hydrogen peroxide, but other nickel compounds, if free from cobalt, do not give the reaction.—J. R.

Silicic acid gel; Action of hydrogen peroxide on ——. A. Komarowsky. Chem.-Zeit., 1914, **38**, 121—122.

By evaporating silicic acid gel with a slight excess of 30 per cent. hydrogen peroxide to dryness on the water-bath, or over sulphuric acid, a glassy amorphous mass is obtained containing 12·6 per cent. of active oxygen, 50·6 per cent. SiO_2 and 36·8 per cent. H_2O. On keeping it gradually loses oxygen in the form of ozone and also water. It liberates chlorine from hydrochloric acid and iodine from potassium iodide, decolourises permanganate, evolves ozone on treatment with concentrated sulphuric acid; and must be regarded as either a persilicic acid or a perhydrogel of silicic acid in which part of the water has been replaced by hydrogen peroxide.—A. S.

Cupric oxide jellies. L. S. Finch. J. Phys. Chem., 1914, **18**, 26—33.

The author confirms Foerster's statement (Ber., 1892, 25, 3416) that copper ammonium acetate, on treatment with water, yields a blue jelly, which, however, is not permanent. Similar jellies, some of which were of a more permanent character, were prepared in various ways, the best results being obtained by adding 4 drops of concentrated sulphuric acid to 50 c.c. of a saturated solution of copper acetate and then adding 3—4 c.c. of dilute ammonia (1 : 1). The jelly dried to a powder when exposed to the air, but on shaking with water a solution was obtained which again set to a jelly, and this sequence of operations could apparently be repeated indefinitely. Good results were also obtained by using potassium sulphate in place of sulphuric acid.—A. S.

Magnesium chloride as mineraliser, and a contribution to the spectrochemistry of the rare earths. K. A. Hofmann and K. Höschele. Ber., 1914, **47**, 238—247.

Anhydrous magnesium chloride melts at 708° C. to a mobile liquid which is stated to be an excellent solvent and crystallising medium for many metallic oxides. In some cases it reacts with the oxides, and especially with sulphates, with formation of volatile chlorides, *e.g.* of beryllium, zinc, iron, and tin. In other cases spinel-like magnesium compounds are formed, probably as the result of decomposition of the magnesium chloride by water vapour from the heating flame or by atmospheric oxygen. Such decomposition must always be taken into consideration, as large octahedra of magnesia are formed which remain admixed with the reaction product; and the crucible may be attacked by hydrochloric acid or chlorine. For example on melting magnesium chloride in an open platinum crucible, aggregates of hexagonal platinum crystals are gradually formed; in a gold crucible, regular crystals of gold; in silver, crystals of silver chloride, and in copper, crystals of cuprite (Cu_2O) are produced. There is, however, little action on porcelain crucibles or on covered platinum crucibles. By heating iron filings, anhydrous ferrous sulphate, or ferric oxide with fused magnesium chloride, according to the conditions crystalline products ranging from magnesium ferrite, $(FeO_2)_2Mg$, to ferrosoferric oxide $(FeO_2)_4Fe$, may be obtained, all of which are strongly magnetic. Other compounds which may be prepared in this way in the form of crystals are magnesium orthoborate from hydrated boric acid, magnesium uranate from uranic acid, cerium dioxide, praseodymium oxide and zirconium dioxide from the corresponding sulphates, and the oxychlorides of erbium neodymium, praseodymium, and samarium from the corresponding sulphates.—A. S.

Uranyl nitrate; Question of the liability of —— to explode. W. Eichhorn. Chem.-Zeit., 1914, **38**, 139.

A sample of Merck's uranyl nitrate, $UO_2(NO_3)_2.6H_2O$, showed triboluminescence phenomena, but gave no indications of exploding when shaken in a flask, as in the case of the samples examined by Iwanow (this J., 1912, 362) and by Andrews (Chem.-Zeit., 1912, 1463). By extracting a concentrated aqueous solution of the salt with ether a product was obtained containing 53·92 per cent. UO_2 and 24·83 per cent. NO_3. On exposing the product to the air rapid absorption of water took place, and it is probable that this is a factor in causing explosion phenomena.—C. A. M.

Carbon dioxide and monoxide dissolved under pressure; Electrolytic reduction of ——. F. Fischer and O. Prziza. Ber., 1914, **47**, 256—260.

Experiments were made with an apparatus similar to that used previously (this J., 1913, 362) for the electrolytic reduction of dissolved oxygen. Using solutions of potassium, sodium, or lithium sulphate saturated with carbon dioxide as electrolyte, and copper coated with zinc and then amalgamated as electrodes, the carbon dioxide was reduced to formic acid even at comparatively high current densities (10—15 ampères per sq. dcm.). For short periods (10 mins.) the current yield was almost quantitative, but high concentrations could not be obtained, owing to migration of the formic anion to the anode. The maximum concentration of formic acid attained was 17·6 grms. of potassium formate in 100 c.c., the current density being 6 ampères per sq. dcm., the current yield 49 per cent., and the pressure nearly 50 atmospheres. Carbon monoxide dissolved under pressure was reduced, in very small quantities, to methyl alcohol, when low current densities were used; no methane was formed.—A. S.

Reactions in non-aqueous solutions. VI. In acetonitrile. A. Naumann. Ber., 1914, **47**, 247—256. (See also this J., 1909, 1195; 1910, 349.)

The solvent was prepared by leaving commercial acetonitrile (contaminated by acetamide) in contact with phosphorus pentoxide in a closed vessel for 3—4 weeks, then distilling, and collecting the fraction boiling at 81·6° C. At 18° C. 1 grm. of acetonitrile dissolved 0·0161 grm. $CuCl_2$, 0·2443 grm. $CuBr_2$, about 0·1333 grm. Cu_2Cl_2, about 0·0386 grm. Cu_2Br_2, 0·0352 grm. Cu_2I_2, 0·1131 grm. KSCN, 0·0752 grm. NH_4SCN, 0·0408 grm. $CoCl_2$, at least 2·9 grms. $AgNO_3$, and 0·0958 grm. $Hg(CN)_2$ respectively. In addition to the salts mentioned, ammonium bromide and calcium nitrate were very sparingly soluble, ammonium nitrate, mercuric and bismuth iodides were slightly soluble, sodium and potassium iodides, sodium thiocyanate, potassium permanganate, aluminium, cadmium and tin chlorides, cobalt, mercuric, cadmium and bismuth bromides were soluble, and lithium, ferric and ferrous bromides, zinc, ferric, ferrous, mercuric and bismuth chlorides, cadmium iodide, chlorine, bromine, iodine, hydrochloric, hydrobromic and hydriodic acids, ammonia, hydrogen sulphide, and sulphur dioxide were easily soluble in acetonitrile. Many of the salts formed addition compounds with the solvent. The reactions of the dissolved substances were studied and are described in detail.—A. S.

Water spray or steam injected into sulphuric acid chambers: Device for regulating, according to the density of the acid in the chambers, the ——. L. Santa. Fr. Pat. 461,641, Aug. 13, 1913. Under Int. Conv., Feb. 7, 1913.

Part of the acid condensing on the walls of the chamber is led into a gutter and thence into a receptacle mounted on one end of a counterpoised lever, connected with clockwork mechanism, by which the movement of the valve controlling the supply of water to the spraying devices is operated. When the density of the acid falls below a certain limit, the acid in the receptacle is not sufficiently heavy to operate the lever, the clockwork is prevented from working, and the supply of water is cut off.—A. S.

Lead chamber for sulphuric acid manufacture. H. Ising. Ger. Pat. 267,513, Feb. 7, 1913.

The walls of the chamber are provided with superposed ledges of such form and width that the acid drops from them directly on to the floor of the chamber. In this way the area of the walls coming directly into contact with the liquid acid is diminished.—A. S.

Nitric acid; Manufacture of —— from nitrates and sulphuric acid. C. Uebel. Fr. Pat. 461,452, Aug. 18, 1913. Under Int. Conv., March 11, 1913.

Sulphuric acid and half the usual charge of nitrate are introduced gradually into a retort which is heated to about 140° C., whereby nitric acid vapour of high concentration is evolved. When the nitrate is completely decomposed, the temperature is raised to 160°—170° C., and the other half of the charge of nitrate is introduced gradually; the acid vapours liberated during this stage of the process are still of a high degree of concentration, though yielding a weaker acid than those from the first stage. The residue is next transferred to another retort in which it is heated to about 250° C. to expel water and the last traces of nitric acid.—A. S.

Nitrous gases; Process for the absorption of ——. Dynamit-A.-G. vorm. A. Nobel und Co. Ger. Pat. 267,874, Nov. 27, 1912.

The claim is for the use of fatty acid esters of alcohols, *e.g.*, amyl acetate, as absorbents. At the ordinary temperature amyl acetate will absorb about 20 per cent. of its weight of nitrogen oxides, and these can be subsequently recovered by passing a current of air or other gas through the liquid and warming or by treatment with water.—A. S.

Phosphoric acid; Process of manufacturing ——. F. Brunschwig, Brooklyn, N.Y. U.S. Pat. 1,083,429, Jan. 6, 1914.

Ground material containing calcium phosphate is treated with sufficient sulphuric acid to render the mass fluid whilst in a state of agitation, and the reaction is stopped before impurities go into solution, the quantity of acid used being such as to allow the calcium phosphate to remain in excess up to 20 per cent.—O. R.

Formates and the like; Process of producing ——. J. E. Bucher, Coventry, R.I. U.S. Pat. 1,083,589, Jan. 6, 1914.

A cyanogen compound of a light metal, especially the cyanide, is vigorously hydrolysed in the presence of the hydroxide of the same metal, at the boiling point of the mixture, with the rapid formation of a carboxylate, especially the corresponding formate.—O. R.

Lead solutions; Process of producing ——, from lead ore. Process of producing lead nitrate solutions. S. W. Anderson and G. C. Kaar, Spokane, Wash. U.S. Pats. 1,083,910 and 1,083,911, Jan. 13, 1914.

Crude lead sulphide is digested with dilute nitric acid (7 per cent. strength) containing an alkali nitrate, and the solution purified by the addition of successive small quantities of an alkali. Iron is eliminated from the solution by first heating the latter with sufficient sodium carbonate to precipitate the greater part of this impurity, and then with that necessary to precipitate the remainder. —W. E. F. P.

Sodium bisulphite; Process of making solid ——. H. Howard, Boston, Mass. U.S. Pat. 1,084,436, Jan. 13, 1914.

Sodium bisulphite solution is exactly neutralised with sodium carbonate, so as to obtain solid sodium sulphite suspended in a solution of the same; by the action of sulphur dioxide, both the suspended and the dissolved sulphite are converted into bisulphite, the solid bisulphite is separated, the residual liquor is neutralised, and the procedure is repeated.—O. R.

Sodium fluoride and aluminium fluoride; Manufacture of a double compound of ——. Humann und Teisler. Fr. Pat. 461,181, Aug. 7, 1913.

The double compound, $6NaF,2Al_2F_6$, is obtained by the interaction of 3 mols. of sodium silicofluoride and 2 mols. of alumina. 2·8 kilos. of sodium silicofluoride suspended in 1—1·5 litres of water is heated to 40° C. and 1·6 kilos. of aluminium hydroxide suspended in 1·5 litres of water and also heated to 40° C., is added with vigorous agitation. The product, although it contains about 20 per cent. of silica, is readily fusible and may be used directly as a clouding agent for enamels and opal glass. (See also Fr. Pat. 458,750; this J., 1913, 1067.)—A. S.

Basic insoluble carbonates [basic magnesium carbonate and white lead]; Manufacture of —— and of their transformation products. Chem. Fabr. Rähnitz Ges. m. b. H. Fr. Pat. 461,397, Aug. 14, 1913. Under Int. Conv., Aug. 15, 1912.

Basic carbonates, especially those of magnesium and lead, are prepared by precipitating a solution of a soluble salt of the metal, with a mixture of a carbonate and a soluble hydroxide. More or less voluminous precipitates are obtained according to the relative proportions of carbonate and hydroxide used and the temperature of precipitation.—A. S.

Tartaric acid; Treatment of materials containing —— for the extraction of calcium and potassium tartrates. T. Gladysz. Fr. Pat. 461,901, Nov. 8, 1912.

Wine lees from which calcium and potassium tartrates cannot readily be extracted ("gummy lees") are first heated in suitable vessels and subjected to the action of almost anhydrous hydrochloric acid gas at about 130° C. This treatment greatly facilitates the subsequent extraction of the tartrates.—J. H. L.

Chlorate solutions; Process for activating ——. K. Hofmann. Ger. Pat. 267,906, Nov. 20, 1912.

Osmium or a compound of the same, especially osmium tetroxide, is added to a neutral or acid solution of the chlorate. (See also this J., 1913, 46, 697, 977.)—A. S.

Cyanogen or hydrogen cyanide; Production of gases containing —— from gaseous mixtures containing carbon, hydrogen, and nitrogen, in the electric arc. Konsortium für Elektrochemische Industrie Ges. m. b. H. Ger. Pat. 268,277, July 1, 1911. Addition to Ger. Pat. 263,692 (this J., 1913, 1067).

The yield is increased by introducing into the arc the vapours of metals or metallic compounds (*e.g.* copper or iron or their salts), capable of exercising a favourable catalytic effect on the reaction.—A. S.

Hydrogen peroxide; Process of producing ——. A. Pietzsch and G. Adolph, Hoellriegelskreuth, Germany U.S. Pat. 1,083,888, Jan. 6, 1914.

A mixture of a persulphate and sulphuric acid is subjecte to the action of steam, with the formation of hydroge peroxide vapour.—O. R.

Graphitising carbon; Apparatus for ——. P. L. Héroult, New York, Assignor to Electrode Co. America, Niagara Falls, N.Y. U.S Pat. 1,084,27 Jan. 13, 1914.

A vertical, tubular graphitising chamber is construct of a series of horizontal, removable, brickwork rings, that the height of the chamber can be regulated at wi Electrodes are disposed at the top and near the botto of the chamber, and the latter is surmounted by a tubul heating chamber, the lower end of which forms a dire extension of the graphitising chamber, the gases from t latter thus passing through the mass of material descending from the heating to the graphitising chamber. —O. R.

Ores of manganese and of iron and manganese ; Use of natural —— in contact processes [e.g., for the production of hydrogen]. A. Messerschmitt. Fr. Pat. 461,480. Aug. 19, 1913. Under Int. Conv., Jan. 10, 1913.

Natural ores of manganese or of manganese and iron are used as contact materials for the production of hydrogen by the alternate action thereon of reducing gases and steam. It is stated that hydrogen is obtained in good yields at 700°—800° C., about 200° C. lower than the temperatures required when spongy iron is used as contact material.—A. S.

Reducing agents ; Manufacture of stable —— from rapidly oxidising substances, such as sodium, potassium, calcium, phosphorus, and the like. P. Goldstein. Ger. Pat. 268,657, Dec. 24, 1912.

Easily oxidisable substances, such as those mentioned in the title, are incorporated with porous materials. Metallic sodium, for example, in long filaments, is incorporated with kieselguhr and heated to about 100° C. with exclusion of air or in an atmosphere of nitrogen. The product, it is stated, is not affected by exposure to air. Metallic oxides which are to be reduced, or metals to be protected from oxidation, may also be incorporated with the porous material.—A. S.

Nitrous gases or vapours ; Process for the absorption of ——. A. T. Schloesing, Paris. Eng. Pat. 22,119 Oct. 1, 1913. Under Int. Conv., Oct. 2, 1912.

See Fr. Pat. 460,328 of 1912 ; this J., 1914, 23.—T. F. B.

Nitric acid ; Process for concentrating aqueous ——. H. Pauling. Fr. Pat. 461,326. Aug. 11, 1913. Under Int. Conv., Aug. 24, 1912.

See U.S. Pat. 1,074,287 of 1913 ; this J., 1913, 1009.—T. F. B.

Sulphuric acid ; Process for concentrating —— by preliminary and final concentrations. A. Zanner. Fr. Pat. 462,016, Aug. 30, 1913. Under Int. Conv., Aug. 30, 1912.

See Ger. Pat. 260,655 of 1912 ; this J., 1913, 751.—T. F. B.

Hydrogen : Process for producing ——. Badische Anilin und Soda Fabrik. Fr. Pat. 461,621, Aug. 4, 1913. Under Int. Conv., Sept. 7, 1912.

VIII.—GLASS ; CERAMICS.

elenium as colouring agent in soda-lime silicate glasses. P. Fenaroli. Chem.-Zeit., 1914, **38**, 177—180.

was shown previously (this J., 1912, 1033) that in estnut-brown selenium glasses the colour is due to lyselenides. Ultramicroscopic examination has now own that in pink glasses, which always contain some tash, the colour is due to elementary colloidal selenium. e colour is affected by a more protracted cooling, uch causes some opacity through the formation of lenites and selenides ; opalescent selenium glasses are oduced in this way. Red colloidal selenium particles have a magnitude less than 40 $\mu\mu$. The colloidal solution has the same properties as other selenium-sols. These glasses exhibit great analogy to boron-selenium ultramarine. The absorption spectrum of colloidal selenium solutions varies from red to yellow according to the size of the sub-microns.—H. H. S.

China clay ; Temperature at which the combined water in —— is expelled. W. Thomson. J. Soc. Dyers and Col., 1914, **30**, 45—46.

Ordinary China clay contains usually about 10 to 16 per cent. H_2O which can be expelled at steam-oven temperature (about 104° C.). On heating to redness a further loss takes place of about 12 per cent. on the dry clay ; this water is held very tenaciously for none of it is given up during an hour's heating at 560° F. (293° C.). The character of the substance is entirely changed by the loss of this combined water.—J. B.

Patent.

Manufacture of a double compound of sodium fluoride and aluminium fluoride. Fr. Pat. 461,181. *See* VII.

IX.—BUILDING MATERIALS.

Portland cement ; Plant and method of manufacture of —— at Limestone Island. F. N. Rhodes. Trans. Australasian Inst. Min. Eng., 1912, **16**, 275—287.

The cement rock of Limestone Island, New Zealand, requires only the addition of a certain amount of high-carbonate limestone to yield a mixture with a composition suitable for making Portland cement. The raw materials are crushed, dried in a rotary dryer, ground, and passed through the kilns, the clinker being burnt fairly hard. The hot clinker is quenched by a stream of water, mixed with 1 per cent. of gypsum, and mixture ground.—T. St.

Patents.

Bituminous compositions [for roads]. J. J. Ingham, Bradford. Eng. Pat. 1458, March 18, 1913.

Bitumen sheeting, *i.e.*, canvas coated with bitumen, is interposed between two layers of a composition formed by boiling together 4 parts of pitch, 1 part of creosote oil, 14 parts of sand, 7 parts of Trinidad bitumen, and 7 parts of petrol pitch.—O. R.

Slime and the like [Portland cement slurry] ; Process of separating and purifying ——. M. Kohn, Brünn, Austria. Eng. Pat. 8129, April 7, 1913.

Thick mud, especially cement slurry, containing large and rough particles, is passed into a closed reservoir, from which it is forced by means of compressed air through an inclined sieve into an outlet pipe or reservoir, the compressed air also serving to remove the residue remaining in the first reservoir by way of a second pipe.—O. R.

Lumber ; Process of treating ——. [*Tinting wood.*] R. L. Gilliam, New York. U.S. Pat. 1,084,266, Jan. 13, 1914.

A pinkish colour is imparted to the sap wood of the sweet gum tree by subjecting the wood in a closed chamber to the action of steam at about 100° C. until the sap is substantially removed, and continuing the treatment in the presence of the exuded sap and of iron, until the desired shade is obtained.—O. R.

X.—METALS ; METALLURGY, INCLUDING ELECTRO-METALLURGY.

Iron ore output of the world. C. K. Leith. Times Eng. Suppl., Feb. 4, 1913.

The annual output of iron ore in the chief producing countries during the latest period (average of 1909, 1910, and 1911) for which figures are available was: United States, 50 million tons; Germany, 27; United Kingdom, 15; France, 14; Spain, 8, and Sweden 5 million tons. Continued heavy production may be expected of the Lake Superior ores, the ores of the Franco-German boundary, the Bilbao ores of Spain, the Cleveland ores of England, and the high-grade magnetites of N. Sweden; whilst increasing quantities of ores may be expected from Sweden and Cuba, and the use of Clinton hæmatites and Adirondack magnetites in the United States will also probably increase. In the near future there will probably become available the Brazilian high-grade hæmatites, Chilean ores, and ore deposits of Western United States, Western Canada, India, and China.—A. S.

Steel refining; Metallurgy of —— in an acid electric furnace. A. Müller. Stahl u. Eisen, 1914, **34**, 89—95.

The most important reaction is the passage of silicon into the steel from the lining and the silica-rich slag. This silicon has a considerable deoxidising action, and makes additions for deoxidising purposes unnecessary. No final desulphurisation or dephosphorisation takes place. A certain amount of desulphurisation is effected probably by the formation of volatile silicon sulphide at the arc temperature, but this only balances the sulphur contained in the coke, etc. The most suitable slags contain CaO about 15, MgO 2 to 5, MnO 10 to 15, FeO about 4, and SiO_2 55 to 60 per cent. Whilst the working of an acid electric furnace requires care and experience, the author considers that where suitable material is available, it has the advantages over the basic furnace, for the production of medium quality steel, of smaller current consumption through a shorter refining period, a saving of deoxidising additions, cheaper first cost and upkeep of the lining, and cheaper fluxes.—T. St.

[Gold and silver.] Treatment of the complex East Gippsland (Victoria) ores. K. A. Mickle. Trans. Australasian Inst. Min. Eng., 1911, **15**, 583—603.

The ore contains iron pyrites, mispickel, pyrrhotine, blende and galena, with smaller amounts of copper pyrites, covellite, stibnite and jamesonite—these minerals occurring as an intimate mixture (totalling about 40 per cent.) in which the first two predominate—and also varying quantities of calcite, magnesium silicate and felspar; the country rock is a greenish-coloured schist, which, in the neighbourhood of a lode, is also usually impregnated with fine-grained sulphides. The ore, containing about 27 dwt. Au and 20 dwt. Ag per ton, is wet-stamped and passed over amalgamated copper plates to cone hydraulic classifiers, whence the sized products are transferred to different Wilfley tables upon each of which a "strip" of sulphides is obtained. The upper part of this strip ("galena concentrate") is roasted and smelted separately, the remainder ("ordinary concentrate") being roasted and chlorinated; the sands and slimes are treated, separately, by cyaniding. The "ordinary concentrate" contains from 55 to 80 dwt. Au per ton, only about 85 per cent. of which is extracted by the present method. Experiments showed that the gold is intimately mixed with the sulphide portion of the ore, much of it being exceedingly fine and probably not "free" even after fine grinding; that during roasting, some of the gold particles become more or less enclosed by reason of the fritting which occurs and thus protected from attack by the chlorine; and that by mixing the raw, with an equal weight of roasted, concentrate (previously chlorinated) and roasting the mixture, a product is obtained which is more amenable to cyanide or chlorination treatment than the ordinary roasted concentrate. (In a large-scale test the residue from the chlorination of the former contained 6 dwt. Au per ton and that from the latter 10—14 dwt.) In the cyanide process, the best results were obtained by first treating the raw concentrate with the solution, then roasting the material slowly and at a low temperature, and finally treating it a second time with cyanide. A higher extraction, however, was obtained by roasting and chlorination than by any other method of treatment with solvents.—W. E. F. P.

Sulpho-telluride gold ore; Roasting —— at the Kalgurli Gold Mines, Ltd. F. G. Brinsden. Trans. Australasian Inst. Min. Eng., 1911, **15**, 71—90.

A description, with drawings, of plant which has a daily output of 360 tons is given. The crushed ore is roasted in Simplex Edwards roasters, and on being discharged is conveyed direct to the agitators, where it is mixed with cyanide solution. It enters the agitators at about 454° C. The aim in roasting is to obtain a product having the minimum quantity of oxygen-absorbing salts, and tests are made by titrating a sodium hydroxide extract of the roasted ore with $N/100$ iodine solution. The roasting enables an average extraction of slightly over 94 per cent. of the gold to be maintained.—T. St.

[Gold and silver.] Cyaniding; Use of lime in ——. A. M. Merton. Min. and Eng. World, 1914, **40**, 58.

The functions of lime in cyaniding practice and its use in the various stages of the ore treatment are discussed. The following method is advocated by the Mines Trials Committee of S. Africa for determining "available" lime in the commercial product:—50 grms. of crystallised sugar and 800 c.c. of water are added to 2 grms. of the sample (60-mesh), the mixture is shaken thoroughly, allowed to stand for a few hours with occasional shaking, and diluted to 1000 c.c. 50 or 100 c.c. of the liquid are withdrawn immediately after shaking and titrated with standard oxalic acid (22·5 grms. per litre: 1 c.c.=0·01 grm. CaO) using phenolphthalein as indicator.—W. E. F. P.

Gold and silver; Precipitation of —— in cyanide solutions by carbon. R. K. Cowles. Trans. Australasian Inst. Min. Eng., 1912, **16**, 58—61.

In treating tailings, which also contained half-burnt coal, etc., from power plants, by fine grinding in a weak cyanide solution for the recovery of gold and silver, it was found that the coal caused first the selective precipitation of the gold, and later of the silver. Experiments showed that ground clinker, half-burnt coal, and charcoal were all effective, but that unconsumed coal-dust had no action. The action appeared to be more rapid with fresh carbon than with carbon that had become saturated with water. The trouble was overcome by passing the tailings over vanners to remove the carbon.—T. St.

Auriferous and argentiferous copper; The electrolytic refining of —— at Lithgow, in New South Wales. G. H. Blakemore. Trans. Australasian Inst. Min. Eng., 1911, **15**, 36—70.

The anodes consist of blister copper containing 99·4 to 99·6 per cent. Cu, with Au from 2 to 4 oz., and Ag from 15 to 20 oz.; and weigh originally 200 lb. each. The electrolyte contains approximately 12 per cent. of free sulphuric acid, and 14 per cent. of crystallised copper sulphate; the temperature is maintained at about 120° to 130° F. (48°—54·5° C.)., and the solution is agitated by jets of compressed air at a pressure of 5 lb. per sq. in. The current density is 12 to 14 amps. per sq. ft. of cathode surface, and the space between the face of each starting sheet and the anode is about 2¼ in. The electrolyte flows from one tank to another, and is finally filtered through sand and returned to the feeding tank. As it gradually becomes richer in copper, it is electrolysed from time to time in special tanks with insoluble lead anodes. The cathodes obtained are melted in a reverberatory furnace used solely for this purpose, and the molten metal, after being brought to "pitch," is ladled into ingots. This copper, which contains about 99·95 pe cent. Cu, is used chiefly for wire making. The mud from the tanks is sifted, washed, heated to a dull red heat, and boiled with concentrated sulphuric acid. The residue i then washed, dried, and fused with sodium carbonate i a small cupel furnace to gold bullion, which usuall assys about 12 to 16 per cent. Au and 82 to 86 per cent Ag. This bullion is parted electrolytically in an electrolyt of silver nitrate solution, a silver plate forming the cathode The gold is caught as a mud in calico bags, and after bein heated with nitric acid, is fused, giving a fineness usually from 990 to 998. The silver is removed by moving wooden arms from the cathodes as fast as it is deposited. The knocked-off crystals are finally collected and fused, the fineness being not less than 996.—T. St.

Copper-welding; New process for ——. W. Schieber.
Chem.-Zeit., 1914, **38**, 188.

THE two pieces of copper, placed in position, are heated at the appropriate point by means of the oxy-hydrogen blowpipe until the requisite degree of softening is attained. Complete reduction is then effected in a flame of specially purified hydrogen, and the welding is accomplished by hammering. It is claimed that the joint is invisible and that the area of juncture is homogeneous in every way with the remainder of the metal.—J. R.

Copper; Action of sulphuric acid on ——. J. T. Cundall.
Chem. Soc. Trans., 1914, **105**, 60—63.

UNDER certain conditions sulphuric acid which has been acting on copper, when poured from the metal into water, yields a reddish-brown precipitate of metallic copper, which appears to be produced by the decomposition of cuprous sulphate. The original acid must be below 94 per cent. strength, and the maximum effect is given by an 87 per cent. acid. If the same acid liquid is heated it deposits either cuprous or cupric sulphide, according to the degree of heating: and these deposits redissolve with evolution of sulphur dioxide on heating still further. Cuprous sulphate is thus regarded as the primary product of the reaction:—

$$(a)\ 8Cu + 4H_2SO_4 = 3Cu_2SO_4 + Cu_2S + 4H_2O,$$
$$(b)\ 2Cu + 2H_2SO_4 = Cu_2SO_4 + 2H_2O + SO_2.$$

Equation (*a*) probably represents a low-temperature reaction. The formation of the secondary products is represented as below:—

$$(c)\ 5Cu_2SO_4 + 4H_2SO_4 = Cu_2S + 8CuSO_4 + 4H_2O,$$
$$(d)\ Cu_2S + 2H_2SO_4 = CuS + CuSO_4 + 2H_2O + SO_2,$$
$$(e)\ CuS + 4H_2SO_4 = CuSO_4 + 4SO_2 + 4H_2O.$$

See also Pickering (Chem. Soc. Trans., 1878, **33**, 112).—J. R.

Mixed sulphides [of lead and zinc]; Treatment of —— by the "Horwood" process. E. J. Horwood. Trans. Australasian Inst. Min. Eng., 1912, **16**, 228—241.

CONCENTRATES containing sulphides of lead and zinc, with possibly the sulphides of iron and copper, are roasted for a short time at 300° to 400° C. The particles of lead sulphide thus become coated with a layer of sulphate, whilst the zinc sulphide is unaffected, and the two may then be separated by an acid oil flotation (see also this J., 1909, 942, and 1911, 342). The best results obtained from Tasmanian complex sulphides were. zinc concentrates with 58·6 Zn, 3·5 Pb; lead residues with 5·8 Zn, 20·0 Pb per cent. Silver and gold were present. The former could be largely recovered in the leady residues. Details are given of crushing, roasting, and flotation, as carried out in an experimental plant.—T. St.

Zinc; The recrystallisation of worked ——. G. Timoféeff.
Rev. Mét., 1914, **11**, 127—132.

THE structure of zinc crushed in a vice becomes homogeneous, no crystals being visible under very high magnifications. The hardness increases considerably. Recrystallisation takes place however extremely readily on annealing the metal, and in time at the ordinary temperature. The growth of the crystals is more rapid the higher the temperature of annealing, and the greater the deformation the zinc has undergone. Under slight shock the large individual crystals composing cast zinc become striated, this effect being produced even by removing the ingots from moulds, if special care is not taken. The best etching reagent for zinc sections, of many tried by the author, is that of a few drops of a mixture of nitric acid 94 and chromic acid 6 per cent., to 100 c.c. of water.—T. St.

Aluminium; Improving the properties of ——. [Aluminium-cobalt alloys.] A. Neuburger. Elektrochem. Zeits., 1914, **20**, 295.

ALLOYING with 9—12 per cent. Co improves aluminium, but it is still deficient in mechanical strength owing to the coarse crystalline structure. This defect can be overcome by addition of a small proportion of tungsten or molybdenum, yielding alloys having a tensile strength three times that of pure aluminium. The best results are obtained with: W 0·8—1·2 and Co 8—10 per cent., or Mo 0·6—1, Co 9—10 per cent. The forging and rolling qualities diminish and the tensile strength increases with increasing content of tungsten (or molybdenum) and cobalt. The alloys containing tungsten are somewhat harder than those containing molybdenum.—A. S.

Cerium and its alloys; Preparation of ——. M. Moldenhauer. Chem.-Zeit., 1914, **38**, 147.

CERIUM fluoride is more suitable than the other halides or the oxide for the preparation of cerium alloys by reduction. An alloy containing per cent. about 86 Ce and 12 Ca was obtained from a mixture of cerium fluoride and calcium (10 per cent. more of the latter than the amount required for reduction). The yield was improved by covering the compressed mixture with a layer of calcium fluoride; a glass tube, passing through this layer served for the introduction of the ignition mixture and magnesium ribbon. Alloys of Ce-Fe, free from calcium, were obtained from mixtures of cerium fluoride, ferric oxide, and calcium. By substituting aluminium for calcium in this mixture, a 60 per cent. yield of an alloy containing per cent. 25·3 Ce, 62·5 Fe, 10·2 Al, and 1·2 Si, was obtained. This product showed similar properties to those of the commercial iron alloys.—L. E.

Foundry plant and machinery. [Die-castings.] J. Horner. Engineering, 1914, **97**, 144—145.

DIE-CASTING or casting under pressure in steel moulds, is adopted for making intricate parts which would be expensive to cast in sand, to stamp in dies or to machine. The accuracy of castings having holes, screw-threads, teeth, etc., is as great as with ordinary machined parts. Only white-metal alloys are suitable. These may contain Zn 50—80, Sn 5—30, Cu 2—20, Al 2—6, and Sb 1—5 per cent. A considerable range of alloys is thus available These alloys are not as strong as bronze or cast iron, but parts made of the latter can be cast in. In the following example, Nos. 1 and 2 are suitable for ordinary work in place of brass, No. 3 is harder and No. 4 harder still.

	No. 1.	No. 2.	No. 3.	No. 4.
	per cent.	per cent.	per cent.	per cent.
Zinc	73·75	72·7	73·8	46·2
Tin	14·75	19·0	12·0	30·8
Copper	5·25	5·0	10·6	20·4
Aluminium	6·25	1·0	3·4	2·6
Lead	—	2·0	—	—
Antimony	—	0·3	—	—

Gas furnaces may be used for melting the metal, the pot being covered to prevent oxidation, and the metal forced through a tube and nozzle into the moulds. A pressure of 80—120 lb. per sq. in. is applied by means of a hand-lever.—A. T. L.

Combustion-analysis by means of tellurium dioxide. Glauser. *See* XXIII.

Patents.

Steel or iron; Process for manufacturing ——. G. Tischenko and H. Paulson, St. Petersburg. Eng. Pat. 27,147, Nov. 26, 1912.

Pure gaseous or vaporised hydrocarbons are passed, by suction or pressure, into electrolytically-refined iron until the metal is carburised to the required degree, the operation being preferably effected in a closed, electric furnace.—W. E. F. P.

[*Iron and steel.*] *Wire; Annealing* ——. M. Woods, Warrington. Eng. Pat. 10,215, April 30, 1913.

In an apparatus of the kind having a seal of sand or other powdery material at one or both ends, provision is made whereby the sand, etc., carried away from the seal by the moving wire is collected in a sealed trap and conveyed back to its original position.—W. E. F. P.

Steel; Method of treating ——. A. J. Rossi, Niagara Falls, N.Y., Assignor to The Titanium Alloy Manufacturing Co., New York. U.S. Pat. 1,084,036, Jan. 13, 1914.

After addition of sufficient carbon to impart the required degree of hardness, titanium and manganese are added to prevent undesirable brittleness. The finished steel contains Ti less than 0·50 and Mn less than 0·60 per cent.—W. E. F. P.

Steel; Method of refining ——. E. Humbert. Fr. Pat 461,459, Aug. 18, 1913.

The refining is effected in two stages; in the second stage, slag (containing lime, carbon, silica and a little fluorspar) is used, and when the metal is tapped, the whole or a part of this slag is left in the furnace. Iron oxide or other oxidising agent is added to oxidise the calcium carbide which has been formed and the heat of this reaction serves to improve the fluidity of the slag. The steel from the Bessemer converter, or the like, is now introduced on top of the slag, whereby energetic dephosphorisation is effected whilst the metal is descending through the molten slag. After about 10 mins. dephosphorisation is practically complete; the slag is removed and fresh slag introduced for the second stage of the refining.—A. S.

Steel alloy for electric dynamos. W. Rübel. Fr. Pat. 461,704, Aug. 22, 1913. Under Int. Conv., Aug. 27, 1912.

The alloy, of high electric resistance, is composed of iron and metals of specific gravity less than iron, such as aluminium and magnesium.—B. N.

Iron, free from carbon; Method and means for the production of —— direct from ores, even of a refractory nature. R. P. Pictet. Fr. Pat. 461,895, Nov. 8, 1912.

A blast furnace of the usual type working with hot blast, is provided with a second lower set of tuyères, through some of which carbon monoxide is supplied, and through the others air enriched with oxygen. The carbon supplied to the furnace with the ore is regulated either to be only sufficient just to reduce the iron oxide, or to give the iron a desired carbon content. The mass which enters the zone between the two sets of tuyères thus contains only a predetermined amount of carbon. In this zone the iron and the slag are melted by the heat of combustion of the carbon monoxide supplied through the lower set of tuyères, the proportions of carbon monoxide and oxygen being regulated according to the refractory nature of the gangue. The molten metal and slag are run off by different apertures from the crucible situated below the lower set of tuyères. The iron in the crucible may be further refined by blowing air through it, or suitable additions, such as chromium, vanadium, nickel, etc., may be made before the metal is run off.—T. St.

[*Steel.*] *Armour plate.* Soc. Anon. des Aciéries et Forges de Firminy. Fr. Pat. 462,087, Nov. 13, 1912.

The steel preferably contains:—C 0·450 to 0·750, Mn under 0·700, Cr 1·60 to 2·80, Ni 2 to 4 per cent. There may be also less than 2·5 per cent. Mo, W and V. After forging, the plate is heated to 775°—900° C., and quenched; heated to 550°—675° C., and quenched; heated so that the temperature falls uniformly from about 850° C. at the face, to below 700° C. at the back, and quenched; reheated to below 500° C. The face may be very superficially hardened by covering it with potassium ferrocyanide during the heating operations.—T. St.

[*Steel.*] *Armour plate; Face-hardened* ——. Soc. Anon. des Aciéries et Forges de Firminy. Fr. Pat. 462,201, Nov. 16, 1912.

The steel employed contains:—C 0·150 to 0·250, Cr 0·900 to 2·500, Ni 4·50 to 6·50, Mn under 0·600 per cent. All or part of the chromium may be replaced by tungsten, molybdenum, and vanadium. Hardening of the face to a depth of more than 15 mm. is brought about during the heat treatment by means of potassium ferrocyanide. On heating the plate before the last quenching, the back of the plate is heated to a slightly lower temperature than the face. As a final operation the plate may be reheated to a temperature below 500° C.—T. St.

Ferro-chromium and pure chromium: Electrometallurgical manufacture of —— and other metals, from metallurgical slags free from iron. C. A. Keller. Fr. Pat. 461,098, Oct. 21, 1912.

Ferro-chromium or ferro-manganese alloys are produced by keeping the amount of reducing agent at a low amount, so that an oxidising slag is obtained in which iron is practically absent, and a slag rich in chromium or manganese oxide is formed. By the reduction of these slags, the pure metals may be obtained, or by the addition of the slags to the original ore, alloys rich in chromium or manganese may be produced.—B. N.

Ores; Treatment of ——. Minerals Separation, Ltd. London. From A. H. Higgins, New York. Eng. Pat 27,323, Nov. 27, 1912.

The recovery of metalliferous material from ores is effecte partly by froth-flotation and partly by treatment wit solvents. The two processes are applied successively simultaneously, the solvent, in the latter case, being th medium in which the mineral-bearing froth is produce In either case the ore or concentrate may be roasted otherwise treated to render any desired portion solubl In the application of the process to lead-bearing ores (*e.g* lead-zinc sulphides) claim is made for the use of ferr chloride (in hot solution) for dissolving the lead co stituents.—W. E. F. P.

Ore concentration [froth-flotation]; Apparatus for — W. Broadbridge and A. C. Howard, Assignors to Miner Separation, Ltd., London. U.S. Pat. 1,084,196, Jan. 1914.

A series of agitating- and aerating-vessels arranged sections and operated in conjunction with a series spitzkasten. Each agitation section has a high-le outlet (provided with pulp-directing baffles) to adjacent spitzkasten; and each of the latter a low-le outlet to the first agitating-vessel of the next section. —W. E. F.

Tungsten; Manufacture of ——. C. Gladitz, Lon Eng. Pat. 27,859, Dec. 3, 1912.

Claim is made for a "fluffy" variety of tungsten prep d as follows:—Tungsten ore, freed from sulphur, arsenic, by roasting, is finely ground and "dissolved in a known manner in ammonia." The solution of ammonium tungstate is filtered and sufficient distilled water added to reduce the sp. gr. to between 1·06 and 1·03 (preferably 1·05), after which the liquid is allowed to flow, from a capillary burette, at the rate of 1000 c.c. in 780—900 (preferably 840) seconds, into twice its volume of boiling hydrochloric acid (8·7° B., sp. gr. 1·065), which is kept agitated by means of superheated steam. The tungsten trioxide so produced (which is stated to be flaky and free from colloidal and granular forms) is dried, sifted through a fine sieve and reduced, by means of hydrogen, in nickel trays which are propelled through a long nickel tube subjected to a progressively increasing temperature (20° to 850° C.) for about 3 m. of its length and not heated for the remaining 2 m.; the arrangement is such that the charge attains its maximum temperature in about 4½ hours and cools during about 3 hours, a sudden fall in temperature occurring immediately after the maximum has been passed.—W. E. F. P.

Tungsten ; Process for fusing ——. Siemens Brothers and Co., Ltd., London. From Siemens und Halske A.-G., Berlin. Eng. Pat. 10,369, May 2, 1913.

The metal is fused in an atmosphere of inert gas in an electric arc furnace the crucible of which is lined with compressed powdered tungsten, the molten metal forming the anode. The tendency of tungsten to form bubbles is prevented by the addition of about 1·7 per cent. of thorium oxide.—W. R. S.

Metallic sheets ; Process of and means for galvanising or coating ——. H. Folland, T. A. Morris, and W. Griffiths, Glanamman, Carmarthen. Eng. Pat. 29,801, Dec. 27, 1912.

The (thin) metal sheet is passed, at one operation and in one bath, through a flux, any desired metal, and molten zinc, in succession; the flux and the zinc are floated upon the "desired metal" at opposite ends of the bath and are retained in position by partitions extending from the upper part of the apparatus to different levels in the bath. (Reference is directed to Eng. Pats. 7332 of 1892, 2509 of 1903 and 5608 of 1910; this J., 1893, 360; 1910, 1392).
—W. E. F. P.

Manganese-brass, manganese-bronze, and similar alloys ; Manufacture of ——. F. Heusler, Dillenburg, Germany, and The British Mining and Metal Co., Ltd., London. Eng. Pat. 1092, Jan. 14, 1913.

The manganese is added in the form of a Mn-Al-Cu alloy (Mn 15—30, Al 5—15 per cent.), which is incorporated with the copper before the addition of the zinc.—W. R. S.

Metals and metal oxides ; Process for preparing ——, *in a minutely divided state.* H. Kast, Berlin. Eng. Pat. 5212, March 1, 1913. Addition to Eng Pat. 19,006, Aug. 19, 1912 (see Ger. Pats. 256,962 and 263,648: this J., 1913, 426, 1011).

Claim is made for the employment of metallic salts of aromatic nitro-carboxylic acids, in place of those of nitrophenols originally specified; and for the admixture, with either, of a volatile, inorganic salt (*e.g.* of ammonium) to modify the fierceness of the combustion.—W. E. F. P.

Electroplating ; Apparatus for ——. G. P. M. Lee and W. A. Brame, London. Eng. Pat. 13,747 of 1912, date of appl., Jan. 13, 1913.

The conveyor, for transporting the material by means of cross rods, is arranged to run on opposite sides of the vat, and an inclined supplementary conveyor is provided for ransportation of material from one vat to another, this latter conveyor, operated by insulated chain wheels, being made to travel faster than the former. The supplementary conveyor has carriers furnished with displaceable stops to allow the carriers to pick up the cross rods, the stops then resuming a normal position and keeping the cross rods in place. The latter are carried on the main conveyor by brackets or cradles. The vat is provided with agitating, heating and filtering means, and an arrangement for imparting partial or complete rotary motion to the work. Several rows of anodes may be employed, with means for applying a higher voltage to the first than to the remainder of a set.—B. N.

Copper ; Process of electrolytic production of ——. N. V. Hybinette, Christiania, Norway. U.S. Pat. 1,084,150, Jan. 13, 1914.

The metal is deposited from a solution containing both copper and iron salts, by adding an electrolyte containing large quantities of ferric salts to the cathode compartment of an electrolytic cell and circulating the solution through a filter from cathode to anode.—W. E. F. P.

Copper ; Process for welding ——. H. Suzuki. Fr. Pat. 461,688, Aug. 21, 1913. Under Int. Conv., Feb. 15, 1913.

The surfaces to be welded are cleaned, polished and placed in contact, and then placed, with or without an anti-oxidising material, such as ammonium carbonate or chloride, on a layer of wood charcoal in a closed vessel, which is heated externally. When they have reached the desired temperature, the pieces are withdrawn and hammered or rolled in the usual way.—A. S.

Copper and nickel ; Process for soldering ——. Autogenwerk Sirius Ges. m. b. H. Fr. Pat. 461,942, Aug. 27, 1913. Under Int. Conv., Sept. 28, 1912.

In joining together pieces, especially wires, of copper or nickel, the metal wire used to facilitate the soldering, contains besides the phosphorus usually employed, also up to 5 per cent. of silver, cadmium, or bismuth, or mixtures of these metals.—A. S.

Ores ; Process for treating ——. C. J. Best, Oakland, Cal. U.S. Pat. 1,084,600, Jan. 20, 1914.

The finely subdivided ore is treated with a "preparing solution" containing potassium nitrate, nitric acid, potassium permanganate, common salt, and sulphuric acid; it is then roasted, and leached successively with solutions of: common salt, sulphuric acid, and manganese peroxide; or potassium nitrate, sal ammoniac (ammonium chloride), nitric acid, common salt, and sulphuric acid.—W. R. S.

Furnace for refining metals. E. C. Wills, Frederick, Md. U.S. Pat. 1,084,991, Jan. 20, 1914.

A horizontal rotatable cylinder (resembling a copper converter), provided at each end with an oil jet and an adjacent flue: each flue has an air inlet and can be used for injecting blast or drawing off the products of combustion.—W. R. S.

Zinc ; Method of preventing the formation of "zinc powder" during the condensation of ——. J. B. M. E. Vuigner. Fr. Pat. 461,893, Nov. 8, 1912.

To free zinc vapours from oxygen and so prevent the formation of "zinc powder," lumps of calcium carbide or carborundum are placed either in the condensers, or in a chamber between the furnace and the condensers.—T. St.

Zinc ; Manufacture of pure ——. H. Speckter. Fr. Pat. 461,905, Aug. 26, 1913. Under Int. Conv., Sept. 7, 1912.

Impurities in the ore are separated before the zinc itself is liberated. By gradually heating the ore mixed with reducing agents in a suitable furnace, such as a rotary furnace, cadmium and lead are volatilised between 950° and 1000° C., and when, at about 1050° C., zinc begins to volatilise, the charge is transferred to the zinc furnace proper. Zinciferous material containing zinc chloride may be leached with water, or the zinc chloride, with other volatile chlorides, may be volatilised by a preliminary heating. In this case the condensed zinc chloride is dissolved in water and the zinc precipitated as hydroxide. —T. St.

Metals; Method for the extraction of useful —— contained in metallurgical slags. J. B. M. E. Vuigner. Fr. Pat. 462,194, Nov. 15, 1912.

The molten slags are subjected to the action of reducing agents formed at temperatures much higher than those possessed by the slags on their discharge from furnaces. Reducing agents of special value are ferrosilicon and calcium carbide. Slags containing copper or nickel are treated, as they leave the furnace, with ferrosilicon and sulphur (free or combined) in order to form a matte. Slags containing zinc are stirred with ferrosilicon under a layer of carbon. Poor or complex ores of zinc may be similarly treated after being brought into a state of fusion. The reducing agent may also be formed *in situ* by running the molten slag into an electric furnace, and adding carbon and, if desired, a little lime.—T. St.

Condensation of vapours of volatile metals, especially of zinc vapour; Process and apparatus for the ——. F. C. W. Timm, Hamburg, Germany. Eng. Pat. 1701, Jan. 21, 1913. Under Int. Conv., Feb. 20, 1912.

See Fr. Pat. 454,495 of 1913; this J., 1913, 871.—T. F. B.

Tunnel kilns or furnaces for tempering, cementation, and like processes. G. Richter, Stettin, Germany. Eng. Pat. 11,632, May 19, 1913. Under Int. Conv., Feb. 25, 1913.

See Ger. Pat. 265,761 of 1913; this J., 1913, 1161.—T.F.B.

Alloys resistant to the action of concentrated acids; Process for making ——. W. and R. Borchers. Fr. Pat. 461,242, Aug. 9, 1913.

See Ger. Pats. 265,076 and 265,328 of 1913; this J., 1913. 1160.—T. F. B.

Ores; Process for reducing —— to metals. J. A. McLarty. Fr. Pat. 461,399, Aug. 14, 1913.

See U.S. Pat. 1,079,788 of 1913; this J., 1914, 31.—T.F.B

Electroplating apparatus. G. P. M. Lee and W. A. Brame. Fr. Pat. 461,565, July 12, 1913.

See Eng. Pat. 13,746 of 1912; this J., 1913, 831.—T.F.B.

Electrolytic reduction of carbon dioxide and monoxide dissolved under pressure. Fischer and Prziza. *See* VII.

Patents.

Alkali compounds; Electrolytic processes and apparatus, particularly applicable to the production of ——. C. White, London. Eng. Pat. 1935, Jan. 23, 1913.

The process is applicable to the electrolysis of sodium or potassium chloride or nitrate in non-diaphragm cells, in which the anode tubes each dip into a pocket or well in the cell, the pockets being preferably formed of or lined with non-conducting material. Heat is applied locally by means of heating coils to portions of the electrolyte near to the anodes, and this part of the electrolyte is kept above the level of the electrolyte in the cell by the action of an exhaust pump. The portion of the electrolyte below the anodes may be cooled by cold liquid flowing through a coil, or the cold electrolyte may be admitted at a point below the heating coils.—B. N.

Electro-osmotic processes; Method of and apparatus for ——. Ges. für Elektro-Osmose m. b. H., Frankfurt a/Main, Germany. Eng. Pat. 26,061, Nov. 13, 1913. Under Int. Conv., July 21, 1913.

In its passage to the anode, the liquid holding solid matter in suspension is caused to wash against as large a cathode surface as possible, this end being attained by employing cathodes composed of laminæ spaced apart so as to divide the liquid into a number of streams.—W. E. F. P.

Metallic objects; Electrolytic cleansing of ——. A. Lévy. Fr. Pat. 461,285, Oct. 24, 1912.

The alkali cyanide commonly used is replaced by potassium ferrocyanide, and lime is added to the bath, the action of the electrolyte on the metal of the anodes being thus prevented.—B. N.

Separation of particles in suspension from gaseous bodies; Utilisation of high tension electricity for the ——. E. Möller. Fr. Pat. 461,370, Aug. 13, 1913. Under Int. Conv., Aug. 13, 1912.

The ionising non-metallic electrodes are arranged alternately with the non-ionising intermediate electrodes, and the gas to be treated is passed between them. The former electrodes consist of narrow strips of mica with serrated edges supported between conducting pieces, and forming a rod-like electrode, with its length at right angles to the direction of the gas, and so that the latter impinges on the serrated edges. The intermediate electrodes consist of smooth sheets, with their longitudinal dimensions transverse to but with their planes parallel to the direction in which the gas is moving. The ionising electrodes are mounted on an insulated rod passing through a tube closed by an insulating disc, and the gas which circulates in the tube is maintained electrically pure by passing it over an auxiliary ionising electrode in the form of a ring mounted on the rod.—B. N.

Furnaces; Electric ——. W. N. Crafts. Fr. Pat. 461,847 Aug. 8, 1913.

See U.S. Pats. 1,069,923 and 1,069,924 of 1913; this J., 1913, 915.—T. F. B.

Electrically insulating sheets, plates, etc., from mica waste Process for making ——. F. Bölling. Fr. Pat. 462,000 Aug. 29, 1913. Under Int. Conv., Sept. 4 and 20, 1912

See Eng. Pat. 21,445 of 1912; this J., 1913, 290.—T. F. B

Electrolytic apparatus for the clarification of sugar solutions U.S. Pat. 1,084,556. *See* XVII.

XII.—FATS; OILS; WAXES.

Hydrogenated fats. J. Leimdörfer. Seifensieder-Zeit 1913, **40**, 1317—1318. Chem. Zentr., 1914, **1**, 304—30

Experiments with pure hydrogenated fats, from whic the catalyst had been completely removed, indicat that whilst the stearic acid present therein was identical chemically with that contained in natural fats, the stearin of the hydrogenated fats differed in crystalline character, behaviour on exposure to light and heat, and other physical properties from the stearin of natural fats. Hydrogenated fats change in odour and colour when preserved even in a vacuum. Soaps prepared from them have an unpleasant odour and inferior lathering properties. The speed of saponification of hydrogenated fats is greater than that of an analogous natural fat (tallow) under similar conditions. It is concluded that the stearin produced by hydrogenation is an allotropic modification of ordinary stearin, of greater reactivity.—A. S.

Glycerol; Determination of —— in commercial glycerins and soap-lyes. M. Tortelli and A. Ceccherelli. Chem.-Zeit., 1913, **37**, 1505—1506, 1573—1574; 1914, **38**, 3—5, 28—31, 46—48.

The results of the authors' experiments upon the estimation of glycerol in commercial glycerins lead them to the conclusion that the acetin method prescribed in the International Standard Methods 1911 (this J., 1911, 556—558) gives low results and they advocate the adoption of the following modification of the Hehner bichromate process as being more accurate and more rapidly carried out. The following reagents are required: 1. *Pure potassium bichromate*, small crystals. 2. *Potassium bichromate solution.* 74·564 grms. per litre. 3. *Dilute bichromate solution.* Solution 2 diluted with water to ten times its volume. 4. *Ferrous ammonium sulphate*, chemically pure, in small crystals: 2 grms. titrated with solution 3 should require 33·5—33·6 c.c. 5. *Ferrous ammonium sulphate solution.* 200 grms. are dissolved in water which has been made slightly acid with sulphuric acid and the solution made up to 1 litre: 10 c.c. should require 33·5—33·6 c.c. of the dilute bichromate solution. 6. *Silver carbonate.* Prepared as required by mixing 4·9 c.c. of $N/1$ sodium carbonate with 150 c.c. of a 0·5 per cent. solution of silver sulphate. The precipitated silver carbonate is washed once by decantation and is then ready for use. 7. *Basic lead acetate.* A 10 per cent. solution of lead acetate is boiled with an excess of litharge for 5 hours, the volume being kept constant, and is then filtered hot. 8. *Sodium sulphate solution.* 10 per cent. 9. *Potassium ferricyanide solution.* A 0·1 per cent. solution which has been filtered through glass wool. 10. *Sulphuric acid.* The concentrated acid diluted with its own volume of water. A. *Estimation of glycerol in crude glycerin. a. Preliminary test to determine approximately the glycerol content.* About 5 grms. of the sample are mixed with 10 c.c. of distilled water and 5 c.c. of basic lead acetate solution in a 100 c.c. glass-stoppered flask, the mixture being well shaken and allowed to stand for a few minutes. 10 c.c. of sodium sulphate solution are then added, the volume of the solution made up to 100 c.c. with water and, after being well shaken and allowed to stand for a short time, the liquid is filtered through a dry filter paper. 10 c.c. of the filtrate are placed in a flask of 250—300 c.c. capacity, mixed with a few drops of dilute sulphuric acid and then 50 c.c. of bichromate solution (reagent 2) and 50 c.c. of sulphuric acid (reagent 10) are added. The mixture is boiled gently for fifteen minutes over a direct flame and, after being cooled, he excess of bichromate is titrated with the ferrous iron olution. *b. Final estimation of glycerol.* A quantity of he sample which will be approximately equal to 5 grms. of glycerol, is diluted with water to 250 c.c. in a graduated lask. 25 c.c. of this solution are treated with the precribed quantity of silver carbonate in a glass-stoppered 00 c.c. flask, and well shaken for 5—10 minutes. Therefter 5 c.c. of basic lead acetate are added, the mixture ell shaken and allowed to stand for 2—3 minutes. 5 c.c. f sodium sulphate solution are then added and, after haking, the volume is made up to 100 c.c. and the liquid ltered through a dry filter, the first 10 c.c. being rejected. 5 c.c. of the filtrate are placed in the same flask as was sed for the oxidation in the preliminary test, the liquid eing made acid with 3 or 4 drops of sulphuric acid (1 : 5), nd then 4 grms. of potassium bichromate (reagent 1) and 25 c.c. of water are added. After the bichromate is dissolved, 50 c.c. of sulphuric acid (reagent 10) are added and the mixture gently boiled over a free flame for 15 minutes. 4 grms. of ferrous ammonium sulphate are added to the contents of the flask after these have cooled to room temperature and the excess of iron salt is titrated back with dilute bichromate solution (reagent 3). If the preliminary test has been properly carried out the titration should require between 25 and 30 c.c. of this solution. B. *Estimation of glycerol in soap lyes.* The amount of the sample taken is increased so as to give approximately corresponding amounts of glycerol in the test solution, and the lye is neutralised with acetic acid before adding the clarifying reagents. Extensive tables are given, the use of which avoids the tedious calculations which otherwise have to be made.—J. A.

Emulsions; Experiments on ——. F. R. Newman. J. Phys. Chem., 1914, **18**, 34—54.

The emulsions were prepared by shaking together the components, in most cases in a shaking machine in which the containing bottle was shaken up and down in a vertical plane at the rate of about 360 oscillations (amplitude about 2 ins.) per minute. For ascertaining the nature of the emulsion, drops were placed on a glass plate and each stirred with a drop of one of the components; the drop of emulsion spread when the added drop was of the same nature as the external phase of the emulsion. In emulsions of benzene and water prepared with sodium oleate, water was always the external phase. Homogeneous emulsions were prepared containing respectively up to 0·5 per cent. and 80—90 per cent. of benzene by volume; at intermediate concentrations the emulsions separated into a creamy upper layer and a watery lower layer. Homogeneous emulsions of high concentration could only be obtained by adding the benzene gradually. With 0·05 grm. of sodium oleate to 1 c.c. of water a stiff jelly could be obtained with 99 c.c. of benzene; with 0·02 grm. of sodium oleate only 98 c.c. of benzene could be incorporated. Using soap, sodium oleate, or caustic soda as emulsifying agents, olive oil and water always gave emulsions of oil in water; the supposed emulsion of water in oil obtained by Robertson (this J., 1910, 888) was probably a "cracked" emulsion in which the appearance of the oil was changed by the presence of suspended solid sodium oleate, etc. For making emulsions of water in benzene, magnesium oleate gave the best results, especially in presence of a small quantity of sodium oleate; homogeneous emulsions were prepared containing 75—96 per cent. of water by volume. With magnesium oleate and sodium oleate, also, an emulsion of water in carbon bisulphide, containing over 94 per cent. of water by volume, was prepared, but was not so stable as the emulsion of water in benzene, "cracking" after 3 days. In mixed paints water was found to be the internal and oil the external phase. A homogeneous, stable emulsion of water in oil was obtained by shaking together 20 c.c. of raw linseed oil and 20 c.c. of water. The oil contained rosin, and it is concluded that rosin is usually the emulsifying agent in the case of mixed paints, since Pickering's work on insoluble emulsifiers (this J., 1908, 88) indicates that the pigments would tend to produce emulsions of oil in water so far as they had any emulsifying action.—A. S.

XIII.—PAINTS; PIGMENTS; VARNISHES; RESINS.

Rosin driers and other metallic resinates. M. Ragg. Farbenzeit., 1913, **19**, 309—311, 364—365, 420—422. Chem. Zentr., 1914, 1, 433—434.

If a "neutral resinate" prepared by fusing colophony with the requisite quantity of calcium hydroxide (calculated from the acid value of the colophony), be analysed by Fahrion's method (treatment with a mixture of alcohol and petroleum ether and titration with alkali), a considerable quantity of free resin acid is frequently found and a basic resinate is precipitated. Experiments showed that besides the known normal metallic resinates, well-defined basic resinates exist, which can be obtained either directly by fusing together the components or by the action of alkali on the normal resinates. Mixed basic resinates can also be obtained. The following have been prepared (Ac=the resin acid residue, $C_{19}H_{29}{\cdot}CO_2$): $2Ac_2Ca,CaO$; Ac_2Pb,PbO; Ac_2Zn,ZnO; $2Ac_2Zn,3ZnO$; $Ac_2Zn,3ZnO$; $Ac_2Zn,10ZnO$; $Ac_2Mn,4MnO,5AcNa$; $6Ac_2Mn,2MnO,4AcNa$; $2Ac_3Mn,MnO$; Ac_3Mn,MnO; $Ac_3Mn,2MnO$, $Ac_3Mn,2Mn_3O_4$, $2MnO$; $Ac_2Pb,PbO,2Ac_2Mn$; $Ac_2Pb,4PbO,Ac_2Mn$. The metallic salts of higher fatty acids, especially of the acids of linseed oil, behave in an analogous manner to the metallic resinates.—A. S.

XIV.—INDIA-RUBBER; GUTTA-PERCHA.

Rubber; Determination of the total sulphur in ——. Utz Gummi-Zeit., 1914, **28**, 631—632.

A review of some of the methods which have been proposed for the determination of total sulphur in vulcanise rubber. Carius' method gives the best results but require special apparatus. The rapid method of Kaye and Shar (India-Rubber J., Dec. 7, 1912, 5) when tested wit different kinds of vulcanised rubber gave results in fa agreement with those obtained by the more tedio method of Frank and Marckwald (method b, Lunge-Ber Chem.-techn. Untersuchungsmethoden, 6 Aufl., III. Bd S. 858), and the author recommends it for technic purposes. It is carried out as follows:—0·25—0·5 gr of the finely-divided sample is intimately mixed wi 5 parts by weight of pure zinc oxide and 4 parts of pota sium nitrate in a porcelain crucible, a thin layer of zi oxide is distributed over the mixture, and the cover crucible is carefully heated. When the reaction begi the flame is removed for a time, and subsequently t crucible is heated with the full flame for 5 mins. Aft cooling, the contents of the crucible are dissolved in dil hydrochloric acid, and the sulphur precipitated as bari sulphate.—A. S.

Patents.

Indiarubber; Coagulating and curing of ——. E. J. Byrne, London. Eng. Pat. 849, Jan. 11, 1913.

The latex is delivered on to a rotating drum, endless band, or the like, from a trough above. One side of the trough is separate and adjustable in end guides, thus forming a slot of variable width and of a length equal or nearly equal to the width of the drum, and opening on its outer side on to an inclined shoot with end flanges, from the end of which the latex drops on to the drum. The latex may be forced through the slot by air pressure, and to prevent it overflowing from the top edge of the trough, the latter may be provided with a suitable overflow pipe. The shoot may be hinged so as to allow its free edge to rise as the thickness of the rubber on the drum increases. On the rear side of the drum, a heat radiator is provided for delivering hot air under pressure on to the coagulated latex, thus effecting partial drying before it again reaches the delivery shoot.—B. N.

Rubber; Process of purifying ——. C. E. Anquetil. Fr. Pat. 462,156, Nov. 14, 1912.

The crude rubber is dissolved in a chloro-derivative of ethylene or of ethane, and the comparatively fluid solution, after removal of the insoluble impurities, is run into a vessel containing alcohol, or is evaporated, in order to separate the dissolved rubber. The most suitable solvent is trichloroethylene: other compounds mentioned are di- and per-chloroethylene and tetra- and penta-chloroethane.—A. S.

Caoutchouc substance and process of making same. F. Hofmann, C. Coutelle, K. Meisenburg, and K. Delbrück, Assignors to Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. U.S. Pat. 1,082,522, Dec. 30, 1913.

An alkyl derivative of erythrene, which has at least one substituent containing more than one atom of carbon (*e.g.*, an ethyl-erythrene), is polymerised until a product is formed which is insoluble in alcohol but soluble in benzene.—T. F. B.

Caoutchouc; Manufacture of synthetic ——. A. Heinemann. Fr. Pat. 461,232, Aug. 9, 1913. Under Int. Conv., Aug. 12, 1912.

XV.—LEATHER; BONE; HORN; GLUE.

Leather analysis; Change in methods. (Glucose determination.) J. Amer. Leather Chem. Assoc., 1914, 9, 2—3.

The revised method for the estimation of glucose in leather extracts adopted by the Amer. Leather Chemists Association. 200 c.c. of leather extract are mixed with 25 c.c. of a saturated solution of normal lead acetate in a 500 c.c. flask, shaken frequently during 5—10 mins., and filtered. Excess of solid potassium oxalate is added to the filtrate which is again filtered after 15 mins. 150 c.c. of the filtrate are boiled in a 600 c.c. Erlenmeyer flask with 5 c.c. of concentrated hydrochloric acid under a reflux condenser for 2 hours. After cooling and neutralising with anhydrous sodium carbonate, the solution is made up to 200 c.c., and filtered till clear. 25 c.c. of copper sulphate solution (34·639 grms. of the crystallised salt per 500 c.c., filtered through asbestos) and 25 c.c. of alkaline tartrate solution (173 grms. of Rochelle salt and 50 grms. of caustic soda per 500 c.c., filtered through asbestos after standing for 2 days) are placed in a 400 c.c. beaker and 50 c.c. of the clear neutral solution added, heated to boiling in exactly 4 mins. and boiled for 2 mins The precipitate is collected immediately on asbestos, without diluting, washed with hot water, alcohol, and ether, and weighed as cuprous oxide after drying for 30 mins. in the water oven. The quantity of glucose is ascertained from Munson and Walker's table (Bull. 107, Rev., U.S. Bureau of Chem., 243; also this J., 1906, 656).—D. J. L.

Patents.

Tanning; New method of ——*and production of new tanning agents.* Badische Anilin und Soda Fabrik. First Addition, dated July 31, 1913 (under Int. Conv., May 17, 1913), to Fr. Pat. 443,730, May 11, 1912 (this J., 1912, 1045).

The products obtained by the interaction of formaldehyde and aromatic hydroxy compounds specified in the chief patent may be replaced by other aromatic hydroxy-compounds, soluble in water, of a non-crystalline character and capable of precipitating gelatin solutions. They are characterised by the presence, in the molecule, of two or more aromatic nuclei containing at most one hydroxy group each and united by one or more plurivalent atoms or atomic groups. They must also contain one or more salt-forming acid groups in addition to the hydroxy groups. *Example* 1. The limed and prepared skin is suspended in a 2·5 per cent. aqueous solution of sulphonated dimethyldihydroxysulphobenzide neutralised until only moderately acid. The solution is gradually strengthened and the skin is tanned in about 10 days. Sodium chloride may also be added to the liquors and tanning may be carried out in the drum. After tanning, the leather is neutralised and is of a white colour. The tanning agent is prepared by stirring 50 kilos. of dimethyldihydroxysulphobenzide, obtained by heating *o*-cresol with sulphuric acid, with 200 kilos. of fuming sulphuric acid (23 per cent. SO_3) until the product becomes soluble in water. The mixture is then poured on 200 kilos. of ice and excess of sulphuric acid removed by lime or baryta. The solution thus obtained is used either at once or after concentration. *Example* 2. The product obtained by the action of sulphur chloride on the sulphonated product of crude cresol is partly neutralised with caustic soda and water is added to make a 5 per cent. solution which constitutes a tanning liquor and is used according to the usual methods. *Example* 3. 100 kilos. of thionaphtholsulphonic acid B, obtained according to Ger. Pat. 50,077, is dissolved to make a 5 per cent. solution and used as a tanning liquor according to the above methods.
—D. J. L.

Colloids; Method of rendering —— *insoluble.* P. Mercier. Fr. Pat. 461,287, Oct. 24, 1912.

Colloids such as gelatin, casein, albumin or blood serum are rendered insoluble, apart from any action of light, by adding to them together or separately the following substances. Chromates or bichromates with a reducing agent used as a photographic developer such as metol, quinol, pyrocatechol, ferrous salts (acidified or mixed with alkali sulphites to restrain their reducing properties), resorcinol or an alkali sulphite or bisulphite. The reduction is carried out so slowly that the colloid may be used for moulding or other purposes. Trioxymethylene may also be used if an alkali sulphite or metabisulphite is added to accelerate its transformation into formaldehyde which will render the colloid insoluble.—D. J. L.

Leather; Process for treating iron-tanned ——. J. Bystron and K. von Vietinghoff. Fr. Pat. 461,103, Oct. 21, 1912.

See Ger. Pat. 256,350 of 1911 and Eng. Pat. 21,175 of 1912; this J., 1913, 438, 618.—T. F. B.

Tanning preparations; Soluble ——. Badische Anilin und Soda Fabrik. Fr. Pat. 461,746, Nov. 5, 1912.

See Eng. Pat. 24,982 of 1912; this J., 1913, 919.—T. F. B.

XVI.—SOILS ; FERTILISERS.

Nitrate contents of arable soils : Nature and amount of the fluctuations of the ——. E. J. Russell. J. Agric. Sci., 1914, **6**, 18—57.

The amount of nitrate in arable soil fluctuates regularly, but in the author's experiments it rarely exceeded 6 parts per million (28 lb. per acre for a depth of 18 ins.) for sand, 23 parts per million (115 lb. per acre) for loam, and 14 parts per million (60 lb. per acre) for clay. These figures do not refer to heavily dunged land, where it rose to 37 parts per million on loam. The principal accumulation of nitrate appeared usually to take place in late spring or early summer. After this there was very frequently a loss, but in hot dry autumns (*e.g.* 1911) the accumulation sometimes continued till September. During winter loss of nitrate took place, which was more marked in wet than in dry winters. The fluctuations in nitrate content were most pronounced on loams. Clays lost less in winter but gained more in summer, while sandy soils lost a fairly large amount in winter without accumulating a great deal in summer. The main cause of loss in winter appeared to be leaching and not denitrification. On comparing cropped with fallow land, it was found that the fallow was richer in nitrate during the late summer, even after allowing for that taken up by the crop, in fact there was no evidence that any nitrate formation took place during the period of growth of the crop, even though it might be in rapid progress on adjacent fallow land. The data to hand did not, however, enable any definite conclusions to be drawn as to the influence of the growth of crop on the rate of nitrate production. The rapid rise in nitrate content in the spring lagged for some time behind the arrival of the warm weather, and there were indications of greater bacterial activity in early summer than later on, which was in accordance with the author's views on the soil population (see this J., 1913, 1136). In general it was found that as the supply of nitrate was an important factor in crop growth, those factors which determine the accumulation of nitrate played a great part in determining crop production. Heavy winter rainfall tended to reduce crops, while hot dry summers followed by dry winters were favourable to growth.—W. H. P.

Acid and alkaline peats ; The humus of ——. J. A. Hanley. J. Agric. Sci., 1914, **6**, 63—76.

The author has attempted to devise a method for distinguishing chemically between normal or alkaline peats, and acid peats. The former are usually fertile, while the latter are usually non-fertile peats from bogs, moors, etc. In ordinary soil analysis the total humus is estimated by decomposing the humates with dilute hydrochloric acid and then extracting the "humic acid" with ammonia. A great deal of the humus even from alkaline peat, is however capable of being extracted by ammonia without previous acid treatment and the proportion of the whole does not give any idea of the nature of the soil. It was found on analysis that all soils containing no calcium carbonate were acid to litmus and no soil containing calcium carbonate gave an acid reaction. Determination of the amount of nitrogen extracted from the peat by ammonia before and after treatment with acid did not lead to any more reliable information as to the nature of the soil, but the use of caustic soda instead gave more significant results. The readily available proteins as measured by the yield of ammonia on hydrolysis with 20 per cent. hydrochloric acid were very low in normal peats and practically nil in acid peats, so that this method would not serve to give a clear differentiation. The most valuable method tested by the author, and the one most in agreement with the known fertility of the soils tested, was the determination of the amount of sugar inverted on boiling a 1·25 per cent. solution (100 c.c.) of sucrose with a suitable quantity (2—10 grms.) of the soil for 2 hours. The alkaline soils always gave much less cuprous oxide than the acid soils, and treatment with acid invariably led to an increase in the inverting power of a soil, even after most careful washing.—W. H. P.

Iron pan ; The solution and precipitation of iron in the formation of ——. C. G. T. Morison and D. B. Sothers. J. Agric. Sci., 1914, **6**, 84—96.

"Iron pans" may vary from 10 to 60 cm. in thickness; they consist mainly of ferric and aluminium hydroxides with silica and varying amounts of organic matter; it is yellowish brown to black in colour. The authors attribute them to the formation of colloidal humus compounds of iron and aluminium which are carried down into the soil and there precipitated by soluble salts, by loss of water or by change of bases. Experiments which show that peat though a strong reducing agent is not capable of reducing ferric to ferrous oxide, or to form from ferric oxide a solution of ferrous humate. In the presence of water, however, peat will remove considerable quantities of minerals, especially ferric oxide, aluminium oxide and lime, as colloidal suspensions, which are not very sensitive to changes in concentration. Evaporation to dryness destroys to some extent their capacity for suspension. The order in which the minerals are removed from the upper layer of what ultimately becomes bleached sand is lime, alumina, ferric oxide.—W. H. P.

Soils ; Ferrous iron in ——. C. G. T. Morison and H. C. Doyne. J. Agric. Sci., 1914, **6**, 97—101.

In the extraction of soil with acid the organic matter present is capable of reducing the ferric salt formed by the action of the acid on insoluble ferric compounds in the soil. Such a method of treatment will therefore lead to incorrect results in determining ferrous iron in soils, and it is in fact improbable that ferrous iron exists in normal soils to any extent. It is also very improbable that ferric iron is present in the normal soil solution, since 100 grms. of soil will remove all the iron from 200 c.c. of $N/200$ ferric chloride.—W. H. P.

Soils ; Selective adsorption by ——. E. G. Parker. J. Agric. Research, 1913, **1**, 179—188.

Soils adsorb dissolved salts from solution and also remove one ion to a greater extent than the other. The presence of soil bases (lime, magnesia, etc.) in solution after passing a neutral salt (of potassium for example) through a soil is attributed to selective adsorption of the cation. Chlorine ions are much less rapidly adsorbed from solution by soils than potassium ions, and the selective adsorption of potassium from potassium chloride increases with the concentration of the salt solution up to a certain point and then remains constant. The percentage of the potassium removed from a potassium chloride solution increases asymptotically as the concentration of the chloride is diminished, adsorption being practically complete at low concentrations. In general, the selective adsorption of potassium is greater the smaller the soil particles. The presence of sodium nitrate increases the adsorption of potassium from potassium chloride when there is over 37·5 grms. per litre present, but decreases at lower concentrations. Monobasic calcium phosphate has practically no effect.—W. H. P.

Surface of soils ; Determination of ——. J. A. Hanley. J. Agric. Sci., 1914, **6**, 58—62.

The author compares the total surface of different soils by measuring the amounts of adsorbed methyl violet on 5 grms. of each soil, which are in equilibrium with the same methyl violet solution. The equilibrium solution should contain about 0·05 per cent. of the dye, and this involves testing each soil with a range of about four solutions whose initial known strength is greater in the case of clays than in the case of loams, and again smaller in the case of sands. From comparisons (accurately made with Nessler glasses) of the two equilibrium solutions nearest to the standard with the standard (0·05 per cent.) itself, it is easy to deduce the amount of adsorbed dyestuff which would be in equilibrium with the standard solution.—W. H. P.

Manure from vinasse; Process for obtaining a non-hygroscopic ——. H. Stoltzenberg, Breslau, Germany. Eng. Pat. 14,884, June 27, 1913.

See Fr. Pat. 459,872 of 1913; this J., 1913, 1165.—T. F. B.

XVII.—SUGARS; STARCHES; GUMS.

Sugar cane; Experiments with —— at Sabour (India) I. Character and quantity of fibre in different varieties. II. Effect of different manures on the time of ripening of cane. C. S. Taylor. Agric. Research Inst., Pusa. Bull. No. 37, 1913. Pp. 17.

I. The fibre-content of 36 varieties of cane was found to range from 8·59 to 16·6 per cent. without any well-marked break, and hence could not serve to classify the varieties into distinct groups. The fibre-content of the corresponding megasses, however, fell in three groups comprised between the limits: 34·3 ± 1·7, 40·9 ± 2·3, and 46·9 ± 2·7 respectively. These distinctions indicate differences in the structure of the fibre, and though there is a tendency to grow canes of higher fibre-content owing to their greater resistance to disease, a cane giving as dry a megass as possible is obviously advantageous. The *Khari* variety containing 16·41 per cent. of fibre and yielding a megass with 46·3 per cent., gave slightly more juice than the *Mango* variety containing 13·16 per cent. of fibre and yielding a megass with 34·2 per cent. It is suggested that the absorptive power of the megass may depend on some hereditary character of the cane variety.

II. Experiments in which canes were grown on untreated soil and on soil manured with ammonium sulphate or superphosphate, or with both, showed that these fertilisers delay the ripening of the cane by about a fortnight but do not appreciably affect the ultimate sugar-content or composition of the juice.—L. E.

Beet; Excessive leaf growth of the ——. A. Vivien. Bull. Assoc. Chim. Sucr., 1914, **31**, 501—505.

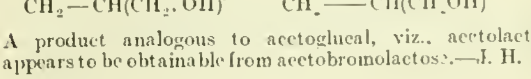
Comparative investigations of beets grown on soils treated with (1) abundance of organic nitrogenous manure, (2) little or no manure, showed that in the former case the leaf growth was excessive and the roots contained a lower percentage of sugar. The results do not bear out the view that the sugar is elaborated only in the leaves. —L. E.

Dextrose; New reduction-products of ——: glucal and hydroglucal. E. Fischer. Ber., 1914, **47**, 196—210.

Tetra-acetobromoglucose is reduced by zinc dust and acetic acid at 0° C., and a compound $C_{12}H_{16}O_7$ is produced, thus,

$$C_{14}H_{19}O_9Br+2H=C_{12}H_{16}O_7+C_2H_4O_2+HBr.$$

The new compound contains three acetyl groups· it is lævorotatory and crystallises well (m. pt. 55° C.). When boiled for a short time with water it loses one mol. of acetic acid and yields a diacetyl derivative. Dissolved in chloroform it readily takes up two atoms of hydrogen, and is saponified by cold alkalis with production of a thick syrup, very soluble in water and alcohol. This syrup shows the reactions of aldehydes but does not yield an osazone. It readily decolourises aqueous solutions of bromine and is converted into a dark amorphous mass by mineral acids. In presence of hydrochloric acid it colours pine shavings an intense green. Its formula appears to be $C_6H_{10}O_4$, for in aqueous solutions it readily absorbs two atoms of hydrogen in presence of platinum, and yields a crystalline compound $C_6H_{12}O_4$, which is also obtained by reducing and saponifying the triacetyl compound (m.pt. 55° C.) mentioned above. The syrupy compound, $C_6H_{10}O_4$, is termed "glucal." It is the representative of a class of substances hitherto unknown. Hydro-glucal, $C_6H_{12}O_4$, formed by reduction of glucal, is saturated and shows none of the reactions of aldehydes. The following formulæ are suggested for glucal and hydro-glucal respectively :—

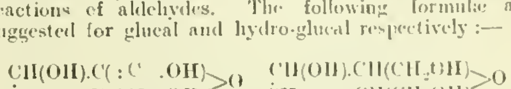


$$\left.\begin{matrix}\text{CH(OH).C(:C\ \ .OH)}\\ \dot{\text{C}}\text{H}_2\text{—CH(CH}_2\text{.OH)}\end{matrix}\right>\text{O} \qquad \left.\begin{matrix}\text{CH(OH).CH(CH}_2\text{.OH)}\\ \dot{\text{C}}\text{H}_2\text{——CH(CH}_2\text{.OH)}\end{matrix}\right>\text{O}$$

A product analogous to acetoglucal, viz., acetolactal appears to be obtainable from acetobromolactose.—J. H. L.

Methylpentoses; Constitution of the ——. I. Synthesis of an i-methyl tetrose and an i-methyl tetritol. R. Gilmour. Chem. Soc. Trans., 1914, **105**, 73—81.

Dihydroxyvalerolactone (obtained by oxidation of Δ^{α}-angelicalactone by potassium permanganate), reduced with sodium amalgam, gave rise to about 6 per cent. of a reducing sugar, from which a methyltetrosazone (m. pt. 140°—142° C.) and a methyltetrosephenylbenzylhydrazone (m. pt. 99°—100° C.) were prepared. The aqueous solution from the preparation of the hydrazone yielded a methyltetritol as a yellow syrup, which on benzoylation gave rise to a tetrabenzoyl derivative (m. pt. 136°—137° C.). The methyltetrose, obtained in the free state by decomposition of the phenylbenzylhydrazone with formaldehyde, proved to be a pale yellow strongly reducing syrup. Its constitution must be represented by one of the following formulæ :—



$$\text{CHO}\cdot\underset{\text{H}}{\overset{\text{OH}}{\text{C}}}\cdot\underset{\text{H}}{\overset{\text{OH}}{\text{C}}}\cdot\underset{\text{OH}}{\overset{\text{H}}{\text{C}}}\cdot\text{CH}_3 \quad \text{or} \quad \text{CHO}\cdot\underset{\text{OH}}{\overset{\text{H}}{\text{C}}}\cdot\underset{\text{OH}}{\overset{\text{H}}{\text{C}}}\,.\,\underset{\text{OH}}{\overset{\text{H}}{\text{C}}}\cdot\text{CH}_3$$

—J. H. L.

Patents.

Sugar from cane; Process of making ——. F. G. P. Leao, New York. U.S. Pat. 1,083,545, Jan. 6, 1914.

Sugar cane is finely divided, dried at a temperature below 158° F. (70° C.), and then saturated with water. The liquid portion is next separated by pressure, evaporated, and the residue obtained is subjected to refining processes.—W. P. S.

Sugar solutions; Electrolytic apparatus for the clarification of ——. H. McCubbin, Lahaina, Hawaii. U.S. Pat. 1,084,556, Jan. 13, 1914.

A closed horizontal tank is provided with a sludge sump and tap and with a number of adjustable electrodes. The sugar solution is admitted at the lower part of the tank near one end and leaves at the top near the other end. The electrodes are mounted on insulating supports moving on longitudinal guide-ways.—W. P. S.

Sugar; Manufacturing refined ——. M. Weinrich, Yonkers, N.Y. U.S. Pat. 1,084,771, Jan. 20, 1914.

Cold raw cane juice is mixed with raw cane sugar to a magma or syrup. The latter is charged with finely powdered caustic lime, and before the lime is completely slaked, the whole is mixed with more raw cane juice. The mixture is carbonatated, heated and filtered, the evaporated filtrate being worked up for refined sugar.—L. E.

Sugar ; Process of defecating raw cane —— or cane sugar syrup. M. Weinrich. Yonkers, N.Y. U.S. Pat. 1,084,772, Jan. 20, 1914.

Cold raw cane sugar or syrup is intimately mixed with a small percentage of finely powdered caustic lime and then slowly run into raw cane juice or water (at a temperature of about 30° C.) which at the same time is carbonatated and stirred. Carbonatation is stopped before any precipitated impurities begin to re-dissolve, the liquid then being fully neutralised by a suitable acid (whereby a second carbonatation and filtration are avoided) and finally heated and filtered.—L. E.

Sugar ; Decolourising ——. I. Larrondo C. Fr. Pat. 461,628, Aug. 6, 1913.

The sugar in the solid state is treated for a few minutes at the ordinary temperature with oxidising agents such as nascent oxygen, potassium permanganate, chlorine or iodine, and afterwards with a solution of sulphurous acid in alcohol or some other liquid in which sugar is insoluble. —J. H. L.

Sugar beets ; Preparation of —— for the extraction of juice. M. Lindner. Ger. Pat. 268,530, Dec. 12, 1912.

The beet slices or pulp, before extraction of the juice, are treated with aluminium hydroxide, whereby, it is claimed, pure light-coloured syrups are obtained, which can be worked up directly to raw sugar of low mineral content or to marketable white sugar. (See also this J., 1914, 96.) —A. S.

Evaporation of liquids, particularly saccharine juices. Fr. Pat. 461,208. *See* I.

XVIII.—FERMENTATION INDUSTRIES.

Mash filters. L. Briant, H. Harman and C. Vaux. J. Inst. Brew., 1914, **20**, 1—15.

The construction and method of working of a modern mash filter (Weigel type, holding 17½ quarters of malt) are described. The malt is ground more finely than for the ordinary mash tun but the husk should be as whole as possible. The stirring machinery is kept running during the whole of the mashing operations, say 10 mins., and the mash is then allowed to stand until shortly before it is transferred to the filter. The normal mashing period may be reduced from two hours to one hour, without any loss of extract. When this period has elapsed the rakes are set in motion and the mash is heated to about 158° F. (70° C.) and stirred continuously until the whole has been transferred to the filter. The filling of the filter occupies about 30 mins. and immediately afterwards washing is commenced and continued without interruption. The final runnings may be brought to a gravity of 1001 with a relatively small quantity of water as compared with mash-tun sparging. The possible saving of extract by use of the filter-press is estimated at 1·5—2 lb. per quarter of malt. The spent grains contain less starch, digestible fibre, etc., than those from mash-tun practice (*e.g.*, 36·8 compared with 44·7 per cent. of the dried grains), and the proportions of the other constituents are correspondingly increased. The use of the filter-press does not in any way impair the stability or brilliance of the beer or the character of the yeast, and its only effect on the flavour of the beer is to produce a marked softening, accompanied by increased palate-fulness. The beer also carries a much more lasting head when poured out, than corresponding beer prepared by the normal mash-tun process.—J. H. L.

Yeast ; Formation of higher alcohols from aldehydes by ——. II. Conversion of valeric aldehyde into amyl alcohol, and the enzymic nature of the reaction. C. Neuberg and H. Steenbock. Biochem. Zeits., 1914, **59**, 188—192. (See also this J., 1913, 803.)

Attempts to obtain a better yield than that obtained previously (*loc. cit.*), in the conversion of valeric aldehyde into amyl alcohol by living yeast in absence of sugar, were unsuccessful. That these transformations are enzymic is proved by the fact that yeast maceration juice, prepared by von Lebedeff's method (this J., 1911, 1081) and treated with sugar, was found capable of converting added valeric aldehyde into amyl alcohol with a yield of at least 12 per cent.—J. H. L.

Beer ; Concentration of hydrogen ions in —— and in brewing processes. F. Emslander. Z. ges. Brauw., 1914, **37**, 2—5, 16—19, 27—30, 37—41.

The question of acidity in relation to brewing processes and products is treated from the point of view of the concentration of hydrogen ions, as distinguished from the acidity determined by titration. The subjects thus considered are brewing water, malt, brewing processes, beer and gluten turbidity. An apparatus is described by means of which the concentration of hydrogen ions in malt liquors can be determined from the potential difference between the liquids and a "hydrogen electrode" of platinum immersed in them.—J. H. L.

Malt-wines and their relation to the (German) law. P. Kulisch. Z. Unters. Nähr. Genussm., 1913, **26**, 705—726.

Within recent years a new industry has developed in Germany, particularly in Alsace, *viz.*, the production of malt-wines, containing very little sugar, and much lighter in character than "Malton-wines" (see List, this J., 1897, 347). The new products are strongly acid and resemble, in their content of alcohol and extract, the light German wines, with the cheaper kinds of which they enter into keen competition, for in some parts of Alsace they are sold at 35 Pf. per litre (2d. per pint). The annual production at present is estimated at 150,000 hl (3,300,000 galls.). The composition of the product is subject to rather wide variations, and probably the process of manufacture is not well controlled. The outline of the process appears to be as follows :—The ground malt is extracted several times with hot water, opportunity being given for saccharification, but the yield of extract is not very satisfactory. The united extracts are treated with sugar and fermented. The character of the product seems to depend much more on its acidity and on the ratio of alcohol to extract, than on the type of yeast employed, and probably beer- or distillery-yeast could be used. The acidity develops spontaneously and doubtless depends on the rate of fermentation. The subsequent treatment of the fermented wort is very similar to that of grape wines. The quantities of materials used are estimated at 6—8 kilos. of malt and 8—15 kilos. of sugar per 100 litres of malt-wine. The following figures represent the limits of composition of sixteen samples from Alsace :—sp. gr. 0·9931—1·0076, alcohol 4·71—7·66 grms., extract 1·22—4·65 grms., sugar-free extract, 1·13—3·15 grms., ash 0·056—0·190 grm., total acidity (calculated as tartaric acid) 0·27—0·61 grm., volatile acidity (calculated as acetic acid) 0·01—0·15 grm. lactic acid 0·23—0·37 grm., reducing sugar 0·10—1·67 grm., and glycerol 0·3—0·5 grm. per 100 c.c. Neither tartaric nor citric acid was present. The optical rotation (in 200 mm. tube) ranged from +0·6 to +2·3 sugar degrees, and remained distinctly dextro-rotatory after fermentation. According to the author it is possible to detect the presence of only 10 per cent. of malt-wine in dry grape wines by polarising after suitable concentration.—J. H. L.

Wines ; Presence of citric acid in ——. Blarez, Denigès and Gayon. Ann. Falsif., 1914, **7**, 9—11.

Analyses of 38 authentic wines from the Sauterne Montbazillac, Anjou, and Rhine districts show that citr acid is a natural constituent of these wines, the amount found varying from a trace to 0·45 grm. per litre. The juices from 16 samples of black and white grapes, before and after fermentation, contained from 0·08 to 0·70 grm. of citric acid per litre.—W. P. S.

White wines ; Presence of oxalic acid in ——. H. Fonzes-Diacon. Ann. Falsif., 1914, **7**, 22—28.

White wines are liable to become opalescent or turbid and to give a white sediment, and to prevent this defect ("*casse blanche*") the practice has arisen of treating the wine with from 18 to 20 grms. of oxalic acid per hectolitre, with the object of precipitating the calcium salts present, as the turbidity is attributed to these compounds. The calcium oxalate formed is not, however, precipitated completely from the wine, a certain proportion, in quantity depending on the acidity of the wine and the presence of sulphurous acid, remaining in solution. A wine free from oxalic acid when treated similarly will remain clear for about 3 days, after which, crystals of calcium tartrate are deposited. The author has separated as much as 0·06 grm. of oxalic acid from a litre of white wine.—W. P. S.

Tannin : Determination of —— *in cider.* C. W. Spiers. J. Agric. Sci., 1914, **6**, 77—83.

The author criticises the various methods in use for the determination of tannin, and finally recommends the use of fat-free casein as a detannising agent, the amount of tannin removed being determined by the loss in permanganate value on titration, since casein removes nothing but tannin from solution (see this J., 1911, 126). Detannising is accomplished by shaking 50 c.c. with 1 grm. of casein for 15 min. The permanganate was standardised by means of various pure commercial tannins and the figure adopted is 1 grm. of ammonium oxalate=0·4648 grm. of tannin.—W. H. P.

Alcohol ; Manufacture of ethyl —— *from sawdust.* Junien. Bull. Assoc. Chim. Sucr., 1914, **31**, 500—501.

Foth (Bull. Assoc. Chim. Sucr., 1913, **31**, 463) has stated that it is unnecessary to use lead-lined vessels in saccharifying sawdust with sulphurous acid in presence of a small quantity of water, steel being sufficiently resistant under these conditions. The author's experience does not confirm this. Thus, it has been found that on heating mixtures of 1500 kilos. of sawdust (containing 30—35 per cent. of water), 81 kilos. of sulphurous anhydride, and 400 litres of water, in apparatus made of unprotected steel, the metal is rapidly attacked ; in the course of 200 operations, the thickness of the steel sheeting was diminished from 22 to 15 mm. Further, the iron sulphate thus introduced into the saccharification product, seriously retarded the subsequent fermentation.—L. E.

Vinasse from beetroot distilleries : Methods of purification of ——. A. Müntz and E. Lainé. Bull. Soc. d'Encour., 1913, **120**, 535—563.

After a description of various methods proposed for the purification and disposal of vinasse from distilleries in which beetroots are employed, the author presents details of experiments on a new biological process. The vinasse is allowed to flow very slowly over a series of shallow trays whilst aerobic organisms, such as mycoderma yeasts or moulds are cultivated on its surface. In one series of experiments described, ten trays (each 38 cm. by 57 cm.) were disposed one above another, and the liquid passed over each in turn in a layer 0·5 cm. deep, and at such a rate that 9—13 litres were treated per day. All the trays were inoculated with spores of *Sterigmatocystis nigra*, and the crops produced were collected every 3—4 days, but from only 5 trays at a time so that there were always at least 5 trays covered with well-developed cultures. The following table shows the composition of the vinasse before and after treatment, expressed in grms. per litre :—

	Before.	After.
Ammoniacal nitrogen ..	0·023	0·073
Soluble organic nitrogen	0·394	0·146
Insoluble organic nitrogen	0·269	0·034
Soluble organic matter	10·43	2·53
Insoluble organic matter	3·18	0·28

The vinasse underwent considerable concentration by evaporation, and about one-half of its total organic matter was oxidised to carbon dioxide and water by the mould. The acidity was also greatly reduced. The use of pure cultures of *Sterigmatocystis nigra* was found to prevent serious invasion of the trays by mycoderma yeasts, which are undesirable as they are not so readily separate from the liquid, and do not trap suspended matters to the same extent as the felted mould growths. The mould crops, containing about 50 per cent. of the nitrogen and 30 per cent. of the phosphorus of the vinasse, can be very readily removed from the liquid, and after being dried and powdered, they constitute a valuable manure containing : N about 8·27, P_2O_5 3·51 and K_2O 2·68 per cent. The yield of dried mould is about 3·5 kilos. per cb. m. of vinasse. After treatment by the process described above, and neutralisation of the residual acidity, the vinasse is amenable to further purification on nitrifying bacterial beds (see this J., 1911, 506, 707, 1403), whereby it can be rendered free from ammonia and almost free from organic nitrogen and organic matter. Thus purified the liquid is perfectly limpid and inodorous although coloured yellowish brown : it contains : P_2O_5 about 0·2, K_2O 1·6 and CaO 0·4 per cent., and is well suited for watering growing plants.—J. H. L.

Patents.

Diastatic preparations ; Manufacture of ——. C. F. Cross and R. F. L. Turner, London, and H. F. Fuller, Burnham, Bucks. Eng. Pat. 737, Jan. 9, 1913.

A concentrated diastatic extract is incorporated with such a quantity of previously dried starch or starchy material that a solid and apparently dry product is obtained.—L. E.

Yeast ; Transformation of beer —— *into bakers' yeast.* E. A. Barbet. Fr. Pat. 461,742, Nov. 5, 1912.

Pressed beer yeast is first liquefied by admixture with a suitable salt (*e.g.*, 2 per cent. of common salt). The cell juices, containing bitter substances, are thus drawn out of the cells, and may be separated from them by filtration, but this is not necessary. The liquefied yeast is regenerated by growth in a dilute, filtered, saccharified wort similar to those employed in the manufacture of yeast by the aeration process.—J. H. L.

Yeast ; Collection of —— *from fermentation vats.* R. Reik. Fr. Pat. 462,207, Sept. 4, 1913. Under Int. Conv., Sept. 6, 1912.

The yeast head is drawn off from the top of fermented wort, into the mouthpiece of a flexible pipe and is carried along the pipe to closed receivers which are in communication with an exhaust pump.—J. H. L.

Amylaceous materials : Process for the liquefaction, saccharification and fermentation of ——. A. Boidin and J. Effront. Fr. Pat. 461,853, Nov. 7, 1912.

The material is preferably first steeped in water at about 70° C. and ground in the moist state. The starch is liquefied by the action of *Bac. subtilis* or *Bac. mesentericus* in an alkaline medium, saccharified by malt diastase or suitable moulds in a neutral or acid medium, and fermented by yeast.—J. H. L.

Malt ; Process of manufacturing ——. J. von der Kammer, Berlin. Assignor to B. von der Kammer, Chicago. U.S. Pat. 1,084,943, Jan. 20, 1914.

See Fr. Pat. 454,534 of 1913 ; this J., 1913, 880.—T. F. B.

Diastase; Process for obtaining pure ——. S. Fränkel. Fr. Pat. 461,385, Aug. 13, 1913.

See Eng. Pat. 18,427 of 1913; this J., 1913, 1166.—T.F.B.

Non-alcoholic beverages; Manufacture of ——. C. R. Wagner, Sonnenberg, Germany. U.S. Pat. 1,084,833, Jan. 20, 1914.

See Eng. Pat. 16,707 of 1910; this J., 1911, 916.—T. F. B.

Crystallised liquids: Process for preparing ——. U. Wegener. Fr. Pat. 461,392, Aug. 14, 1913.

See Eng. Pat. 20,061 of 1913; this J., 1914, 157.—T. F. B.

Distillery and like residues; Impts. in and apparatus for recovering valuable products from ——. C. E. Geiger, W. E. Koop, and G. W. Fiske, Louisville, Ky., U.S.A. Eng. Pat. 4052, Feb. 17, 1913.

See U.S. Pat. 1,057,142 of 1913; this J., 1913, 444.—T.F.B.

Plastic composition [from yeast and spent hops]. U.S. Pat. 1,084,900. *See* V.

Treatment of materials containing tartaric acid for the extraction of calcium and potassium tartrates. Fr. Pat. 461,901. *See* VII.

Preparation of yeast for the manufacture of extracts. Fr. Pat. 462,198. *See* XIXa.

XIXa.—FOODS.

Flour containing barium carbonate; Cases of poisoning caused by ——. L. Hugounenq. Ann. Falsif., 1914, **7**, 54—56.

Numerous cases of more or less acute poisoning investigated by the author were found to be caused by the presence of barium carbonate in the flour which had been consumed by the patients. Analysis of the flour showed that it contained from 5 to 21 per cent. of barium carbonate, whilst bread made from the flour contained from 2 to 7·5 per cent. (calculated on the dry substance). No definite evidence was obtained as to how the barium carbonate came to be mixed with the flour.—W. P. S.

Milk; Detection of added water in —— by a simplified molecular concentration constant. L. Mathieu and L. Ferré. Ann. Falsif., 1914, **7**, 12—21.

The simplified molecular concentration constant denotes the sum of the weight of crystallised lactose and of the sodium chloride expressed as the isotonic equivalent of lactose. For instance, a milk containing 54·5 grms. of lactose and 1·4 grm. of sodium chloride per litre would give a constant of $54{\cdot}5+(1{\cdot}4\times11{\cdot}9)=71{\cdot}2$, since 1 grm. of sodium chloride is the isotonic equivalent of 11·9 grms. of lactose. The constant must be corrected for the volume of the fat and casein; the volume of the calcium phosphate may be neglected. This correction, taking extreme cases, varies from 1·03 to 1·10 and in the majority of milks it is 1·07, that is to say, the constant found as above must be multiplied by 1·07 to give the true value. With most milks the value of the constant lies between 74 and 79 and will fall below 73 when the milk contains from 5 to 8 per cent. of added water.—W. P. S.

[*Milk.*] *Separator-slime; The lipoids of —— and their importance for the formation of milk fat.* O. Laxa and A. Konecny. Milchwirtschaftl. Zentr., 1913, **42**, 663—671, 691—697. Chem. Zentr., 1914, **1**, 281—282.

The separator-slime examined was derived mostly from milk which had been pasteurised at 85° C. It contained 53·32—60·78 (average 56·52) per cent. of water, 28·56—55·12 (32·12) of protein, 0·61—4·25 (2·32) of fat, and 4·40—6·08 (5·23) per cent. of ash. The dried slime contained 0·103—0·107 per cent. P_2O_5 soluble in alcohol and 0·21 per cent. of cholesterol. Slime from raw milk contained 71·86—75·32 per cent. of water, 16·73—21·91 of protein, and 2·85—3·07 of fat; and the dry substance contained 0·157 per cent. P_2O_5 soluble in alcohol. The fat extracted by ether was separated into a liquid portion (greatly preponderating) and a solid portion. The residue left after extracting the slime with ether yielded to alcohol a further quantity of pale green fat rich in chlorophyll. The characters of the different specimens of fat are shown in the following table:—

	Fat extracted by ether.			Fat extracted by alcohol.
	Whole fat.	Liquid fat.	Solid fat.	
Solidif. pt...........	—	+6° C.	28·3° C.	—
Melting point	—	18°—28° C.	38°—39° C.	—
Saponif. value	192·2—192·9	191·9—192·8	180·1—180·3	210—210·8
Acid value	119	69·3	—	—
Reichert-Meissl value	12·8	17·2—17·6	12·7	8·5
Polenske value......	4·3	3·2	3·6	1·8
Refractometer reading (40° C.)	47	—	46·5	—
Iodine value	40·8—43·6	45·5—45·9	34·6—35·2	38·1—38·6
Hehner value	—	88·2—88·8	91·5	—
Mol. wt. of insol. acids	—	315	309	291

The fatty acids of the liquid fat contained: erucic acid, 49·56; oleic acid, 21·24; palmitic, stearic, myristic and lauric acids, 17·70; soluble volatile acids, 4·90 per cent.—A. S.

Butter; Preservation of —— by means of sodium bicarbonate and sodium nitrate. F. Bordas. Ann. Falsif., 1914, **7**, 45—49.

The results of an investigation, in which quantities of 100 grms. of butter were mixed with 0·857 grm. of sodium bicarbonate or with this quantity of bicarbonate and 0·143 grm. of sodium nitrate, and then kept for 14 days, showed that, although the alkali prevented the acidity of the butter from increasing, it modified the colour and taste; the addition of the sodium nitrate was without effect. —W. P. S.

Cottonseed hulls; Determination of —— in cottonseed meal. C. Grimme. Chem.-Zeit., 1914, **38**, 137—139.

The difficulties of manipulation in Fraps' method (this J., 1909, 590) are obviated by basing the calculation upon the results of hydrolysis with 1 per cent. hydrochloric acid. The amounts of residues thus obtained with the seed kernels of N. American, Brazilian, Egyptian and Caucasian cotton ranged from 10·32 to 11·58 per cent., whilst the hulls gave 69·64 to 70·07 per cent. Only in the case of cottonseed grown in Togo was there any pronounced variation from these results, the residues then ranging from 10·45 to 11·54 (kernels) and from 59·10 to 65·0 (hulls). As the exports of Togo cottonseed are relatively negligible the values of 70 for the hulls and of 11 for the kernels was adopted for the calculation. 2 grms. of the finely-powdered meal (freed from fat) are digested fo 30 mins. (from the time of boiling) beneath a reflux condenser with 200 c.c. of 1 per cent. hydrochloric acid, and th liquid then diluted to 1000 c.c. with hot water, and filtered through asbestos. The residue is washed with hot water then three times with alcohol and once with ether, an dried at 105°—110° C. until constant in weight, afte which it is ignited and the amount of ash deducted fro the first weight. The percentage of hulls is calculated by the formula $x = \frac{(y-11)\,100}{59}$, where y represents the amount of ash-free residue. The results agreed closely with those obtained by the method of Fraps, the difference lying between −0·3 and +0·8 per cent.—C. A. M.

Patents.

Meat; Process of preserving ——. A. Danilevsky, St Petersburg. Eng. Pat. 14,784, June 26, 1913.

Immediately after the animal has been slaughtered an incision is made in the heart, and a solution consisting of water, 100 parts, sodium chloride, 1 to 3, and hydrogen peroxide, 0·005 to 0·5 part, is introduced into the artery and forced through the blood vessels under a pressure not exceeding 0·33 atmosphere. When the solution has replaced all the blood in the vessels, as is shown by the solution flowing in a colourless condition from the right ventricle, the carcase is eviscerated, skinned, immersed in a tank filled with the solution, and then wrapped in linen saturated with the solution.—W. P. S.

Protein compounds from fish; Process for the preparation of soluble ——. Naamlooze Vennootschap Algemeene Exploitatie Maatschappij, Amsterdam. Eng. Pat. 22,462, Oct. 6, 1913. Addition to Eng. Pat. 7700 of 1913, dated Nov. 6, 1912 (this J., 1913, 957).

In order to avoid the use of carbon dioxide for carbonating the excess of calcium hydroxide employed in the process described in the former patent (*loc. cit.*), the mixture obtained on digesting fish with calcium hydroxide is diluted with water, and filtered. The insoluble portion of the calcium hydroxide is thus removed, and the filtrate is then carbonated and the proteins separated.—W. P. S.

Milk; Process for curdling ——. J. Brensike, Hustisford, Wis. U.S. Pat. 1,083,659, Jan. 6, 1914.

Stomachs and intestines of fish are freed from their contents, soaked in water, and heated for 1 hour, or more. The liquid portion is then separated, filtered, a suitable proportion of rennet is added to the filtrate, and this mixture is added to milk.—W. P. S.

Milk; Machine for drying ——. P. M. Thardy. Fr. Pat. 461,584, July 23, 1913.

Circular glass or polished metal plates are mounted vertically on a rotating shaft; each plate is surrounded by a steam-jacket which covers three-fourths of the surface, and means are provided for exhausting the air from the space between the jacket and the plate. The milk is delivered on to both sides of the plates by oppositely rotating rollers, the lower parts of which dip into a vessel containing the milk; a pair of rollers is provided for each plate. The film of dried milk is removed from the plates by scrapers.—W. P. S.

Artificial milk and a process and apparatus for its manufacture. G. von Rigler. Fr. Pat. 461,131, Aug. 5, 1913. Under Int. Conv., Oct. 29, 1912.

Crude gluten (150 grms.) is dissolved in 1 litre of a solution containing 0·01 to 0·015 per cent. of potassium hydroxide and 0·5 per cent. of alcohol; suitable quantities of sodium chloride, lime-water, phosphoric acid, and sugar, are then added (care being taken that the solution still remains alkaline in reaction), and the solution, while being gradually heated from 70°—100° C., is emulsified with 3·5 per cent. of its weight of a vegetable oil such as cocoanut oil. The mixture is maintained at 100° C. for 30 mins., then filtered, cooled, and transferred to sterilised bottles. The different parts of the apparatus are all in connection with each other so that, during the various operations, the mixture may be kept out of contact with the atmosphere.—W. P. S.

Margarine and analogous substances; Manufacture of —— *using cooling surfaces for cooling the liquid fats or emulsions.* E. Schou. First Addition, dated July 30, 1913, to Fr. Pat. 454,640, Feb. 20, 1913 (this J., 1913, 880). Under Int. Conv., Oct 21, 1912.

The thin films of fat removed by the scrapers are heated rapidly so as to yield a homogeneous mass.—W. P. S.

Pectinous alimentary products; Process of extracting —— *from fruits and legumes.* R. Douglas. Fr. Pat. 462,044, Sept. 1, 1913.

Fruit (apple) pulp, after the removal of the natural juices and sugar, is extracted with hot water containing a small quantity of an acid. The aqueous solution is evaporated, preferably under reduced pressure, to a syrupy consistence. Leguminous substances may also be used as the source of the pectin.—W. P. S.

Alimentary products [jellies, jams, etc.], and process of manufacturing them. R. Douglas. Fr. Pat. 462,045, Sept. 1, 1913.

Crushed fruit, or fruit juice, is mixed with sugar and an amount of concentrated pectin solution sufficient to convert the whole into a jelly without concentration. The mixture is then sterilised by heating, and cooled.—W. P. S.

Yeast; Preparation of —— *for the manufacture of extracts.* "Visca" Nahrungsmittel-Ges. m. b. H. Fr. Pat. 462,198, Nov. 16, 1912.

For the preparation of yeast-extracts analogous to extracts of meat, the yeast is first washed to remove bitter substances and other impurities, and then allowed to ferment an aqueous solution of sugar. It is killed when fermentation is in full vigour, and the quantity of sugar employed is so chosen that a small excess remains in the yeast.—J. H. L.

Flour; Process and machine for treating ——. C. Herendeen. Fr. Pat. 461,138, Aug. 6, 1913.

See U.S. Pats. 1,073,985 and 1,073,986 of 1913; this J., 1913, 987.—T. F. B.

Transformation of beer yeast into bakers' yeast. Fr. Pat. 461,742. *See* XVIII.

XIXb.—WATER PURIFICATION; SANITATION.

Experiments on emulsions. Newman. *See* XII.

Patents.

Water; Apparatus for the treatment [softening] of —— *and for similar purposes.* W. R. Ormandy, Manchester. Eng. Pat. 25,261, Nov. 4, 1912.

A rotating horizontal cylinder is divided into compartments by perforated partitions; zeolites are placed in these compartments and are brought into intimate contact with the water passing through the cylinder by means of curved blades attached to the inner walls. A filter is provided at each end of the cylinder. The water may be passed in either direction, alternately, through the cylinder, and a regenerating solution may be admitted when required, or the zeolites may be removed and treated with the solution in a separate vessel. In a modification of the apparatus, the cylinder is fixed and contains a central rotating shaft fitted with blades.
—W. P. S.

Water; Method of and apparatus for heating and purifying ——. N. Tikhomiroff, Moscow. Eng. Pat. 131, Jan. 2, 1913.

Waste furnace gases are passed upwards through three or more superposed chambers, and the water mixed with a suitable reagent (aluminium sulphate, calcium hydroxide, sodium carbonate) is sprayed through an atomiser into the upper chamber, then collected from the latter and sprayed into the next lower chamber, and so on. A tank, divided into compartments, is provided for collecting separately the water flowing from the different chambers, and the hot water from the last chamber may be passed through a filter before it is conducted to the boiler. —W. P. S.

Water; Method and means for softening ——. H. J. Wheaton, Spondon, Derbyshire. Eng. Pat. 4188, Feb. 18, 1913.

In an apparatus where the water to be softened is passed downwards through a bed of softening material such as zeolites and then through a layer of sand, the zeolites are regenerated by leading a solution of sodium chloride from a tank (situated above the softening chamber) to a space below the zeolite bed and allowing it to flow upwards through the same. Water is then admitted to the upper part of the chamber in order to wash the zeolites. The sodium chloride solution is prepared in a tank at the ground level and then pumped into the upper tank. —W. P. S.

Refuse destructors. Comp. d'Incinération Industrielle, Paris. Eng. Pat. 12,668, May 30, 1913. Under Int. Conv., June 28, 1912.

The destructor consists of a number of furnaces, each having a preliminary drying chamber with an inclined arch on which the fresh refuse is dried and distilled before it falls on to the grate; the distillation gases pass into a combustion chamber heated by a coke furnace, the latter being supplied with a current of heated air from the refuse chamber or from the front of the furnace. The gases from the combustion chamber are then conducted under a boiler and through a preheater and dust collector before being allowed to escape into the atmosphere. Means are provided for removing clinker from the furnaces. —W. P. S.

Charcoal Manufacture of active powdered —— *[from refuse] for purifying and filtering purposes.* L. Pilaski. Ger. Pat. 267,443, Aug. 16, 1912.

House refuse and road sweepings are sifted to remove the fine material; from the coarser portion, stones, cinders, etc. are removed, and the residue is treated with quicklime and subjected to destructive distillation.—A. S.

Sterilisation of liquids: Apparatus for the ——. V. Henri, A. Helbronner, and M. von Recklinghausen, Paris. Eng. Pat. 28,660, Dec. 12, 1912. Under Int. Conv., Dec. 21, 1911.

See Addition of Dec. 21, 1911, to Fr. Pat. 424,369 of 1910; this J., 1913, 504.—T. F. B.

Charcoal for purification and filtration; Process for making powdered ——. L. Pilaski. Fr. Pat. 461,599, July 30, 1913.

See Ger. Pat. 267,443 of 1912; preceding.—T. F. B.

Sewage; Apparatus for purifying ——. P. Bunzel, Fr. Pat. 461,622, Aug. 4, 1913.

See U.S. Pat. 1,079,391 of 1913; this J., 1914, 39.—T. F. B.

XX.—ORGANIC PRODUCTS; MEDICINAL SUBSTANCES; ESSENTIAL OILS.

Strophanthin in seeds and tincture; Determination of ——. J. B. Lampart and A. Müller. Arch. Pharm., 1913, **251**, 609—632.

Comparisons have been made of a number of methods for the determination of strophanthin in strophanthus seeds or tincture. The most satisfactory is that described by Fromme in 1910 (Geschäfts-Ber., Cæsar and Loretz, 1910, 118; 1911, 142). 7·0 grms. of the finely-crushed seeds are boiled in a reflux apparatus for an hour with 70·0 grms. of absolute alcohol. When cold, the whole is made up to the original weight with absolute alcohol, and 50·5 grms. filtered into a porcelain basin. The alcohol is evaporated and the residue washed with light petroleum which is poured through a filter. The insoluble residue in the filter and basin are boiled with 5—8 grms. of water, treated with 5 drops of lead acetate solution and about 0·2 grm. of kieselguhr, well mixed and filtered into a 100 c.c. flask. The insoluble portion is washed till the runnings no longer have a bitter taste. The filtrate is treated with 5 drops of hydrochloric acid and boiled gently for 2 hours, the volume being kept between 10—20 c.c. by the addition of distilled water. When cold, the liquid is extracted twice with 10 c.c. of chloroform which is filtered into a tared flask. The aqueous portion is again boiled for half-an-hour, cooled and extracted three times with 10 c.c. of chloroform. If the aqueous portion after warming still tastes bitter, the boiling and extraction with chloroform are repeated. The chloroform is distilled off, the residue dried in a desiccator and then weighed. It consists of strophanthidin, one part of which corresponds to 2·187 parts of pure strophanthin. For the tincture 51 grms. (equivalent to 5·0 grms. of the seeds) are heated on the water bath to remove the alcohol, the residue taken up with 20 grms. of hot water, treated with 15 drops of lead acetate solution and 0·2 grm. of kieselguhr. It is then treated by the method described above for the seeds.—F. Shdn.

Harmine and harmaline. O. Fischer. Ber., 1914, **47**, 99—107. (See also this J., 1912, 659.)

After discussing the formulæ that have been proposed for harmine and harmaline, including those of Perkin and Robinson (*loc. cit.*), further formulæ are put forward for harmine which are better in accordance with the behaviour of this substance. Methylharmaline hydrochloride crystallised from hot water and melted at 265° C. with decomposition. It was reduced by boiling with sodium and amyl alcohol to methyldihydroharmaline $C_{14}H_{18}N_2O$, which was crystallised from benzene and formed nearly colourless leaflets, m. pt. 173°—174° C. The latter substance gave a methiodide, m. pt. 203° C., which was converted into a pseudo-base with the composition of a quaternary dimethylharmaline ammonium hydroxide, $C_{15}H_{22}N_2O_2$, m. pt. 129° C., on boiling with potassium hydroxide and methyl alcohol. When dimethylharmaline iodide was boiled with aqueous potassium hydroxide trimethylamine was split off. Harmaline was condense with hydroxylamine by boiling an alcoholic solution o the two substances, with the formation of a product $C_{13}H_{17}N_3O_2$, m. pt. 180° C. after crystallising from alcohol Harmine and dihydroharmaline could not be condensed i this way. Dihydroharmaline and benzaldehyde wer boiled in concentrated solution and the product precipitate by the addition of hydrochloric acid. After washing wit ether, nearly colourless crystals of a condensation produc were obtained with the composition, $C_{33}H_{38}N_4O_2Cl$ Harminic acid was oxidised by heating 1—1·5 grm. wit 2 c.c. of nitric acid (sp.gr. 1·4) and 6 c.c. of water to 180°-200° C., when isonicotinic acid, $C_6H_5NO_2$, m. pt. 307°-308° C., was obtained.—F. Shdn.

Digitoxin and gitalin. H. Kiliani. Arch. Pharm.. 191 **251**, 562—587.

Gitalin is not readily converted into anhydrogitalin boiling with water or treatment with solvents as w stated by Kraft (Arch. Pharm., 1912, **250**, 118 ; compare also this J., 1912, 256). A method for analysing digitalis preparations is proposed, based on the fact that when a solution of digitoxin, gitalin and anhydrogitalin in a mixture of equal volumes of chloroform and methyl alcohol is treated with ether, digitoxin and anhydrogitalin are precipitated, whilst gitalin remains in the solution. Good yields of digitoxigenin can be obtained by boiling 1 part of digitoxin with about 10 parts of a mixture of 100 parts of 50 per cent. alcohol and 1 part of concentrated hydrochloric acid for 15 minutes. Digitoxose, produced together with digitoxigenin by the hydrolysis of digitoxin, is readily decomposed by boiling with dilute aqueous hydrochloric acid. This sugar behaves quite differently to *l*-arabinose and does not yield furfural on distillation with hydrochloric acid. It has the composition, $C_6H_{12}O_4$. When digitoxinic acid lactone is boiled with an aqueous alcoholic solution of quinine, a quinine salt of the acid is formed melting at 164° C. The brucine salt formed in the same way melts at 124° C.—F. Shdn.

Purine bases ; Synthetic glucosides of the ——. E. Fischer and B. Helferich. Ber., 1914, **47**, 210—235.

By interaction of acetobromoglucose or its derivatives, and salts of the purine bases with heavy metals (especially silver salts), in water-free solvents, the authors succeeded in preparing glucosides of these bases. Thus, by heating together the silver salt of theophylline and acetobromoglucose, in boiling xylene, a tetra-acetyl derivative of theophylline-*d*-glucoside was obtained, which when hydrolysed by alcoholic ammonia yielded theophylline-*d*-glucoside. This compound (which probably contains the dextrose residue attached to one of the nitrogen atoms of the imidazole ring) was very readily hydrolysed by hot dilute acids, but not by emulsin or yeast enzymes. It is probably a β-glucoside like all those hitherto prepared from acetobromoglucose. Glucosides of theobromine and hydroxycaffeine were prepared in a similar manner ; the former underwent slow hydrolysis in cold aqueous solutions. Dichloro-adenine served for the preparation of several of these glucosides. Thus, by careful reduction of dichloro-adenine-glucoside with hydriodic acid and phosphonium iodide, adenine-*d*-glucoside was obtained and this was converted into hypoxanthine-glucoside by the action of nitrous acid ; both of these were similar to natural ribosides of adenine and hypoxanthine. Dichloro-adenine-glucoside was also converted into the monochloro compound by heating with water and zinc dust at 140° C. ; the amino group was removed by means of nitrous acid and, by subsequent treatment of the product with alcoholic ammonia at 150° C. a crystallisable substance, probably guanine-glucoside, was obtained. The nucleic acids and the closely related, but more simply constituted nucleotides, contain not only bases and sugars but also phosphoric acid, and the latter appears to be combined with the sugar residue. By combining theophylline-*d*-glucoside with phosphoric acid by the procedure of Neuberg and Pollak (this J., 1910, 291, 967) products were obtained which, though they resembled the nucleotides in many respects, were only monobasic and they were not obtained crystalline.—J. H. L.

Sarsaparilla root ; Chemical examination of ——. F. B. Power and A. H. Salway. Chem. Soc. Trans., 1914, **105**, 201—219.

OMMERCIAL grey Jamaica sarsaparilla root (*Smilax ornata*, Hooker, fil.) was found to contain a small quantity of an nzyme which slowly hydrolysed amygdalin. 22·1 kilos. f the ground root were extracted by continuous percolaion with hot alcohol, and after removal of the greater art of the solvent, the viscid dark-coloured extract 2·95 kilos.) was distilled with steam. The distillate ontained 2·6 grms. of a pale yellow essential oil, which ad the sp. gr. 0·977 at 15°/15° C., was not completely luble in 70 per cent. alcohol, and distilled between 70° nd 200° C. at 15 mm. The following compounds were olated from the alcoholic extract :—A crystalline glucoside, sarsasaponin, $C_{44}H_{76}O_{20},7H_2O$ (m. pt. 248° C., $[\alpha]_D=-48{\cdot}5°$ in aqueous solution), a phytosterolin (sitosterol-*d*-glucoside), $C_{33}H_{56}O_6$, m. pt. 280—285 C., with decomposition, sitosterol, $C_{27}H_{46}O$, m. pt. 135°—136° C., $[\alpha]_D=-27{\cdot}3$ in chloroform, stigmasterol, $C_{30}H_{50}O$, a new, crystalline dicarboxylic acid, *sarsapic acid*, $C_4H_2O_2(CO_2H)_2$, m. pt. 305° C., dextrose, and a mixture of palmitic, stearic, behenic, oleic, and linolic acids. There were also present a considerable quantity of potassium nitrate and a small quantity of a substance having the characters of cetyl-*d*-glucoside. The total quantity of resinous material extracted by alcohol was equivalent to about 1·25 per cent. of the weight of the root. Sarsasaponin, on hydrolysis, yielded 1 mol. of sarsasapogenin, $C_{26}H_{42}O_3$, m. pt. 183° C., $[\alpha]_D=-60{\cdot}3°$ in methyl alcohol, and 3 mols. of dextrose. Jamaica sarsaparilla root thus contains only one definite saponin-glucoside, namely sarsasaponin, but it also contains a phystosterol-glucoside or phytosterolin (sitosterol-*d*-glucoside), and it is probable that the parillin of earlier investigators consisted of a mixture of sarsasaponin and a phytosterolin. Commercial smilacin, the smilasaponin of v. Schulz (Pharm. J., 1892, **52**, 6 ; Arb. des pharmakol. Inst. zu Dorpat, 1896, **14**, 14), was found to consist of a relatively small proportion of sarsasaponin together with indefinite amorphous products.—A. S.

Sulphur dioxide-camphor ; The system ——. I. Bellucci and L. Grassi. Atti R. Accad. dei Lincei Roma, 1913, **22**, II., 676—680.

A careful study of mixtures of camphor and sulphur dioxide by the method of thermal analysis showed that two compounds are formed, viz., $C_{10}H_{16}O,2SO_2$, m. pt. —45° C., and $C_{10}H_{16}O,SO_2$, m. pt. —24° C. It is probable that the action of camphor in facilitating the union of sulphur dioxide and chlorine to sulphuryl chloride is connected with the formation of these compounds. This view is borne out by the statement in Ger. Pat. 138,531 (U.S. Pat. 716,248 of 1902 ; this J., 1903, 110) that good yields of sulphuryl chloride can be obtained by adding liquid chlorine to a previously prepared, cooled liquid mixture of sulphur dioxide and camphor, *i.e.*, under conditions specially favourable to the formation of the compounds mentioned.—A. S.

Salicylic acid chloride ; Preparation of ——. E. Kopetschni and L. Karczag. Ber., 1914, **47**, 235—237.

Sodium salicylate was added slowly to thionyl chloride cooled with ice. Sulphur dioxide was evolved and the mixture turned into a gelatinous mass which became more or less transparent on standing. This consisted of a mixture of salicylic acid chloride, $C_6H_4(OH)COCl$, and sodium chloride. The excess of thionyl chloride was removed by warming gently in a vacuum. The mass was then heated and the salicylic acid chloride distilled off at 90°—115° C. at 12 mm. It then formed a clear, highly refractive, stable liquid with a characteristic odour. When cooled on ice it solidified and then melted again at 17·5°—18·0° C. A better yield was obtained by extracting the mass with light petroleum, but the product was found to be liable to spontaneous decomposition.—F. Shdn.

Aldehydes and ketones ; Reduction of the carbonyl group in —— *to the methylene group.* E. Clemmensen. Ber., 1914, **47**, 51—63.

A general and practically quantitative reduction is effected by amalgamated zinc and hydrochloric acid (which is usually of 1 : 1 or 1 : 2 strength), and the products are of high purity. The reactions are represented thus ;

$$R.CO.Ar(OH)+2H_2=R.CH_2.Ar(OH)+H_2O \text{ and}$$
$$Ar(OH).CHO+2H_2=Ar(OH).CH_3+H_2O.$$

For ketones the complete mixture is heated for several hours ; but, owing to the resinification of certain aldehydes by acid, the aldehyde is usually added in portions to the reducing mixture. The following phenols have thus been prepared from the corresponding hydroxy-ketones: *p*-ethylphenol, *p*-propylphenol, *m*-ethyl-*o*-cresol, ethylresorcinol, ethylquinol, ethylcatechol, ethylpyrogallol and diethylpyrogallol. The phenols obtained by the reduction of aromatic hydroxy-aldehydes include the three cresols and *p*-methylthymol. As a typical case, the preparation of *o*-cresol from salicylaldehyde may be quoted. Good commercial granulated zinc is left for a few hours in a 5 per cent. solution of corrosive sublimate. The liquid is poured off and the zinc (150 grms.) transferred directly to a flask provided with a reflux condenser. Concentrated hydrochloric acid (200 c.c.) is added, the mixture is warmed till reaction sets well in, and salicylaldehyde (25 grms.) run in gradually from a dropping funnel. The completed mixture is boiled for an hour; further small quantities of acid being introduced from time to time during the whole course of the reaction. Finally, the *o*-cresol is distilled with steam, separated by the addition of common salt, dried and re-distilled. The yield is about 70 per cent. The colour reactions of the extremely pure cresols so obtained, are described, and the author attributes the unpleasant smell of commercial phenol to the presence of *p*-cresol and *p*-ethylphenol.—J. R.

Alkoxy groups; The action of Grignard's reagent on ——. H. Simonis and P. Remmert. Ber., 1914, **47**, 269—271.

The alkoxy group is only indifferent to Grignard's reagent (alkyl magnesium iodide) at comparatively low temperatures, thus anisol is not acted upon at 100° C., but at its boiling point (155° C.) is completely decomposed: $C_6H_5.OCH_3+CH_3.MgI=C_6H_5.OMgI+C_2H_6$. Phenetol similarly gives phenol and propane. Dimethoxy-compounds behave in the same way, quinol-dimethylether giving a good yield of quinol together with a little of the mono-ether when the reaction is carried out at 250° C. in petroleum solution.—J. B.

Sodium alkyl thiosulphates; Action of hydrogen peroxide on the ——. D. F. Twiss. Chem. Soc. Trans., 1914, **105**, 36—39.

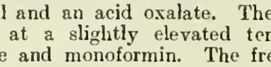
In slightly acid solution the sodium alkyl thiosulphates are readily oxidised by hydrogen peroxide, forming disulphides,

e.g., $2C_6H_5.CH_2.S_2O_3Na+H_2O_2=(C_6H_5.CH_2)_2S_2+2NaHSO_4$.

The disulphides of the benzyl, *o*-nitrobenzyl, *p*-nitrobenzyl and allyl radicles have been prepared in this manner. *o*-Nitrobenzyl-selenosulphate has similarly been oxidised to yield di-*o*-nitrobenzyl diselenide. The method has the advantage of not giving rise to by-products of unpleasant smell. Dibenzyl diselenide suspended in glacial acetic acid is oxidised almost quantitatively by hydrogen peroxide to selenious acid and benzyl alcohol.—J. R.

Glycerol and oxalic acid, Interaction of ——. F. D. Chattaway. Chem. Soc. Trans., 1914, **105**, 151—156.

The explanation of this action usually given in the text-books is incorrect. Oxalic acid forms with glycerol both a normal and an acid oxalate. The latter decomposes readily at a slightly elevated temperature into carbon dioxide and monoformin. The fresh oxalic acid displaces formic acid from the monoformin, and the cycle of operations is repeated. This is shown by the fact that on adding ammonia or aniline to the reaction mixture, oxamic or oxanilic acids can be obtained, demonstrating the existence of the acid glyceryloxalate in the melt. Using ethyl alcohol instead of glycerol the whole series of reactions can be carried out and the products isolated at every stage. The allyl alcohol obtained when the reaction mixture is rapidly heated to a higher temperature results from the decomposition of the normal glyceryl ester, dioxalin,



$$\begin{array}{l}CH_2\text{———}CH{\cdot}CH_2{\cdot}OH.\\ \;| \qquad\qquad\quad |\\ O\text{—}CO\text{—}CO\text{—}O\end{array}$$

This can be shown to be present in such a reaction mixture by the formation of oxamide or oxanilide, and on heating it decomposes into allyl alcohol and carbon dioxide.

—W. H. P.

Patents.

Preparations containing formic aldehyde [*and sugars*]. H. Sefton-Jones, London. From J. A. von Wülfing, Berlin. Eng. Pat. 17,616, Aug. 2, 1911.

See U.S. Pat. 1,062,501 of 1913; this J. 1913, 672. Similar products are obtained from one mol. of a biose or two mols. of a monose and one, two, three, or four mols. of formaldehyde.—T. F. B.

Formaldehyde; Process for the manufacture of crystalline polymerisation products of ——. F. Pollak, Berlin. Eng. Pat. 25,830, Nov. 11, 1913. Under Int. Conv., Dec. 13, 1912.

The various crystalline polymerisation products of formaldehyde (polyoxymethylenes) can be obtained by dissolving amorphous paraformaldehyde in solutions of acids or acid salts by heating, or by treating it with such solutions heated to a temperature below that required for complete solution; on cooling the polymerisation products separate from the liquid. For example, 500 parts of dry amorphous paraformaldehyde are dissolved in 680 parts by weight of sulphuric acid (22·8 vols. per cent.) at 90°—95° C., the solution is filtered and allowed to cool slowly: the product consists of pure α-polyoxymethylene, which is soluble in aqueous sodium sulphite solution and does not react exothermically with phenols without contact media. When stronger acid is used, and in greater quantity, the β- and γ-polymers, which are reactive with phenols, and are soluble and insoluble, respectively, in sodium sulphite solution, are obtained.

—T. F. B.

Pharmaceutical compounds [*fatty acids containing arsenic and phosphorus*]; *Manufacture of* ——. F. Heinemann, Berlin. Eng. Pat. 10,378, May 2, 1913. Addition to Eng. Pat. 18,732 of 1912, dated Nov. 29, 1911 (see this J., 1913, 109).

Fatty acids of the acetylene series containing arsenic can be obtained by treating the acids with arsenic trioxide and hydrohalogen acids in presence of dehydrating agents. Other mixtures yielding trihalogen derivatives of arsenic or phosphorus may be used to produce acids containing arsenic or phosphorus, respectively.—T. F. B.

Organic arsenic compounds; Process for preparing ——. H. Bart. Ger. Pat. 268,172, Sept. 20, 1912. Addition to Ger. Pat. 250,264 (see Eng. Pat. 568 of 1911; this J., 1911, 1087).

An aromatic diazo compound is treated in alkaline solution with arsenious acid or its salts or compounds which contain either of the groupings, $.As(OK)_2$ or $.As:O$, in presence of a catalyst, such as metallic copper, silver, nickel, or cobalt, or their compounds. By this process, amino-5-hydroxy-2-phenylurethane is converted into hydroxy-4-carboxyethylamino-3-phenylarsinic acid and *p*-aminophenol into *p*-hydroxyphenylarsinic acid.—T. F. B

Arseno-precious metal compounds; Process for preparin ——. Farbwerke vorm. Meister, Lucius, und Brüning. Ger. Pats. 268,220 and 268,221, July 21 and Sept. 27 1912.

An aqueous solution of a salt of 3.3′-diamino-4.4′-dihydroxy arsenobenzene or of its formaldehyde-sulphoxylate compound is treated with a salt of gold or of a metal of th platinum group, and the products are separated fror the solutions by evaporation or by addition of an organi solvent. The complex compounds thus obtained may b used in medicine on account of their bactericidal pr perties.—T. F. B.

Aromatic stibino-compounds, aromatic stibinoxides and their derivatives; Process for preparing ——. Chem. Fabr. von Heyden. Ger. Pat. 268,451, Dec. 28, 1911.

When monoarylstibinic acids or their derivatives are treated with reducing agents, stibino-compounds or stibinoxides or their derivatives are produced, according to the conditions of the reaction.—T. F. B.

Glycerol-halogen-hydrins and poly-oxy-fatty acid esters; Process for directly producing ——. H. Fairbrother, London. From E. Zollinger, Zürich, Switzerland. Eng. Pat. 14,767, June 26, 1913.

Triglycerides (fats and oils) are converted into glycerol-halogen-hydrins by treatment with the calculated quantity or with an excess of hydro-halogen acid under pressure, either in the form of a gas or in solution in methyl or ethyl alcohol: the fat or oil may be used undiluted or in solution. Usually a further reaction takes place, owing to the dehydrating action of the hydrohalogen acid on the fatty acid liberated. Thus, in the case of castor oil, the principal products of the reaction are mono- and di-halogen-hydrins and the esters of polyricinoleic acid, together with small quantities of glycerol and free di- and tri-ricinoleic acid. The yield of chlorhydrins obtained from castor oil and hydrochloric acid gas dissolved in ethyl alcohol, is said to be from 90 to 98 per cent. of the theoretical yield.
—T. F. B.

Emetine: Manufacture of ——. H. S. Wellcome, London, and F. H. Carr and F. L. Pyman, Dartford. Eng. Pat. 17,483, July 30, 1913. Addition to Eng. Pat. 14,677, June 25, 1913 (see this J., 1914, 102).

Yields of emetine much greater than those produced as described in the principal patent, are obtained by boiling cephaeline with sodium amylate and anhydrous sodium methyl sulphate in anhydrous fusel oil, subsequently extracting the emetine from the mixture by means of dilute acid.—T. F. B.

Aldol and crotonic aldehyde; Manufacture of ——. Consortium f. Elektrochem. Industrie G. m. b. H., Nürnberg, Germany. Eng. Pat. 19,463, Aug. 28, 1913. Under Int. Conv., Sept. 3, 1912.

Acetaldehyde is converted into aldol by treating it, in absence of water, with a small quantity of an alkali-metal or alkaline-earth metal, or one of their alloys or compounds soluble in aldehyde: the amount of condensing agent required is not more than 5 per cent., and is preferably much less. It is possible, by using a very small quantity of the condensing agent, to prevent almost entirely the formation of higher condensation products and resinous substances, so that the aldol may be distilled *in vacuo* directly from the reaction product. Further, the crude reaction product may be worked up directly to crotonic aldehyde, *e.g.*, by slow distillation under ordinary pressure. In the examples given, the amounts of condensing agent used are 70 parts of 2 per cent. calcium amalgam or 2 parts of potassium cyanide to 1000 parts of acetaldehyde.—T. F. B.

Pipitzahoic acid; Extraction of ——. Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. Eng. Pat. 24,692, Oct. 30, 1913. Under Int. Conv., Nov. 14, 1912.

Extraction of the root of *Perezia adnata* (*syn. Dumerilia humboldtiana, Trixis pipitzahuac, Compos. Mexico*) with hot alcohol gives a maximum yield of 3·7 per cent. of pipitzahoic acid, owing to partial decomposition and ntramolecular change of the product occurring, with ormation of an isomeric compound, of m. pt. 136° C., hich does not possess the therapeutic properties of pipitzahoic acid. It is now found that the decomposition an be almost entirely prevented, with the consequent production of higher yields of the pure product (m. pt. 04—106° C.) if the root be extracted at the ordinary emperature with an organic solvent, such as benzene.
—T. F. B.

Low-freezing liquid. M. A. Hunter, Troy, N.Y. U.S. Pat. 1,082,528, Dec. 30, 1913.

A mixture of carbon tetrachloride and carbon dichloride ($C_2H_2Cl_2$ dieline) with or without addition of another liquid, is claimed as a "low-freezing mixture."—T. F. B.

Solvents [of nitrocellulose]; Production of —— by means of halogen compounds. W. E. Masland, Assignor to E. I. du Pont de Nemours Powder Co., Wilmington, Del. U.S. Pat. 1,082,513, Dec. 30, 1913.

An unsaturated chlorohydrocarbon is used to render miscible a series of normally immiscible liquids, *e.g.*, wood alcohol and benzine. The product may be used as a solvent of nitrocellulose.—T. F. B.

Esters and ethers of ethylidene glycol and of vinyl alcohol; Manufacture of ——. F. Klatte, Schwanheim, Assignor to Chem. Fabr. Griesheim-Elektron, Frankfort on Maine, Germany. U.S. Pat. 1,084,581, Jan. 13, 1914.

Acetylene can be made to react with various organic hydroxy-compounds in presence of a mercury salt (*e.g.*, mercuric sulphate), to form ethers and esters of ethylidene-glycol and of vinyl alcohol.—T. F. B.

p-Nitrophenylcarbamyl chloride [and diarylureas]; Process for making ——. Farbwerke vorm. Meister, Lucius, und Brüning. First Addition, dated July 11, 1913, to Fr. Pat. 459,885, June 12, 1913. Under Int. Conv., July 25, 1912.

The *p*-nitrophenylcarbamyl chloride described in the principal patent (see this J., 1913, 1129) is treated with a primary or secondary base or a substitution product thereof (sulphonic acids, hydroxysulphonic acids, etc.), with or without adding a substance to neutralise the hydrochloric acid. When *p*-nitraniline is used as the base, *pp′*-dinitrodiphenylurea is produced. The products can be obtained in one operation by treating with phosgene two mols. of the same base or one mol. each of two different bases.—T. F. B.

Sulphocarboxylic anhydrides and their alkali and alkaline-earth salts: Process for producing ——. Naamlooze Vennootschap Fabriek van Chemische Producten Fr. Pat. 461,539, May 16, 1913.

The conversion of monocarboxylic acids or their anhydrides into the sulphacids by the action of sulphuric anhydride or fuming sulphuric acid, respectively, is found to take place in two stages, the first stage being the formation of a sulphocarboxylic anhydride, *e.g.*, $CH_3.CO.OSO_3H$, which is rapidly converted into the sulphacid (sulphacetic acid) at the ordinary temperatures. This second stage is very slow, however, at temperatures below 0° C., so that the sulphocarboxylic anhydrides can be prepared by carrying out the reaction at low temperatures. For example, a quantitative yield of acetylsulphuric acid is obtained by adding gradually 80 kilos. of sulphuric anhydride to 60 kilos. of acetic acid at a temperature below 0° C. The anhydrides thus formed can be converted into their alkali or alkaline-earth salts by mixing them with a suitable anhydrous alkali or alkaline-earth salt at a temperature below 0° C.—T. F. B.

Anhydrides of monobasic organic carboxylic acids: Process for producing ——. Naamlooze Vennootschap Fabriek van Chemische Producten. Fr. Pat. 461,540, May 16, 1913.

The alkali or alkaline-earth salts of sulphocarboxylic anhydrides of organic acids (see Fr. Pat. 461,539; preceding) are converted into the corresponding carboxylic anhydrides by heating alone or in presence of an indifferent liquid, such as acetic acid. Simple or mixed anhydrides are also obtained by heating alkali or alkaline-earth salts of sulphocarboxylic anhydrides with alkali or alkaline-earth salts of monocarboxylic acids. The preparation o acetic anhydride from sodium sulphacetate and sodium acetate is described in detail.—T. F. B.

Calcium salt of acetylsalicylic acid; Process for making the ——. Soc. Chimique des Usines du Rhône. Fr. Pat. 462,161. Sept. 3, 1913. Under Int. Conv., Oct. 4, 1912.

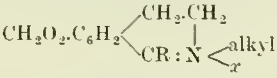
Quantitative yields of calcuim acetylsalicylate are stated to be obtained by introducing ammonia into a solution of salicylic acid and calcium chloride in methyl or ethyl alcohol.—T. F. B.

Hydrastinine from dihydrohydrastinine; Process for preparing ——. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 267,272, Jan. 19, 1913.

Dihydrohydrastinine is converted into hydrastinime by treatment with iodine dissolved in an organic solvent, preferably in presence of a substance which will combine with the hydrohalogen acid. If alcohol has been used as a solvent, the insoluble hydriodide of hydrastininc separates out, and may be converted into the free base, of m. pt. 115°—116° C.—T. F. B.

Salts of hydrastinine and its homologues; Process for preparing ——. H. Decker. Ger. Pat. 267,699, Feb. 2, 1912. Addition to Ger. Pat. 234,850 (this J., 1911, 923).

Salts of hydrastinine and its homologues of the general formula,



$$CH_2O_2.C_6H_2\left\langle\begin{matrix}CH_2.CH_2\\ \qquad\quad|\\ CR:N\left\langle\begin{matrix}\text{alkyl}\\ x\end{matrix}\right.\end{matrix}\right.$$

(where R represents hydrogen, alkyl, aralkyl, or aryl, and x an acid residue), are obtained by treating with a condensing agent the N-acidyl derivatives of homopiperonylamine,

$$CH_2O_2.C_6H_3.CH_2.CH_2.N\left\langle\begin{matrix}\text{acidyl}\\ \text{alkyl},\end{matrix}\right.$$

and converting the dihydro-isoquinoline compound into its salts by the usual methods (see also Ger. Pats. 245,095 and 249,723; this J., 1912, 483, 953).—T. F. B.

N-Monoalkyl derivatives of homopiperonylamine; Process for preparing ——. H. Decker. Ger. Pat. 267,700, Feb. 2, 1912.

The condensation products of homopiperonylamine and aldehydes, obtained aocording to Ger. Pat. 257,138 (see this *J.*, 1913, 507), are treated with alkylating agents in absence of water, and the quaternary ammonium compounds thus formed are decomposed by the usual methods to produce the free base.—T. F. B.

Guanidine salts; Process for preparing ——. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 267,380, Aug. 18, 1912.

Dicyanodiamide or its equivalent is treated with an acid substance, without application of pressure, the reaction being stopped as soon as the dicyanodiamidine has been decomposed.—T. F. B.

Mercury substituted amino-compounds; Process for preparing ——. Dr. Bayer und Co. Ger. Pats. 267,411 and 267,412, July 2 and Dec. 20, 1912.

Tyrosine is heated in aqueous solution with mercuric oxide or a mercuric salt, such as mercuric acetate. The products are stated to be non-irritant and to possess powerful bactericidal properties.—T. F. B.

Saponin; Process for preparing decomposition products of ——. F. Hoffmann-La Roche und Co. Ger. Pat. 267,815, June 24, 1911.

Solutions of saponin in dilute mineral acids are allowed to remain for a long time at temperatures not exceeding blood heat. The pentosides separate in the form of a fine snow-white, non-crystalline mass, which can be purified by dissolving in a small quantity of alcohol and pouring into water. The product does not possess the hæmolytic properties of saponin. Further hydrolysis with acids results in the formation of sapogenin and pentoses which are soluble in water.—T. F. B.

Hydrogen peroxide and hexamethylenetetramine; Preparation of a compound containing —— *in solid, stable form.* Diamalt A.-G. Ger. Pat. 267,816, March 5, 1912. Addition to Ger. Pat. 264,111 (see Eng. Pat. 29,373 of 1912; this J., 1913, 672).

The stability of the product mentioned in the principal patent is increased by addition of a small quantity of an acid anhydride or of an acetyl compound of an aromatic hydroxy-acid and an albuminoid compound or a polysaccharide. These additions serve to absorb the small quantities of ammonia and formaldehyde which are evolved.—T. F. B.

C-Allylphenols and their analogues; Process for preparing ——. L. Claisen. Ger. Pat. 268,099, Nov. 3, 1912.

O-Allylphenols (allylphenyl ethers), or their analogues or nucleus-substitution products, can be converted into the corresponding C-allylphenols by prolonged heating at high temperatures. The allyl group takes up a position *ortho* or *para* to the hydroxyl group.—T. F. B.

Lecithin salts; Process for preparing ——. P. Bergell. Ger. Pat. 268,103, Nov. 2, 1912.

One mol. of citric acid is mixed with a solution of one, two, or three mols. of lecithin, or one mol. of glycerophosphoric acid is added to a solution of one or two mols. of lecithin, and the salts are separated from the solutions by evaporation or precipitation. Alternatively, citric acid or glycerophosphoric acid is added in excess to a solution of lecithin in a solvent which is not miscible with water, the solution is extracted with water or very dilute alcohol, and the lecithin salt solution evaporated to dryness *in vacuo*. —T. F. B.

p-Aminophenyl ester of salicylic acid; Preparation of derivatives of —— *containing sulphur.* I. Abelin, E. Bürgi, and M. Perelstein. Ger. Pat. 268,174, Feb. 18, 1913.

Salicylic acid *p*-aminophenyl ester is treated with an alkali salt or an ammonium salt of ω-methylsulphonic acid. The products are soluble in water, and may be used for therapeutic purposes.—T. F. B.

Curative agents for tuberculosis, smallpox, and foot-and-mouth disease; Preparation of ——. W. Ponndorf. Ger. Pat. 268,293, Nov. 14, 1911. Addition to Ger. Pat. 265,207.

The skin of animals treated as described in the principal patent and in Ger. Pat. 265,208 (see this J., 1913, 1129) is not dried, but is frozen by means of liquid air, liquid carbon dioxide, etc., finely powdered, sterilised, and further treated as described in the prior patents.—T. F. B

Allyl halides; Process for preparing ——. Chem. Fab auf Actien, vorm. E. Schering. Ger. Pat. 268,34 Dec. 14, 1912.

Esters of allyl alcohol are converted into allyl halides b treatment with gaseous hydrogen halides, preferably i presence of aqueous hydrohalogen acids. The proce may be carried out under increased pressure. Esters allyl alcohol may also be treated with gaseous hydroge halides in presence of catalysts. The yields of allyl halid are said to be almost quantitative.—T. F. B.

Carbonic esters [of polyhydric alcohols, etc]; Process for preparing —— A. Hochstetter. Ger. Pat. 268,452, June 13, 1912.

Polyhydric alcohols other than glycerol, or hydroxyaldehydes or hydroxyketones of the carbohydrate series, are heated with phenol carbonate to a temperature about 130° C.; mono- or polyhydric phenols may be added as solvents. The resulting carbonic esters are generally sparingly soluble in the usual solvents; hot glacial acetic acid, methyl oxalate, and formamide are the best solvents Dextrose carbonate, which can be crystallised from these solvents, is also soluble in hot water. All the carbonates are decomposed after prolonged boiling with water, carbon dioxide being evolved.—T. F. B

Nicotine from tobacco waste; Process for preparing —— W. Halle. Ger. Pat. 268,453, April 12, 1913 Addition to Ger. Pat. 262,453 (see Eng. Pat. 11,758 of 1911; this J., 1912, 1147).

The dry tobacco is extracted with an organic solvent, the solvent is separated from the extract, and the residue is fractionated in a vacuum.—T. F. B.

Ointment-like or gelatinous masses for medicinal or cosmetic purposes; Preparation of ——. A. Eichengrün. Ger. Pat. 268,489, Nov 24, 1911

Aqueous-alcoholic solutions of cellulose hydro-acetates or cellulose sulphacetates are mixed with medicinal substances, perfumes, or sweetening or flavouring agents which are themselves solvents of acetylcellulose, or if they are not soluble, they are dissolved in indifferent solvents or brought in contact with solvents during the process. —T. F. B

Alkaloids of opium free from morphine; Production of a preparation containing all the —— soluble in water. F. Hoffmann-La Roche und Co. Ger Pat. 268,555, Aug. 13, 1911.

Opium is extracted with a dilute mineral acid, preferably sulphuric acid, the solution is neutralised with alkali, extracted with chloroform, made alkaline by addition of an alkali carbonate (preferably a bicarbonate) and shaken out with chloroform. The latter chloroform solution, which contains all the alkaloids except morphine, is washed with dilute caustic soda solution and evaporated to dryness, and the residue is converted into soluble salts. It is stated that the mixture of these alkaloids, in the proportions in which they exist in opium, is a highly effective soporific agent.—T. F. B.

Esters of aromatic carboxylic acids; Process for preparing ——. Badische Anilin und Soda Fabrik. Ger. Pat. 268,621, Nov. 14, 1912.

Salts of aromatic carboxylic acids are treated with halogenides of alcohols in presence of organic bases.—T. F. B.

Diaminodiphenylurea: Process for preparing a [chloro] substituted ——. Farbwerke vorm. Meister, Lucius, und Brüning. Ger. Pat. 268,658, Sept. 14, 1912.

2.6-Dichloro-*p*-phenylenediamine or one of its salts is treated with phosgene to form tetrachloro-diamino-diphenylurea.—T. F. B.

Solvents for the difficultly soluble compounds formed in organismal concretions; Method of producing ——. C. Luckow, Cologne, Germany. Eng. Pat. 1427, Jan. 17, 1913.

EE Fr. Pat. 454,183 of 1913: this J., 1913. 884.—T. F. B.

-Allylphenols and their analogues; Process for producing ——. L. Claisen, Godesberg on Rhine, Germany. Eng. Pat. 24,932, Nov. 1, 1913. Under Int. Conv., Nov. 2, 1912.

EE Ger. Pat. 268,099 of 1912; preceding.—T. F. B.

Ether-salts and ether-oxides of ethylideneglycol and of vinyl alcohol; Process for producing ——. Chem. Fabr. Griesheim-Elektron. Fr. Pat. 461,223 Aug. 8, 1913.

See U.S. Pat. 1,084,581 of 1914; preceding.—T. F. B.

Sulphochlorides of phenol-o-carboxylic acids and of their derivatives; Process for preparing ——. Farbenfabr. vorm. F. Bayer und Co. Fr. Pat. 461,320, Aug. 11, 1913. Under Int. Conv., Aug. 13, 1912.

See Ger. Pat. 264,786 of 1912; this J., 1913, 1003.—T.F.B

Aldol from acetaldehyde; Process for preparing ——. Consortium f. Elektrochem. Industrie G. m. b. H. Fr. Pat. 461,734, Aug. 23, 1913.

See Eng. Pat. 19,163 of 1913; preceding.—T. F. B.

Butadiene and its homologues; Manufacture of ——. W. H. Perkin and F. E. Matthews. Fr. Pat. 461,829, July 21, 1913. Under Int. Conv., July 24, 1912.

See Eng. Pat. 17,235 of 1912; this J, 1913, 884.—T. F. B.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

Photomicrography; Media of high refractive power for ——. C. Jones. Photogr. J., 1914, **54**. 14—26.

The media are considered chiefly for use in the examination of skeleton diatoms (refractive index, 1·43). Some details of the keeping, optical, and other properties of styrax (1·58), liquidambar, monobromonaphthalene (1·66), piperine (1·68), piperine with Canada balsam (between 1·52 and 1·68) and with bromide of arsenic or antimony, are given, with notes on their preparation. Canada balsam, styrax, and piperine give the full advantage of homogeneous immersion, with maximum resolving power, but as a dry mount they are inferior to air, while realgar, As_2S_2 (2·45) is superior. The chief published methods for using substances containing arsenic and sulphur, loosely called "realgar," are reviewed; the author finds that cleanliness is the chief condition: the materials should be twice distilled before use; 7 parts of arsenic to 22½—30 sulphur are satisfactory proportions. To secure mounts free from air-bubbles, the medium must be worked at a low temperature: this is made possible by supporting the cover with a slip, so that more pressure than usual may be applied. The addition of arsenious bromide lowers the melting-point, but is to be avoided. Selenium and sulphur, and selenium and realgar, give media of high refractive index, but of deep red colour.—O. E. M.

Patents.

Photographic printing paper and transfer processes. F. W. Kent, Clapham. Eng. Pat. 29,616, Dec. 23, 1912.

Paper saturated with paraffin wax or other wax is employed as the basis for photographic prints or transfers: this ensures permanence of dimensions of the basis, and easy separation of the film when the transfer is made. The emulsion consists preferably of a gelatin emulsion containing pyroxylin, which adheres satisfactorily to the waxed base.—T. F. B.

Photographic sensitive plates and the like. R. E. Crowther, Carlisle. Eng. Pat. 29,919, Dec. 30, 1912.

Photographic emulsions which will not produce reversal of the image as a result of excessive over-exposure, can be produced by treating an ordinary silver salt emulsion with *p*-phenylenediamine or with a methyl derivative thereof, or with a salt of either of these. For example, a sensitive plate is immersed for from 30 secs. to 2 mins. in a solution of one part of *p*-toluylenediamine hydrochloride and one part of sodium sulphite crystals in 75 parts (by weight) of water, to which one-third of the volume of alcohol has been added. The sulphite and alcohol are used as preservatives, and are not essential. If it is desired to treat the emulsion prior to coating, the above solution is added in the proportion of 120 c.c. to each 20 grms. of silver in the emulsion. Plates or papers prepared in this way are stated to give equally good results whether used with short exposure and subsequent development or by "printing-out." Developers which act slowly should be used with these emulsions (compare Eng. Pat. 14,744 of 1911; this J., 1912, 747).—T. F. B.

Colour photography. M. F. Ungerer, Offenbach on Maine, Germany. Eng. Pat. 17,979, Aug. 7, 1913.

Three part negatives are made from Lumière autochrome plates or other colour-sensitive coated plates, employing the usual three subtractive colour filters, but without the use of lineal, cross, or similar lining frames. The copying is done by contact on panchromatic plates, and the three part negatives are printed successively on the same printing surface, which is suitably stained after each printing.—T. F. B.

Coloured reliefs for use in preparing cinematograph films or other photographic transparencies; Process for producing ——. F. W. Kent. Fr. Pat. 461,920, Aug. 27, 1913. Under Int. Conv., Sept. 9, 1912.

See Eng. Pat. 20,555 of 1912; this J., 1913, 990.—T. F. B.

XXII.—EXPLOSIVES; MATCHES.

Nitrocellulose for collodion; Manufacture of ——. T. Chandelon. Bull. Soc. Chim. Belg., 1914, **28**, 13—23.

Lunge has shown (this J., 1901, 1021; 1907, 33) that although the complete solubility of a nitrocellulose depends upon the water-content of the nitrating bath, the quantity of ether-alcohol required for solution varies with the conditions of nitration. To determine whether increase of solubility in this sense is set off by decreased yield or other disadvantage, nitrations were carried out with baths containing 15, 20, and 25 per cent. of nitric acid, 67, 62, and 57 per cent. of sulphuric acid, and 18 per cent. of water, at 35° or 40° C. for 1 to 4 hours. Three samples of cotton were used. It was found that solubility, as measured by the fluidity of the resulting collodion, was increased by the use of a bath containing 15 to 20 per cent. of nitric acid, but that with the lower limit the loss was 11 per cent. for 2 hours' nitration at 40° C., and in some cases reached 18 per cent. Although the loss was also dependent on the nature of the cotton, it could not be predicted with accuracy from a low copper number (Schwalbe, this J., 1907, 548; 1910, 689).—O. E. M.

Collodions; Viscosity of ——. T. Chandelon. Bull. Soc. Chim. Belg., 1914, **28**, 24—32.

The viscosities of 4·5 per cent. collodions having been observed to differ according to whether the nitrating mixture contained 15 or 20 per cent. of nitric acid, this difference was investigated for higher concentrations of the collodions. The material was specially prepared, and the Cochius' viscometer used for the determinations. It was found that a 5 per cent. collodion made with nitrocellulose from the 20 per cent. bath gave a viscosity equal to that of a 5·74 per cent. collodion from the 15 per cent. bath, and that this ratio (1·33), called the coefficient of viscosity, was maintained up to about an 8 per cent. collodion. Mixtures of 1 to 2 and of 3 to 2 alcohol-ether gave collodions of about equal viscosity from equal percentages of a nitrocellulose. A commercial nitrocellulose was found to have a coefficient of 0·62. From the coefficient the quantity of solvent to give a required viscosity may be calculated. For collodions so viscous as to be above the range of the viscometer, an instrument was constructed by means of which the extensibility (viscosity) was measured as the distance at which a film of the collodion drawn out between two discs was just ruptured. From experiments on solutions containing from 12·82 to 19·3 per cent. of nitrocellulose, the coefficient was found to be 1·41. Hence, although the use of a nitrating mixture containing 15 per cent. nitric acid involves a loss of 11 per cent. in yield, the resulting nitrocellulose requires only 1 part of solvent where a nitrocellulose made with a 20 per cent. mixture, without loss, would require from 1·33 to 1·41 parts.

—O. E. M.

Patents.

Explosives; Manufacture of —— *of the Sprengel type.* T. Hawkins. Fr. Pat. 461,332, Aug. 12, 1913. Under Int. Conv., Sept. 23, 1912.

A cartridge of potassium chlorate contained in a porous envelope is dipped in a liquid prepared as described below, and then allowed to drain. To prepare the liquid, about 85 grms. of powdered Australian Grasstree gum are covered to a depth of not less than 15 cm. by about 4½ litres of petrol containing 1 per cent. each of acetone and turpentine, and about 170 grms. of fuming nitric acid (sp. gr. 1·5) are then added drop by drop.—T. St.

Nitrocellulose; Process for purifying ——. J. Duclaux. Fr. Pat. 461,785, Aug. 25, 1913.

The purification of nitrocellulose, whether of new manufacture or deteriorated with age, is effected by solution and then reprecipitating in a finely divided form by a liquid which is a solvent of the impurities to be eliminated but not of nitrocellulose. For dissolving the nitrocellulose, acetone is a suitable solvent. This solution may be purified by dialysis through a cellulose membrane under a pressure sufficient to determine osmosis outwards instead of inwards. Alternatively the solution may be precipitated by water, which removes acid impurities, or by benzene or other suitable organic medium, which removes resinous impurities. Preferably the two modes of precipitation may be combined by adding a quantity of benzene insufficient to determine precipitation and then emulsifying the mixture by the gradual addition of water.—J. F. B.

Explosive charges for mining and military purposes; Manufacture of ——. C. Claessen, Berlin. Eng. Pat. 13,086, June 5, 1913.

See Fr. Pat. 459,979 of 1913; this J., 1913, 1171.—T. F. B.

Nitrating cotton in vacuo; Process and apparatus for ——. L. Dumons, Landerneau, France. Eng. Pat. 14,003, June 17, 1913. Under Int. Conv., July 6, 1912.

See Fr. Pat. 445,833 of 1912; this J., 1912, 1203.—T. F. B.

Production of solvents [of nitrocellulose] by means of halogen compounds. U.S. Pat. 1,082,543. *See* XX.

XXIII.—ANALYTICAL PROCESSES.

Carbon bisulphide as a laboratory solvent. L. E. Vlies J. Soc. Dyers and Col., 1914, **30**, 46—48.

Carbon bisulphide has been stated to increase the sulphu content of wool (Pearson, J. Soc. Dyers and Col., 1906, 65 The author finds that carbon bisulphide very carefully pur fied by treatment with bromine permanganate and fumi nitric acid, left a deposit when boiled for a long time in Soxblet apparatus. This residue (probably a polymeric of carbon bisulphide) had a brown colour, was soluble in carbon bisulphide but not in sodium sulphide, and varied in amount between 0·003 and 0·0076 per cent., a fact which the author considers might be due to the varying intensity of the light at the time the experiments were made. The experiments show the necessity of a blank test in exact analytical work.—J. B.

Carbon; Determination of —— by the wet method. Simultaneous determination of halogens. F. H. Thies. Chem.-Zeit., 1914, **38**, 115—116.

An extension of Messinger's method (this J., 1890, 1069) in combination with that of Baubigny and Chavanne (this J., 1903, 761; 1904, 136), whereby without special apparatus, carbon and halogens (and nitrogen) can be determined simultaneously in organic compounds; explosive organo-metallic compounds, such as silver carbide, silver-allylene, etc., can be safely analysed by the method. The material is oxidised by a mixture of sulphuric acid and potassium bichromate, with addition of silver nitrate in the case of iodo-compounds (compare Baubigny and Chavanne, *loc. cit.*); a larger quantity of the oxidising mixture than that recommended by Baubigny and Chavanne is required to ensure the complete oxidation of the carbon to carbon dioxide, and the concentration must be sufficiently high to allow of a temperature of 200° C. being attained. The gases are passed through a layer of ignited lime (Brügelmann, Z. anal. Chem., 1876, **15**, 1, 175; 1877, **16**, 1, 24), about 15 cm. by 6 mm., between two asbestos plugs in a tube of potash glass, 30 cm. long, and then through two soda-lime tubes; the lime is heated during the process. Iodine is retained in the oxidation flask as silver iodide; carbon dioxide, chlorine, and bromine are absorbed by the lime, the two latter quantitatively, whilst any traces of carbon dioxide which pass are retained by the first soda-lime tube. The lime (plus carbonate and halogen compounds) is subsequently decomposed by nitric acid free from halogens, the carbon dioxide determined from the loss in weight, and the halogens in the solution determined with silver nitrate.—A. S.

Combustion-analysis by means of tellurium dioxide. R. Glauser. Chem.-Zeit., 1914, **38**, 187.

The general use of tellurium dioxide is no longer prohibited by the excessive price of tellurium, from which it is prepared. At a red heat the molten substance readily oxidises many otherwise refractory substances; and in the case of carbides, cyanamides, and similar products the quantitative absorption or collection of the resulting gases presents no difficulties. Thus, nitrogen has been determined in aluminium nitride, carbon and nitrogen in calcium cyanamide, and carbon in several specimens of hard steel: the last-named were readily dissolved by the molten dioxide, even in the form of coarse lumps. The method is expeditious; the results, after practice, are said to be very reliable; and the tellurium is readily recovered. The method is being investigated with respect to the determination of sulphur in ores.—J. R.

Patents.

Viscosimeter. J. Axer. Ger. Pat. 267,917, May 7, 1913.

The apparatus consists of an upright cylinder to contain the material to be tested, and a second cylinder, which fits closely within the first but not in contact with it: the inner cylinder is perforated, so that the material to be tested flows inside it as it sinks in the outer cylinder. The inner cylinder may be provided with straight or spirally-curved guide-bars, to give it a direct or spiral motion.—T. F. B.

Reactions; Apparatus for carrying out and observing ——. B. and E. Sági. Ger. Pat. 268,897, Feb. 15, 1913.

By means of suitable gearing connected with a common shaft, measured quantities of the substance under examination and of the necessary reagents are introduced (*e.g.*, from tilting receptacles) into the transparent reaction vessel, a source of heat is brought into operation, and after a predetermined time, the reaction vessel is emptied, this and the other vessels are rinsed, and the different parts are all restored to their original positions ready for another test, these operations being performed automatically and in the order mentioned.—A. S.

Instruments for measuring the flow of fluid through a conduit. Eng. Pat. 2417. *See* I.

Apparatus for measuring the content of methane or other inflammable gases in the air. Ger. Pat. 268,844. *See* IIa.

Detecting methane or other inflammable gases in the air. Ger. Pat. 268,845. *See* IIa.

XXIV.—MISCELLANEOUS ABSTRACTS.

Carbon sulpho-telluride. A. Stock and P. Praetorius. Ber., 1914, **47**, 131—144.

An arc-discharge between electrodes of a pure tellurium-graphite mixture beneath carbon bisulphide results in the production of two volatile products, namely, carbon subsulphide, C_3S_2, and carbon sulpho-telluride, CSTe. These are very unstable, and the isolation of the latter, which melts at —54° C. and decomposes spontaneously, is extremely difficult. (See also following abstracts.)—J. R.

Carbon sulpho-selenide. A. Stock and E. Willfroth. Ber., 1914, **47**, 144—154.

This substance, CSSe, prepared in a similar manner to the corresponding tellurium compound (see above), is a yellow liquid boiling at 84° C. and is comparatively stable towards many reagents, although it decomposes slowly on keeping.—J. R.

Volatile substances ; Manipulation of small quantities of ——. A. Stock. Ber., 1914, **47**, 154—156.

The author recommends distillation in a closed apparatus below the ordinary temperature by the use of a high-vacuum pump. The several parts of the apparatus are cooled in suitable baths : such as ice, ice and salt (—20° C.), liquid ammonia (—30° to —50° C.), carbon dioxide and acetone (—80° C.), melting carbon bisulphide (—112° C.), melting ether (—124° C.), and liquid air (—190° C.). The homogeneity and purity of the fraction may in most cases be readily and very accurately determined by measuring the tension of the vapour from the 0° C. bath. The fractionation is extremely effective ; and the process, besides being very economical, facilitates the handling of unstable substances. In general, it may be applied to substances boiling not higher than 200° C. at ordinary pressures.—J. R.

Formaldehyde and acetaldehyde ; Formation by oxidising agents. L. Rosenthaler. Arch. Pharm., 1913, **251**, 587—595.

According to von Baeyer's hypothesis, carbon dioxide is reduced in plants to formaldehyde which is further transformed into carbohydrates. This theory has been supported by proof of the occurrence of formaldehyde in leaves (see this J., 1912, 706). The author has found that a number of substances oxidised with permanganate and dilute sulphuric acid, and distilled, give distillates in which formaldehyde can be readily detected. Substances which yield formaldehyde in this way contain a methoxy-, methylenedioxy-, or methylimido-grouping. The higher aliphatic alcohols such as glycerol and most carbohydrates behave in the same way. Rhamnose and certain other substances containing an ethoxy- or ethylimido-grouping yield acetaldehyde on oxidation. Formaldehyde may therefore be an intermediate product in the breakdown of carbohydrates.—F. Shdn.

Books Received.

Taschenbuch für die anorganisch-chemische Grossindustrie. Herausgegeben von Prof. Dr. G. Lunge und Dr. E. Berl. Fünfte, umgearbeitete Auflage. Julius Springer's Verlag., Luikstr. 23—24. Berlin W. 9. 1914. Price M. 8.

This, the fifth edition of the "Pocket Book" (6¾ by 4⅜ ins.), contains 297 pages of subject matter and tables (against 288 pages in the 4th edition), and 8 pages of alphabetical index, with 24 blank pages for written notes and addenda. The text is illustrated with 15 engravings. The subject matter is arranged under the following heads : General Data and Tabulated Matter. Special. I. Fuels, etc. Steam boilers. Feed water for boilers. II. Sulphuric acid manufacture. III. Salt cake and hydrochloric acid manufacture. IV. Bleaching powder, etc. V. Alkali manufacture. VI. Sulphur recovery from the Leblanc alkali waste. VII. Nitric acid manufacture. VIII. Potash industry. IX. Ammonia industry. X. Illuminating gas manufacture. XI. Calcium carbide and acetylene. XII. Investigation of the raw materials and products of the manure manufacture. XIII. Alumina preparations. XIV. Cement industry. XV. Preparation of normal volumetric solutions. XVI. Preparation of average samples. XVII. Comparison of the various hydrometer scales.

Evaporation in the Cane and the Beet Sugar Factory. A theoretical and practical treatise. By Edward Koppeschaar. Formerly Technical Manager of the Vierverlaten Sugar Factory, Holland. Norman Rodger. St. Dunstan's Hill, London, E.C. 1914. Price 7s. 6d. net.

This volume (10 by 6⅜ ins.), contains 116 pages of subject matter, with nine plates and 31 illustrations in the text. The subject matter is classified as follows :—I. Introduction. Necessity for evaporation, etc. II. The study of steam. Its application to evaporation, and to multiple effect evaporation in particular. III. Historical development of evaporation in the cane and beet sugar factory, including the introduction of multiple evaporation. IV. Comparative study of evaporation. V. Multiple effect apparatus. VI. Fundamental parts and accessories of evaporating apparatus. VII. Control of evaporating apparatus. VIII. Special designs. IX. Evaporation and crystallisation in vacuum pans.

Principles and Practice of Agricultural Analysis. A Manual for the Study of Soils, Fertilizers, and Agricultural Products. For the Use of Analysts, Teachers, and Students of Agricultural Chemistry Second edition, revised and enlarged. Volume III. Agricultural Products. By Harvey W. Wiley, A.M., Ph.D. The Chemical Publishing Co., Easton, Pa., U.S.A. 1914. Price $6.00. Williams and Norgate, 14. Henrietta Street, Covent Garden, W.C.

This volume (9⅛ by 6¼ ins.), contains 807 pages of subject matter, with 127 illustrations, and alphabetical indexes of authors and subjects. The subject matter is classified as follows :—I. Sampling, drying, incineration and extraction, etc. II. Sugars and starches. Analysis by density of solution. Determination of sugar with polarized light. Preparation of pure sucrose, and its use. Chemical methods of estimating sugar, etc. III. Processes for detecting and determining sugars and starches and other carbohydrates in crude or manufactured agricultural products, etc. IV. Fats and oils. Their physical and chemical properties. V. Separation and estimation of bodies containing nitrogen. Qualitative tests for nitrogenous bodies. Estimation in agricultural products. Separation of protein bodies in vegetable and in animal products. VI. Dairy products. VII. Miscellaneous agricultural products, such as cereals and cereal foods : fodders, grasses and ensilage; flesh products, etc. tannins and allied bodies ; tobaccos, etc. Fermente beverages, etc.

Quantitative Analysis. By Edward G. Mahin, Ph.D Assoc. Professor in Purdue University. McGraw-Hi Book Company, Inc., 239, West 39th Street, New Yor 6, Bouverie Street, London, E.C. 1914. Price 12s. 6 net.

This volume (8⅜ by 5⅞ ins.), contains 493 pages of subje matter, and an alphabetical index of subjects. The are 120 illustrations. The classification of the subjec matter is as follows :—I. General principles. II. Grav metric analysis. III. Experimental gravimetric analys IV. Electro-analysis. V. Volumetric analysis. VI. Colo change of indicators. VII. Standardisation. VII Experimental volumetric analysis. IX. Oxidation a reduction. X. Titrations involving the formation precipitates. XI. Analysis of industrial products a raw materials.

Journal of the Society of Chemical Industry.

No. 5, Vol. XXXIII. MARCH 16, 1914. No. 5, Vol. XXXIII.

New York Section.

Meeting held at Rumford Hall, New York, on Friday, January 23rd, 1914.

MR. G. W. THOMPSON IN THE CHAIR.

PRESENTATION OF THE PERKIN MEDAL TO MR. JOHN WESLEY HYATT.

The Chairman opened the proceedings with an address, in which he said :—

At this meeting of the New York Section of the Society of Chemical Industry, it is our pleasant duty to award the Perkin medal to the person selected as most worthy for valuable work done in applied chemistry. In the past it has generally been considered that this work should be in the nature of original or inventive work which has proved of great public value. The question I would propound to you to-night is: What is the mental faculty which has made the recipients of the Perkin medal what they are? In what respect do these men differ from their fellow chemists, so as to render them especially successful in the application of chemistry to the arts? I have given considerable thought to this question, and I wish to submit my conclusions for your consideration, believing that they may be of some suggestive value.

In 1870, Tyndall delivered his famous discourse on the "Scientific Use of the Imagination." In this discourse, he showed the value of the imagination properly made use of in solving some of the most difficult problems of physics. Thousands of instances could be given showing that practically all of the progress made in the science of chemistry has been due to this proper use of the imagination; but considering the work done in applied chemistry, we see clearly that it was imagination that enabled Herreshoff to develop the metallurgy of copper, that inspired Behr in his work on the separation of the oil contained in the germs of corn, and Acheson, who argued that, if flocculating agents existed, there were probably also *de*-flocculating agents, and Hall, who believed that somewhere there was a solvent for alumina, from which aluminium could be obtained electrolytically, and Frasch, to whom the oil and salt wells suggested the possibility of recovering sulphur from the bowels of the earth, and Gayley, who saw the possibility of the dry blast in increasing the output and decreasing the cost of the blast furnace; and now, in the case of Hyatt, who saw in the drop of dried collodion the possibility of producing a plastic mass, which was finally obtained in celluloid.

We must not think, however, of imagination as being the sole factor, although it is probably the principal factor, in the production of valuable works. There must be energy, concentration, and persistence. Nevertheless, the imagination is the most important factor.

We see this imaginative faculty in all degrees of development, and I would ask those who are educators, in whose hands are being moulded the minds of future chemists, whether the work which they are doing tends to develop this imaginative faculty, or whether it is indeed possible for them to sow in the minds of their students the seeds of imagination if they do not already exist there? It seems to me that there is no better place, no better occasion, than this place and this occasion, when we are honouring, by the presentation of the Perkin medal, a man in whom the imaginative faculty is highly developed, to put before you the need of the imaginative faculty in as emphatic a manner as possible and to urge that in our educational institutions this faculty should be developed to the highest degree, for, if we are honouring Mr. Hyatt on account of his possession of this faculty, should we not also seek to increase the number of those who possess the faculty in a high degree? Is not the real purpose of the Perkin medal something more than the honouring of its recipients—great as that purpose is—is it not for the purpose of encouraging those faculties on which the presentation of this medal rests?

Prof. Chas. F. Chandler spoke as follows :—

It is my very pleasant privilege as the Senior Past-President of the Society of Chemical Industry, residing in this country, to present to John Wesley Hyatt the eighth impression of the Perkin gold medal, in recognition of his most valuable work in applied chemistry.

Mr. Hyatt was born at Starkey, Yates County, New York, in November, 1837. He was educated in the public school and later in the Eddytown Seminary, where he excelled in mathematics.

In his early boyhood he acquired a strong taste for mechanical affairs in his father's blacksmith shop. In his sixteenth year he went to Illinois and learned the printing business, working at this trade for the following ten years. During this period he made his first invention, which was a family knife sharpener and which included a new method for making solid emery wheels.

He then went to Albany and worked as a journeyman printer for about two years. Seeing a $10,000 offer for a substitute for ivory for billiard balls by Phelan and Collander of New York, he began experimenting nights and Sundays in the hope of gaining the reward. He made a number of useful plastic compositions, none of them however good enough for billiard balls, but he started to make checkers and dominos of pressed wood, and with his two brothers established what is now the Embossing Company of Albany, New York, which has been a highly successful concern for more than 40 years, under the mechanical management of Mr. Hyatt's younger brother, C. M. Hyatt.

In 1870 he invented and patented a machine for turning billiard balls, by which an unskilled workman can do as much as a dozen skilled workmen could accomplish by former methods, securing at the same time perfect accuracy.

His attention having been called to the character of the solid nitrocellulose left by the evaporation of liquid collodion, or artificial skin, as it was called when collodion was first put upon the market for covering cuts and other wounds, he turned his attention to the subject of nitrocellulose as a suitable material for producing plastics. It should be remembered that guncotton or nitrocellulose was first discovered by Schoenbein in 1845. In 1847, Maynard announced the discovery that while nitrocellulose is not soluble either in alcohol or ether alone, it is soluble in a mixture of the two, and he gave the name collodion to the solution, which has since found its way very extensively into medical use. It also served to solve the problem of producing photographic pictures, either positives or negatives, upon glass, practically sounding a death knell for the beautiful though expensive daguerrotype process. The wet collodion process was introduced by Scott Archer in 1851.

Hyatt was entirely ignorant of the various efforts which had been made by Parkes, Spill, and others to utilise soluble nitrocellulose or pyroxylin for the manufacture of plastic materials, and consequently he started out without any hints or suggestions as to how he should proceed. His first success resulted in the manufacture of billiard balls by first making a solid core of another plastic material and covering the same with nitrocellulose dissolved usually in ether and alcohol. The process was so successful that a good business was established in 1870 which continued for several years.

In the meantime Hyatt invented celluloid and began the manufacture of celluloid and bone dust billiard and pool balls. At this time his brother, Isaiah S. Hyatt, joined him, and they worked together until the brother died in March, 1885.

I do not propose to give a detailed history of the progress made by Mr. Hyatt and his brother in establishing the celluloid industry. I will merely remark that Hyatt's Patent 88,633, dated April 6, 1869, was for a moulding composition to imitate ivory and other substances, composed of fibrous material and gum shellac or other solid fusible adhesive gum.

His patent No. 88,634, dated April 6, 1869, was for an improved method of coating billiard balls, consisting in dipping the billiard balls made of some suitable composition into a solution of collodion which might be given any desired colour beforehand.

His patent 89,582, dated May 4, 1869, was for a composition consisting of ivory dust or its equivalent mixed with collodion and subjected to pressure during the evaporation of the solvent.

Patent 91,341, dated June 15, 1869, taken out by the two brothers jointly, was for manufacturing solid collodion with very small quantities of the solvent and dissolving the pyroxylin under heavy pressure, thus securing great economy of solvents and a saving of time.

Their patent 105,338, dated July 12, 1870, shows the fundamental invention of celluloid. It is entitled "Improvement in treating and molding pyroxyline." The three claims of the original patent are: 1. Grinding pyroxylin into a pulp, as and for the purpose described. 2. The use of finely comminuted camphor-gum mixed with pyroxylin pulp, and rendered a solvent thereof by the application of heat, substantially as described. 3. In conjunction with such use of camphor-gum, the employment of pressure, and continuing the same until the mold and contents are cooled, substantially as described.

This patent was reissued three times in order to avoid ambiguities. The claims of the last reissue are as follows:

1. The use of finely-comminuted camphor-gum mixed with pyroxylin pulp, and rendered a solvent thereof by the application of heat, substantially as described.

2. In conjunction with such use of camphor-gum, the employment of pressure, and continuing the same until the mold and contents are cooled, substantially as described.

The specification fixes the proportions at about 1 part of camphor to 2 parts of pyroxylin. Modifications of this process were embodied later in U.S. Patents 156,352 and 156,353.

From this time on celluloid became a most important plastic, superior in almost every respect to any other plastic hitherto proposed, for the manufacture of the greatest variety of articles useful and ornamental.

Seventy-five different patents were taken out either by John Wesley Hyatt alone or in association with his brother, Isaiah S. Hyatt, and an enormous establishment grew up at Newark in the hands of the Celluloid Company.

Mr. Hyatt's activities were not limited to celluloid. Among his other inventions also of great importance, we find a sugar cane mill, very superior to any mill previously used in its efficiency both in increasing the percentage of juice extracted from the cane and greatly diminishing the time necessary to extract it, and giving a higher value to the refuse bagasse as fuel.

In the early 'eighties, Mr. Hyatt and his brother Isaiah took up the subject of water filtration and started a company called the Hyatt Pure Water Company. Isaiah Hyatt invented and patented a very important feature of the filtration process, February 19, 1884, patent 293,740. It marks the beginning of a new era in water purification. Coagulants had been previously used to purify water, but the difficulty was that the water was held in large tanks or cisterns. The coagulant was added to it, the whole was thoroughly agitated and then it was necessary to allow it to stand 12 to 24 hours for the coagulum to settle to the bottom. The Hyatts conceived the idea of employing a coagulant which could be added to the water while it is on the way to the filter, so that no large settling tanks or basins are required and no time is lost. The claim of this patent is as follows:—

"The method herein described of arresting and removing the impurities from water during an uninterrupted passage of the same from a supply pipe into a filtering apparatus, thence through a filter bed contained therein and out through a delivery pipe leading therefrom, which method consists in introducing into the water simultaneously with its passage to or into the filter a substance which will sufficiently coagulate or separate the impurities to facilitate their arrest and removal by the filter bed, thus obviating the necessity of employing settling basins."

I was connected with a litigation which followed the issue of this patent, and studied the process and apparatus at Somerville, N.J., Niagara Falls, and Elmira. The process was unusually successful. At Somerville the river water exhibited a milky opalescence caused by such fine particles of clay that no filter would clarify it. By a proper attachment of an alum box to the feed pipe to the filter, a minute quantity of alum was added to the stream of water on its way to the filter, less than one grain to the gallon, and in the few seconds that elapsed before the water reached the filter bed of the ingeniously constructed Hyatt filter, coagulation had taken place and the coagulum, including the alumina of the alum and the clay, bacteria and other suspended impurities of the water had been converted into such flocks as made it possible for the bed of sand in the filter to arrest it completely. These Hyatt filters are so constructed whether they are on a large scale or small scale, that they can be washed completely at any convenient moment by simply reversing the current through the filter. This churns up the sand and separates from it the accumulated coagulum.

Nearly all the paper mills and woollen mills in the country were and still are supplied with these filters as are also more than 100 cities and towns.

The validity of the patent was established through law suits which were brought against the City of Elmira and the City of Niagara Falls. These cities attempted to evade the Hyatt patents by constructing a chamber underneath the filter through which the water passed on its way to the filter, but we found by examination that while a portion of the coagulum accumulated in the chamber, one-third of it passed on and was separated by the filter.

Judgments in favour of the Hyatt patent were given by the Circuit Court of the United States Judge Shipman, presiding in 1894, by Circuit of Appeals Judge Wise, presiding in 1895; again by Judge Coxe in 1896, and again by Judges Wallace, Lacomb and Shipman in 1897.

In 1891–2, Mr. Hyatt took up the subject of antifriction roller bearings with great success.

I have really occupied far more time than I should have done, but I felt it a duty to take advantage of this opportunity to present the facts with regard to Mr. Hyatt's priority of invention in connection with the celluloid and water purification, which I was in a position to do owing to my experience and knowledge gained in the litigation which arose in both cases.

I think that the facts to which I have called your attention, although very briefly expressed, will satisfy you of the great achievements of Mr. Hyatt and will fully justify your Committee in placing Mr. Hyatt beside Sir William Henry Perkin and the six American chemists who have already received the Perkin Medal.

Presentation of the Medal.

It gives me great pleasure, as the representative of the Society of Chemical Industry, and the affiliated chemical and electrochemical societies, to place in your hands, Mr. Hyatt, this beautiful token of the appreciation and affection of your fellow chemists.

Mr. JOHN WESLEY HYATT acknowledged the receipt of the medal in the following words:—

I have never looked forward to any such honours as you have bestowed upon me, and I do not know how fittingly to express my gratitude. You have overlooked my lack of early training in the sciences with which you are all familiar, and only look to results which have been obtained mainly by persistent, and many times mistaken, experiments. Some successful experiments I might never have made if I had been familiar with the danger theories of some learned men.

From my earliest experiments in nitrocellulose, incited by accidentally finding a dried bit of collodion the size and thickness of my thumb nail, and by my very earnest efforts to find a substitute for ivory billiard balls, it was apparent that a semi-liquid solution of nitrocellulose, three-fourths of the bulk of which was a volatile liquid and that the final solid was less than one-fourth the mass of the original mixture, was far from being adapted to the manufacture of solid articles, and that I must initially produce a solid solution by mechanical means. The only useful solvent known to me at that time was a mixture of alcohol and sulphuric ether; with the old formula (about equal parts of ether and alcohol) I mixed in a closed mill a thick paste of soluble cotton, made by the old firm of Charles Cooper and Co. After mixing, the cover of the mill was removed and the mass evaporated down to a thick dough, which was then forced accurately around the ball (made of another substance), and allowed to dry. This resulted in a rather brittle coating, owing, as I found, to the unequal evaporation, leaving only the alcohol, a poor solvent by itself, at the final shrinkage. This was remedied by using only the least amount of alcohol (five parts ether to one alcohol) necessary as a solvent. Even this coating shrunk to less than half of its original thickness and required to be dried immersed in water under several hundred pounds' pressure per square inch to insure its solidity and freedom from bubbles. It became necessary to strain the mass by forcing it through a very fine sieve to exclude the unnitrated fibres. All these difficulties stood in the way of success, except in high-priced articles like billiard balls. Other seriously objectionable features became apparent. In order to secure strength and beauty only colouring pigments were added, and in the least quantity; consequently a lighted cigar applied would at once result in a serious flame, and occasionally the violent contact of the balls would produce a mild explosion like a percussion guncap. We had a letter from a billiard saloon proprietor in Colorado, mentioning this fact and saying he did not care so much about it, but that instantly every man in the room pulled a gun.

I next had a small beating engine made, to pulp the nitrocellulose. In one experiment I placed a small quantity of this dried pulp in a strong cylinder and forced quickly a minimum quantity of liquid solvent into it with high pressure. The result was a solid substance, as hard as sole-leather, which soon dried, leaving a fine hard disc about three-fourths of an inch in diameter and one-half an inch thick. While no explosion ever resulted from this, there was real danger to be feared, and the matter was dropped.

My brother, I. S. Hyatt, joined with me at that time, and finding it stated in some patents to which I was referred, that a little camphor added to the liquid solvent was beneficial, we conceived the idea that it might be possible to mix solvents mechanically with the pulp and colouring matter while wet, then absorbing the moisture by blotting papers under pressure, and finally submitting the mass to heat and pressure. To our surprise, we noticed a slightly solvent action of the precipitated and washed camphor upon the pulp, even before the heat and pressure, and without other solvent we succeeded in producing a transparent slab one-fourth of an inch thick, fine, and as hard as a piece of wood. My brother took some samples to the American Hard Rubber Company, with the view of interesting them. They employed the late Professor Charles A. Seeley, who had made collodion for the Government during the Civil War, to investigate the matter. He came to our place in Albany, N.Y., and we conducted the whole process for his inspection, very successfully. He remarked that he had come prepared to detect some chicanery, but could see no deception, and expressed himself as satisfied. He kindly advised us that if, accidentally or otherwise, we were to apply a little too high temperature, the quantity we were dealing with would inevitably destroy us with the building and adjacent property. While we did not accept this as true, it was disturbing. The following day between 12 and 1, when all were out, I rigged up a four-inch plank used as a vice-bench, braced it between the floor and ceiling, between the hydraulic press and the hand pump, intending it to shield me from possible harm. I then prepared the mould, heating it to about 500 degrees Fahrenheit, knowing it would certainly ignite the nitrocellulose and camphor, and would abide by the result. The gases hissed sharply out through the joints of the mould, filling the room with the pungent smoke. The mould, press, building and contents were there, including myself, very glad that I did not know as much as the Professor.

The next step was to make a small stuffing machine, consisting of a cylinder, four-inch bore, about a foot long, terminating in a tube three-fourths of an inch bore, ten inches long, immersed in an open oil-jacket, with a gas-burner and thermometer. A cap-nut with one and one-fourth inch screw forced a plunger upon the cakes of incipient celluloid, which were heated at the outlet end of the cylinder passing through the heated tube into moulds, and also through nozzles forming rods, tubes, etc. We found it advisable to lower the melting point of the camphor by adding a small quantity of alcohol or other solvent of camphor. A much larger hydraulic stuffing machine was then made. Dental plate blanks were the principal part of our early business.

My brother interested some New York capitalists—principally composed of General Marshall Lefferts, Joseph Laroeque and Tracey R. Edson—and we removed to Newark, N.J., in the winter of 1872–73 We had nearly all the appliances and machinery to design and build, which progressed with some halts and mistakes for two or three years, when a fire occurred in our four-storey and basement building, utterly destroying all our stock and machinery, and pushing out the whole front of the building (which was very weak), and severely injuring several of our men, who all finally recovered, although one—Mr. Charles S. Lockwood—was in great danger for a long time. We then started our present works, acquiring knowledge and experience, my brother starting a separate factory for making brushes, mirrors and combs. Early in 1878 my brother went to Paris and started the French Celluloid Company.

Before we left Albany we began the use of tissue paper in place of carded cotton or bleached flax, which finally resulted in getting tissue paper of definite thickness and materials, and breaking it up into small separate pieces by a machine I constructed, drying these separate pieces in a loose mass and nitrating them instead of the carded cotton.

In 1876 I was allowed to employ a chemist for determining our acids and to systematize our nitration, instead of merely using hydrometers and thermometers, and Mr. Frank Vanderpoel was selected by me. So far as I know, the analyses of mixed spent acids were not applied to practical work. Professor Seeley proposed that we separate the nitric and sulphuric acids by distillation, and then bring these to the proper strength before mixing; this was not adopted. Vanderpoel first removed the gelatinous flock by adding finely powdered natural barium sulphate and allowing the barium and flock to subside, which was a great success. I had previously tried filtration, which was impractical. After much labour Vanderpoel perfected a quick and accurate method of determination of the spent acids, and then added the required fresh acids. An elaborate and extensive battery of tanks was constructed, the acids being moved through copper pipes, where required, by means of air pressure. The tanks for mixing the comminuted tissue paper with the prepared acids were arranged on a turntable supporting a dozen or more tanks, each holding hundreds of pounds. A rotating stirrer was arranged to stir in the requisite amount of paper in one tank, the turntable being revolved to the next tank, and so on. At a distance embracing about half a dozen tanks from the stirrer was located a centrifugal machine, which separated out most of the acids. The nitrated paper was then thrown into a washing device, and the partly washed paper then fell into large tanks of fresh water and was thoroughly washed. A very considerable number of tons of paper per day were and are treated in this way.

The next procedure was to grind this nitrated paper in a beating engine. The water was then mainly removed by a centrifugal machine. The mixture of pigments, camphor and nitrocellulose was then made, according to the results required, and ground together in a mill, then pressed into slabs or cakes, and still further deprived of moisture by great pressure, and finally deprived entirely of moisture by blotting papers, repeatedly changed.

These cakes were then broken up and alcohol or other desired solvents added and allowed to soak in. The partly dissolved mass was next masticated in heated rolls, turned out into necessarily rough sheets, cut into strips and rolled up into cylinders, ready for the stuffing machine.

The great want was to furnish celluloid in solid perfect sheets, and this neither the rolls nor the stuffing machines could possibly do, with all our experience. I constructed a special nozzle for the stuffing machine, to form a slab about one and one-half inches thick, seven inches wide and several feet long, which was pressed between steam plates, one of them with underent grooves, to hold the slab. A machine was made with shaving knife and reciprocating bed, and by it the slab was shaved into sheets of the desired thickness. These slabs were necessarily imperfect, and were too small. After showing this result to the other directors, I proposed building a hydraulic pressure steam-heated mould, to make a slab or block about two feet by five, and three inches thick, in which to weld and press a pile of rough sheets from the masticating rolls. To those who knew the least about celluloid my suggestion looked pretty good, but to others came a great fear of possible danger and failure to weld up such a mass. At last they gave me authority to build the apparatus, limiting me to less than half its cost if fairly estimated. With this authority, which consisted more of the privilege of trying such an apparatus than in providing for its cost, I ordered the machine, agreeing to pay the machinist all above the appropriation if it failed to work. The machine was built and most carefully tried in the presence of only the new president, who knew little about celluloid, and Mr. Stevens and Mr. Lockwood among the employees. The mould was cooled and opened, and nice sheets were at once made, considering that only scrap material was used, though less than half the block was welded. This meant re-heating, which was at once done, and the whole was known to be a success.

I dwell upon this because of its vast importance to us. It multiplied the value of celluloid many times, making a much stronger and finer material than was produced by the former means.

About this time we were precluded from bleaching the iron out of the pulp, caused by the iron-beating knives, and it was necessary to remedy the serious difficulty. The mixture of nitrated paper, camphor, and pigments was placed in a large revolving drum of copper, through the axis of which was a shaft with beating arms rotating at a very high speed, and the whole was beaten to a pulp without the discoloration of the iron and water, and without the loss in washing and bleaching the fine pulp from the beating engine.

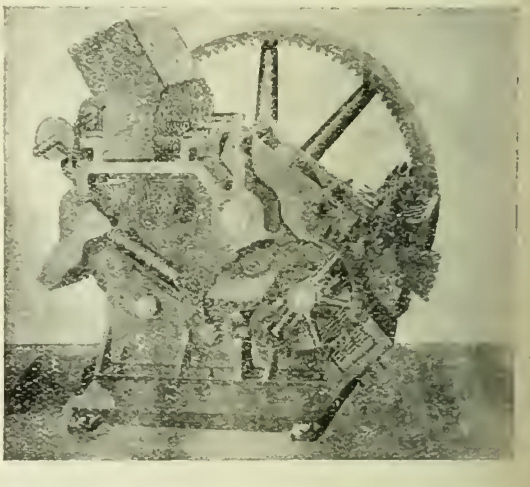
In order clearly to differentiate my work in celluloid from that of others in the nitrocellulose industry, I will summarize as briefly as I can. First, the idea of combining with the nitrocellulose only the exact or approximate amount of solvent required for a solid solution. This required a nearly perfect mechanical mixture before very much solvent action could take place. Second, completing the solution by means of heat and pressure. Third, eliminating the practically unnitrated fibres by pulping. Fourth, employing tissue paper in place of carded fibre. Fifth, avoiding the terrible danger of drying out the moisture by exposure in drying room. Many years ago I patented the process of first pressing out all the water possible and displacing the remainder by forcing alcohol through under pressure. This, I understand, is now used by other nitrocellulose workers, but we prefer the method herein described. Sixth, the stuffing machine process. Seventh, the sheeting process, most essential.

Mr. Stevens has been with me ever since he was fourteen years old, and has invented solvents and many other things of great importance in the art, and stands at the head of nitrocellulose workers at the present time.

Mr. Harrison, in his department, has invented the method of imitating the grain of ivory, of smoked pearl, of onyx, and of many other beautiful colours and effects. He has been with us nearly forty years. Others are entitled to much credit, but it is impossible to name them here.

Description of Sugar-Cane Mill.

In the old method of milling sugar cane the cane is passed between rolls which are generally 34 inches in diameter and 84 inches long. These rolls are grooved and roughened so as to draw all the cane in between them that is possible. Owing to the comparatively obtuse angle formed by the contact of two rolls, the quantity of cane is limited and they are very nearly together at the passage of the cane through the last pair of rolls. The last, say, 15 per cent. of the juice is forced out through five or six inches of highly compressed fibre in the opposite direction from which the cane is moving, so that in practice a considerable portion of the juice is carried through the rolls. For this reason it is repeatedly passed through rolls, each passage removing a small proportion more of the juice. It is found profitable in most cases to add water to the bagasse between each set of rolls so as to dilute the juice that necessarily remains in the bagasse. In order to get the desired quantity of work from the mill the rolls are of great length, from seven to seven and one-half feet. There is generally from 30 to 40 tons of pressure for each foot of face of the rolls. It is not practicable to get any greater pressure than this. I employ four or five times as much pressure per lineal foot.



With my apparatus and method the angle formed between the chain and the upper roll is far more acute and the cane is forced through rolls so that five times more cane goes through the rolls of a given face than is possible with the old mills. If this chain belt were impervious to the juice little or nothing would be gained by this method, but inasmuch as the chain forms a massive screen through which the juice may readily escape from the underside, the juice has only to pass downwards through the mass perhaps one and one-quarter inches at the most to escape, instead of five or six inches in the opposite direction to the progress of the cane, as in the old mill. It does not take any more powerful apparatus to press the cane fibre when it is one inch thick than it does to press fibre that is one-eighth of that thickness, and as I get quite as much cane through my rolls with 12-inch face as will pass through the old rolls of 84-inch face I can readily afford to put several times as much pressure upon each foot of face as is practicable with the old mills. I employ upwards of 150 tons on rolls with 12-inch face.

For the same amount of cane passing six times through the present rolls my mill will not require more than one-third as much power and instead of getting with the best milling a bagasse with 50 per cent. of moisture and 50 per cent. of fibre, I can easily produce a bagasse which has 60 per cent. of fibre and 40 per cent. of moisture. This bagasse is so dry that a quantity of it, either a handful or a bushel, placed upon the ground can be lighted with a match and will burn like carpenter's shavings. My mill is about one-eighth the weight of the present mills with the same capacity, and as the machine work is of the same character the machine will not cost one-quarter as much as the present mills.

In Cuba 71 per cent. of extraction without dilution is as good as can be obtained. With my mill without dilution I can easily get 78 per cent. extraction.

With Louisiana cane, which has less fibre, I can easily get 84 per cent. extraction without dilution. Of course, if the bagasse is passed through a second mill with 12 per cent. dilution, I can get 88 per cent. extraction.

The joints of my sprocket chain belt are self-cleaning and cannot clog; as shown in practice, each revolution of the chain rubs the screen surface together several times. All the links of the chain are alike, and are of drop-forged steel. The concave edges of these links absolutely fit the under roll. The smaller pressing roll is provided with annular grooves coinciding with the longitudinal joints of the chain so that even the last small percentage of juice has a perfectly free outlet.

There is no danger from irregular feeding, as the mass of bagasse between the rolls is about one and one-quarter inches thick, and no loose or open space can possibly exist. The springs yield or follow up, according to the feed. No crusher or shredder is necessary or desirable.

The speed of the surfaces of the rolls and chains is designed to be 30 feet per minute, although I did practically as good work on my previous machine at 40 feet per minute, and it will probably prove that this machine can do equally as good work at 40 feet per minute, but to be safe, I have calculated it for 30 feet per minute. The ordinary cane mills are run at anywhere from 16 to 25 feet per minute, according to the choice of the owner or engineer.

The increased value of the bagasse as fuel, and the avoidance of any peculiar kind of bagasse burner with forced draft, etc., is quite an item. Furthermore, as was shown by my machine at Adeline, Louisiana, the purity of the juice is considerably improved, as the cane is not ground up as in the ordinary mills, but merely flattened by the great pressure.

I have taken out 238 patents (a few of them being joint inventions with others), and several new industries have resulted. The one of next importance to celluloid is named The Hyatt Roller Bearing Co.

The proceedings concluded with an address by Dr. Frank Vanderpoel, in which he recalled some personal details of his association with Mr. Hyatt.

Sydney Section.

Meeting held at Sydney, on Wednesday, 19th November, 1913.

MR. LOXLEY MEGGITT IN THE CHAIR.

EXTRACTION OF RADIUM FROM THE OLARY ORES.

BY S. RADCLIFF.

In May of the year 1906 a prospector forwarded some pieces of a dense dark-coloured mineral, carrying small amounts of a yellow incrustation in the surface crevices, to Adelaide for examination. Mr. W. S. Chapman, the Government Assayer, identified the yellow substance as carnotite, a vanadate of uranium and potassium. He found the material to contain 60 per cent. of uranium oxide and a considerable amount of vanadic oxide.

The locality from which the ore was obtained was shortly afterwards visited by Mr. H. Y. L. Brown, then Government Geologist of South Australia. He stated: "The ore, occurs as yellow and greenish-yellow incrustations and powder on the faces, joints, and cavities of a lode formation, which consists of magnetic titaniferous iron, magnetite, etc., and quartz in association with black mica[1] (biotite).

Dr. Mawson subsequently published an account of a mineralogical examination of the lode-stuff and came to the conclusion that it contained several new minerals.[2]

Some years later a block of the ore, weighing about 16 lb., was forwarded to the Imperial Institute. A detailed mineralogical and chemical examination was there made of the material by Messrs. T. Crook and G. S. Blake.[3]

Some typical specimens of the ore were, I understand, forwarded to Madame Curie; she reported that the ore was only feebly radioactive and of little commercial value, radium at that time being comparatively cheap.

In 1909 a company known as the Radium Hill Company was formed in Sydney to exploit the deposit commercially, and a consignment of about 30 tons of picked ore was taken to England by Dr. Mawson, who brought it under the notice of a number of firms, both in England and on the Continent, interested in the extraction of radium from its ores. A few tons were also sent to America. The low uranium content and the high percentage of titanium present, which rendered treatment difficult, militated against the disposal of the ore, and no offers of any value were received for it.

While these negotiations were in progress, the author of this paper (who, some time prior to the Olary find, had discovered a radioactive copper ore at Moonta, S.A.) was asked to investigate the possibility of treating the ore locally; and after some twelve months' experimental work developed a process which gave promise of commercial success. The preliminary work was done at the Bairnsdale School of Mines, Victoria, which possesses a fairly extensive metallurgical plant, a total quantity of 30 tons being dealt with in the course of the experiments. From the data so obtained the plant now in successful operation at Woolwich on the Parramatta River, Sydney, was designed.

The present communication gives a preliminary account of the treatment process as it is worked at the present time.

The most complete account yet given of the extraction of radium from its ores is that by Haitinger and Ulrich.[4] They describe the methods adopted by them in treating 10 tons of residues derived from about 30 tons of pitchblende ore containing 54·2 per cent. of U_3O_8. The treatment of the ten tons occupied two years, and resulted in the recovery of three grams of radium chloride in a state approaching purity. No analyses are given in this paper and only very scanty details as to the plant used.

As these residues were derived from ore containing 270 milligrams of radium (calculated as bromide) per ton, and as the Olary ore, even when concentrated, contains only eight milligrams, it is obvious that any process to be commercially successful when applied to these latter ores must be comparatively simple in operation, and must allow of a considerable tonnage being put through annually. It may be noted that eight milligrams of bromide to the ton means one part in 125 million or one part of elementary radium in 214 million parts of concentrates.

As first observed by H. Y. L. Brown the amount of visible carnotite in the ore is negligible from an economic point of view, and for practical purposes the ore consists of a mixture of ilmenite, magnetite, and rutile, with small amounts of carnotite and a mineral stated by Crook and Blake to be probably tcheffkinite. Table I. gives:—

(*a*) Analysis of the ore complex excluding the carnotite, taken from Crook and Blake's paper.

(*b*) Analysis of the concentrates now being treated at Woolwich.

(*c*) Analysis of a typical Austrian pitchblende.[5]

The ore is dry crushed at the mine to pass a sieve of 20 holes to the linear inch, and is then concentrated magnetically, the concentrates, amounting to about 30 per cent. of the ore crushed, being forwarded to Sydney for treatment.

One of the most interesting points about analysis (*a*) is that the ratio of the uranium to the thorium is as 16·7 : 1; radium preparations worked up from this ore should therefore contain very little mesothorium. This conclusion has been confirmed in Rutherford's laboratory by Dr. Alexander Russell, who examined a specimen of the bromide and found it to contain as radio-active substances only radium and its decomposition products.

As the concentrates are insoluble in acids, a fusion process is necessary to effect the initial decomposition. The concentrates are mixed with three times their weight of salt cake (acid sulphate of soda) and fused in a reverberatory furnace of sufficient capacity to take 500 kilos. of concentrates and 1500 kilos. of salt cake in a single charge. Three charges can be put through in twenty-four hours. The fused product, crushed to pass a sieve of eight holes to the linear inch, is fed, in small amounts at a time, into wooden vats fitted with agitators. Cold water is fed continuously into the vats at the bottom and an overflow is provided near the top. By suitably adjusting the conditions, it is possible to separate out on the bottoms of the vats a considerable amount of comparatively coarse material which is almost free from radium and uranium. The turbid liquid overflowing carries in suspension the radium, lead, and barium as sulphates, together with a considerable amount of finely divided silica; while in solution we have the uranium rare earths, and part of the iron and acid earths contained in the ore.

The coarse residues are removed from the vats daily, re-washed to free them from any undissolved fused product and sent to the dump. The composition of these residues is given in Table III.

The overflow from the dissolving vats is pumped to large lead-lined settling tanks and allowed to stand all night. The "slimes" settle completely in twelve hours, and the clear liquid is drawn off daily and treated for the recovery of the uranium. The slimes, which amount when dried to approximately 10 per cent. of the weight of the concentrates, are collected weekly and treated for the recovery of the radium as described below.

The further steps in the treatment process may conveniently be described under two heads :—

(*a*) The recovery of the uranium.

(*b*) The recovery of the radium.

(*a*) *Recovery of the uranium.*

The clear solution containing the uranium and much of the iron and other bases in the concentrates, together with a large amount of sodium salts, is fed into a series of vats containing a measured excess of a mixture of carbonate and bicarbonate of soda, and heated and agitated by means of steam jets. The iron, with most of the other bases present is precipitated, while the uranium goes into solution together with some of the rare earths. The bulky iron precipitate is separated partly by settlement and partly by means of vacuum filters. It is difficult to handle and cannot be washed effectually, a portion of the uranium is therefore unavoidably discarded along with this precipitate. The uranium solution is made just acid with sulphuric acid, heated, and the carbon dioxide expelled by a brisk current of air. The uranium is then precipitated by the addition of ammonia. The ammonium uranate is thickened somewhat in conical settling tanks and then further thickened to a pulp in a hydro-extractor. This pulp is dried and dehydrated in large muffles. The dehydrated product is broken up and washed repeatedly with hot water. This treatment removes the bulk of the sodium salts, and a product is obtained which on drying contains about 75 per cent. of U_3O_8. An analysis of this, together with that of the iron precipitate, is given in Table II. Prior to analysis the iron hydroxide was twice dissolved and re-precipitated with ammonia to free it from the larga amount of sodium salts present. The washed precipitate was dried, ignited, and analysed.

Table II.

	Uranium product.	Iron precipitate.
Insoluble matter	3·0	—
Titanium dioxide	—	8·11
Ferric oxide	9·41	74·65
Uranoso-uranic oxide	76·6	2·7
Rare earths	1·57	7·36
Lead oxide	0·51	—
Vanadic oxide	—	1·2
Chromium oxide	—	5·81
Sodium salts	8·21	—

(*b*) *Recovery of the radium.*

The thickened insoluble residue or slime from the settling tank is mixed with half its dry weight of strong sulphuric acid and allowed to stand for several days. It is then washed, first by decantation and then on a vacuum filter, till the washings give only a very slight precipitate with barium chloride. The acid treatment and washing reduces the bulk of the slime considerably, removing large amounts of acid earths and iron salts. The washed slime, in quantities of about 200 kilos. dry weight, is then boiled in large steel boilers with an excess of a 20 per cent. solution of sodium carbonate for two days, the solution being replaced once during the boiling. This treatment dissolves a large amount of silica, and converts much of the lead, radium, and barium sulphates to carbonates. The slime is then washed till the wash water gives no reaction for sulphates; thi takes two days for each lot of 200 kilos. The washed slime is then fed into a warm dilute solution of hydrochloric acid, agitated for a couple of hours, and allowed to settle all night. The clear solution is siphoned off and the lead, barium, and radium precipitated as sulphates. After washing once by decantation, the slime is again treated as above described. Two treatments suffice to extract most of the radium, but the slime is reserved for a further treatment if necessary. The plant as at present arranged, can treat the slime from ten tons of concentrates per week. The weekly yield of crude sulphate is about 12 kilos.

During the past two years I have made a number of experiments, both in the laboratory and on the working scale, to see if the sulphates in the slime could be reduced by heating the material with carbonaceous substances, or else in a current of some reducing gas, but the results so far have not been encouraging.

The crude sulphate is fused with carbonate of soda in large graphite pots, and the product digested with hot water. The insoluble residue after picking out most of the metallic lead is thoroughly washed, and heated with hydrochloric acid, The solution is evaporated to dryness to dehydrate the silica, the residue moistened with acid and digested with hot water and the silica filtered off.

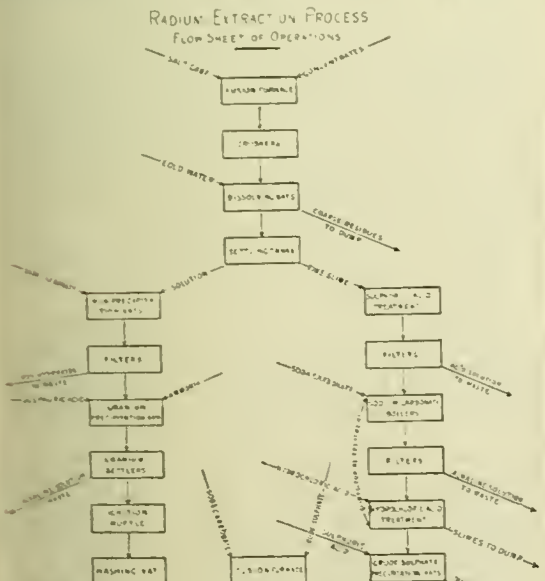
It was found that the method of converting the sulphates to carbonates by boiling with concentrated soda solution was altogether too slow, and the fusion method has the further advantage of removing most of the lead in the metallic state. This lead which is, of course, radio-active (Table IV.) is being stored for examination later. The hydrochloric acid solution, containing the radium and barium, together with large amounts of lead, iron, and acid earths, was formerly treated by the ordinary analytical methods for the removal of the impurities prior to precipitating the radium and barium as carbonates. Bulky precipitates, difficult to handle and wash were obtained; this procedure has been abandoned, and a method due to Soddy* is now used with very satisfactory results.

The chloride solution is saturated with hydrogen chloride and the barium and radium are thrown down nearly free from other elements. The crystalline precipitate is filtered off, freed by suction from most of the adhering liquid and dried. It is dissolved in water, the small amounts of lead, iron, etc., still remaining, removed, and the mixed carbonates of barium and radium finally dissolved in hydrobromic acid for fractionation. About 1500 grams of dry chloride, which when freed from radio-active substances other than radium has an equilibrium activity of from 40 to 50, is obtained weekly.

Table III. gives analysis of the slime, of the tailings or coarse residues, and of the crude sulphate. The whole series of operations is summarised in the accompanying flow sheet.

TABLE III.

	Crude sulphates.	Slimes.	Tailings.
Silica	10·82	51·42	22
Titanium dioxide	3·0	42·40	63·1
Ferric oxide	2·15	4·21	14·23
Rare earths	—	—	0·41
Uranoso-uranic oxide	—	—	—
Lead sulphate	69·24	1·85	trace
Barium sulphate	12·50	0·23	—



The composition of the tailings is of great interest, the high percentage of titanium dioxide being noteworthy. It is apparent that the initial fusion effects a selective decomposition of the ore complex, the uranium minerals are completely decomposed, and the tailings, which contain a large proportion of comparatively coarse grains, seem to consist largely of unaltered rutile.

Repeated assays of the tailings have failed to detect appreciable amounts of uranium. As will be seen too, from Table IV., the amount of radium left in the tailings must be very small.

The economic success of the process apparently depends on the fact that it is only necessary to decompose partly the ore mixture in the fusion furnace, and that therefore, comparatively small amounts of reagents are required. If it had been necessary to decompose the ore completely in order to extract the radium, treatment costs would I think, under local conditions, at least, have been prohibitive. As a matter of fact, about 50 per cent. of the concentrates consists of minerals almost free from radium and uranium, this being the proportion of the material fused sent to the dump each week.

An approximately ten-fold concentration of the radium is therefore effected by the two simple operations of fusing the concentrates and dissolving the fused product under proper conditions.

In Table IV. the relative activities per unit mass of the concentrates, tailings, and slimes are given.

TABLE IV.

	Activity per unit mass.
Uranium oxide	1·0
Tailings	0·007
Concentrates	0·06
Slimes	0·25
Crude sulphate	11·0

The radio-active lead separated out on smelting the sulphate has an activity approximately twice that of uranium oxide when three months old.

The whole of the radium in the concentrates must distribute itself between the tailings and the slimes. As the tailings amount to five times the weight of the slimes, it appears from the relative activities of the two products that 86 per cent. of the radium contents of the ore is concentrated in the slimes, 14 per cent. being rejected in the tailings.

So far I have done nothing in the separation of the other radio-active bodies in the ore. I hope, however, to examine very shortly a portion of the radio-active lead now being stored, as its activity appears too high to be wholly due to radium D and its products. Rutherford* states that "radium D is separated with the large amount of lead usually present in radioactive minerals. In the course of time, radium D produces radium F (polonium) and the ray activity of the lead becomes about equal to that of uranium."

As stated previously, the radio-lead separated on smelting the crude sulphide was about twice this activity. It is possible that this is due to small amounts of radium-barium sulphate included in the lead. The lead accumulated in the course of several years will ultimately form a convenient source for the working up of polonium preparations. As the amount of polonium in equilibrium with a mineral containing one gram of radium is only 0·19 milligram, the direct recovery of polonium from the working solution is obviously out of the question.

It should be possible, on the other hand, to work up fairly active ionium preparations from the rare earths without much difficulty.

While the chief technical problems in connection with this ore may be regarded as solved, much work of a scientific character remains to be done, and I hope to continue investigations on the three following lines:—

---

* F. Soddy, Chemistry of Radio Elements, p. 45.

* E. Rutherford, "The Radio-active Substances," p. 511.

1. To make a complete spectrographic examination of the ore and the various products separated out during treatment.
2. To investigate the radio-active properties of these products.
3. To work up some kilos. of the rare earths in order to examine them in detail.

In conclusion I desire to thank Professor Pollock for his kindness in testing various radium preparations from time to time, and for the friendly interest he has taken in the work throughout.

Discussion.

In reply to questions by the chairman, the author stated that in the examination of radio-active bodies the gold leaf electroscope was 1,000 times as sensitive as the spectroscope. With regard to losses in extraction of the ore, about 13 per cent. of the radium was at present lost in the slimes, in addition to other losses. He hoped soon to diminish this, and to obtain 85 per cent. of the total radium contained in the ore.

Meeting held at Sydney on Wednesday, 10th December, 1913.

MR. LOXLEY MEGGITT IN THE CHAIR.

NOTES ON AUSTRALIAN PINE BARKS.

BY F. A. COOMBS AND A. H. DETTMANN.

In a recent publication entitled "A Research of the Pines of Australia," by R. T. Baker and H. G. Smith, attention is drawn to the tannin values of the barks of the various species of *Callitris* (see this J., 1911, 1353, 1358).

Samples of bark were supplied by Messrs. Baker and Smith to the Tanning Department of the Sydney Technical College. These have been tested quantitatively and qualitatively, and while there is still a considerable amount of work to be carried out in this direction, we wish to make known results which will probably enable interested persons to estimate approximately the true value of these barks as a tanning agent.

We have only dealt with two species, *Callitris calcarata* and *Callitris glauca*, as being worthy of commercial consideration at the present date. The *Callitris* barks appear to be like the hemlock bark of America, the ross being rough with deep fissures and carrying varying proportions of red tannins. The tannin values of *Callitris calcarata* are higher than hemlock or any of the conifer barks, which supports the theory that during the long processes of evolution the dry Australian climate has been a big factor in the growth of barks which contain such liberal supplies of tannin, unequalled in any part of the world. The Australian forests differ considerably from the forests of New Zealand. The former are dry with very little undergrowth and the bark of the trees is clean and practically free from lichens, etc., but the soil of the latter is always damp, the undergrowth is very thick, the sun cannot penetrate through the branches overhead, and the barks of large numbers of the living trees are covered with moss, ferns, and lichens, which will probably affect adversely the tannin values of barks that contain tannin in the ross, such as the black birch (South Island, New Zealand, 16 per cent. tannin). Samples of bark from these birch trees, received at the Sydney Technical College, show that the bark decays in patches on the living tree, a result probably brought about indirectly by the excessive moisture, which is not so pronounced in the Australian forests. The commercial side of the *Callitris* barks has not been thoroughly investigated. Our results show that these barks have not the same high tannin values as the best Australian wattles, but yield tannin values which compare favourably with the average woods and barks used for the manufacture of extracts. The Australian tanner has been very fortunate in having large local supplies of wattle bark (*Acacia pycnantha* and *decurrens*) which range in tannin values from 30 to 38 per cent. in commercial samples, and naturally any new tanning material is compared with these two species of *Acacia*.

We obtained an average tannin value of 20·87 per cent. for *Callitris calcarata* and 12·33 per cent. for *Callitris glauca*. Such results compared with the above-mentioned wattles are not likely to tempt the tanner to use pine bark for its tannin values. The Australian tanners obtain the majority of the tannin required, by leaching bark; the leaching plant is connected with the tannery, and by using the local wattle barks tannin is obtained in solution at a cheaper rate than from imported extracts of equal quality, and as the costs of stripping, freight, and leaching are all inversely proportional to the tannin value, we believe that *Callitris glauca* could never be successfully exploited as a bark for the tanners to leach. The bark of *Callitris calcarata* might find a ready sale if commercial samples return the same tannin values as the samples we have analysed. The average of a number of small samples of bark from trees of various sizes, returns a tannin value varying with the practical experience of the collector, usually higher than tannin values obtained from commercial samples.

A great change has been brought about in the tanning industry during the last twenty years by the introduction of semi-liquid and solid tannin extracts. The large tanning centres of Europe and the United States depend on supplies from abroad. The demand is so strong that barks and woods containing small percentages of tannin are used in the form of extracts.

Australian *Callitris* barks have a tannin value which brings them within the sphere of those substances which are suitable for manufacturing tannin extracts. Belonging to the catechol group, they can be compared with North American hemlock bark (8 to 10 per cent. tannin), South American quebracho wood (20 per cent. tannin), and mangrove bark (30 to 38 per cent. tannin). Both *Callitris calcarata* and *glauca* give a deep red colour to the leather and are therefore not so serviceable as wattle bark for those leather manufacturers who produce dyed leathers or basils, and this fault is shared by the three above-mentioned tannin materials, but when these red leather producing materials are blended with other tannin materials good results, varying with the skill of the tanner, can be obtained on all classes of leather. A primary tanning experiment was carried out with these barks. Liquors containing 3/5 pine bark tannin and 2/5 oakwood extract were used to tan several sections of hide, and the resulting 90 per cent. of leather compared with other results obtained from leather tanned under similar conditions with wattle instead of pine bark, shows that these barks do not prevent the production of good weight returns and a solid leather.

The future of the pine barks will depend on the successful manufacture of an extract, and we hope to carry out further experiments when the extract can be obtained in sufficient quantities.

The factors which brought about the manufacture of "hemlock extract" and a big demand for the bark in the United States, will throw light on the possibilities of exploiting Australian pine bark. The U.S.A. had the hides to tan, and the same can be said of Australia. The former had to depend on hemlock or imported tannin materials; the latter have always had large supplies of wattle bark, and therefore there has not been the same incentive to search for fresh tannin materials and to exploit the inferior pine bark. But at the present time Australia is importing large quantities of wattle bark from South Africa, which means a shortage of local supplies—a factor which shows the necessity of a more complete investigation of the practical value of these pine barks.

In America there were vast tracts of land covered with hemlock trees, and Messrs. Baker and Smith are quite confident that Australia also has large amounts of pine trees whose bark has a high tannin value, and if investigations show that sufficient bark can be obtained, the successful manufacture of extract will depend on the quality and the cost of production.

The United States and Canada are in a better position than Australia to collect the maximum value from their respective forests. The two former countries owe their great advancement and the wealth obtained from natural resources largely to private enterprise, but in Australia private enterprise differs from the same in North America because it does not include the right to build and control railways. The pioneers in America go out in large numbers to take up land, and private enterprise soon follows with a railway, and in some cases the railway goes before the farmer and squatter, enabling land owners to combine if necessary and deal with such items as bark, timber, etc., which would bring in money when the land is being prepared for cultivation, or railways can be laid through forest land to deal with timber, etc., and after the land is cleared the settlers will follow and replace the sawmills, etc., with cultivated land. In Australia and New Zealand the land has been taken up by scattered units who are too far apart to organise and unite their labour in an effort to convert the forests into money, which is only possible when the timber can be sent by rail or river to the various markets. These isolated settlers, who cannot place the products of the forests on the market within a reasonable time, are forced to burn the growing trees to enable them to cultivate the land, and these fires have brought about great losses to Australia of timber and bark. The utilisation of timber and its by-products depending almost entirely on private enterprise, which, under certain circumstances, is powerless without a railway, it would appear that State ownership of railways places some industries at a disadvantage. The railways are one of the most important factors in developing a young country, and it is quite possible that Australia would benefit considerably if, instead of prohibiting private individuals from controlling railways, the State were to lay down a system which would prevent the evils of monopolies, etc., and containing a clause allowing the State to resume and control after certain periods.

America appears to have been in a better position to treat hemlock than Australia is to treat the local pine barks, but at the present time the supplies of tannin materials are decreasing, and if an extract of good quality is manufactured from the local pine bark we have no doubt that a ready sale will be found for it.

Baker and Smith, in "The Pines of Australia," point out that there are considerable belts of rocky mountainous land supporting the growth of these trees, which would not be suitable for cultivation but which with care would give continual supplies of timber, sandarac, and bark.

Briefly the position may be summed up as follows:— The supplies of bark are apparently large; the tannin value is quite sufficient for the successful manufacture of extract, and the quality of the tannin is not inferior to that obtained from hemlock, quebracho and mangrove, but a commercial investigation is required to deal with the quantity available and cost of carriage to certain centres near a railway, and a more complete analysis of commercial samples, the latter to be taken from not less than 500 tons of bark. If this amount of bark were stripped, as suggested in a recent paper from this Department on "Australian Mangrove Bark" (Leather World, December, 1912), factors would be obtained which would go a long way towards solving the commercial value of *Callitris* barks.

The tannins from these pine barks are decidedly red. A imple method of decolourising their extracts would mprove the value considerably, but research workers in his direction should keep in view the action of the lecolourising agents on the process of tanning. Dumesny, n his book on "Wood Products," places the problem of lecolourisation in a very clear light. (He writes: "the ecolourisation of the future does not lie in the use of hemical products, nor in more or less complicated proesses; tanning is an industry far too complex to stand . It requires and will require before and above all, ure extracts of a well determined nature, with a high perentage of tannin soluble in cold water, and finally of as onstant and uniform a composition as possible.") There an be no objection to the use of albuminous substances remove suspensoids and the catechol tannins or reds, hich have almost reached the stage of suspended matter; ut while chemical substances such as the alkali sulphites ve been great factors in the production of cheap extracts, ey are not without drawbacks in the tannery.

Qualitative reactions.

The qualitative reactions of the tannins in *Callitris* barks were tested by the methods and reagents used by Stiasny and Wilkinson (see this J., 1911, 1172). The tannins in the barks of *C. calcarata* and *C. glauca* belong distinctly to the catechol group. Both species give a complete precipitate with the formaldehyde test, and no immediate precipitate with the ammonium sulphide test, but slight traces after standing overnight. With *Callitris calcarata* the filtrate from the acetic acid and lead acetate test, on the addition of iron alum, gives a slate blue precipitate by reflected light, and with *C. glauca* a greenish-brown. The other tests gave the following results in the case of both varieties:—*Bromine*, precipitate. *Normal or basic lead acetate filtrate and caustic soda*, colourless. *Copper sulphate and ammonia*, no. ppt. *Tartar emetic and ammonium acetate*, clear. The qualitative reactions of the tannins of *Callitris* barks do not give abnormal results when compared with other well-known pine barks. The fermentable sugars, noted by the amount of acid in the liquors, are slightly higher in *Callitris* barks than in wattle barks, but the acidity value, as far as our experiments have gone, is not nearly as high as in some European pine barks.

The deal shaving test gave a pink colour with *C. calcarata* and slight pink with *C. glauca*. Iron alum tests gave brownish-green and green, respectively.

The following table will show the tannin values of 11 samples of *C. calcarata* and 6 samples of *C. glauca*:—

Discussion.

Mr. H. G. Smith said that the production of wattle bark in Australia was now unremunerative, the supply being drawn from Natal, but the cultivation of white pine would be very profitable. Large areas, useless for agriculture, were covered with white pine scrub, which could be cut down and quickly grown again. The supply was unlimited, and the bark was easily stripped.

THE ACTION OF CONCENTRATED SULPHURIC ACID ON IRON.

BY CHARLES E. FAWSITT AND CHARLES W. R. POWELL.

In commerce it is customary to carry concentrated sulphuric acid in iron drums and to store it in iron tanks. It appears to be generally supposed that the acid has no action on iron in the cold. A certain amount of action does go on, however, and the following investigation was undertaken to determine its nature and extent.

In several respects iron appears to stand out from other metals as peculiar. For one thing it is rendered passive very easily; and again, its behaviour in the matter of rusting and of corrosion generally is erratic.

Peculiarities noticed in regard to its passivity and corrosion are in many cases connected with the surface condition of the metal, and as a result of the present investigation it appears that certain irregularities observed with respect to the action of sulphuric acid may be due to special conditions of the surface of the metal. The Laboratory Experiments (Part I.) in this paper were performed by C. W. R. Powell (Science Research Scholar of the University of Sydney), while C. E. Fawsitt is responsible for the experiments conducted with a drum of acid (Part II.).

Part I.—Laboratory Experiments.

The effect of temperature, quality of acid, and quality of iron, on the products and rate of reaction were investigated. The temperatures varied from 25° to 200° C.

The experiments were conducted mainly with sulphuric acid "Pure for analysis" which contained 97·5 per cent. of sulphuric acid by analysis. Unless otherwise expressly stated, this is the acid used as "concentrated sulphuric acid." No attempt was made to obtain the acid quite free from water, as it was thought that more particular interest attached to experiments with commercial acid. Experiments were also carried out with commercial acid (94·6 per cent. by density) and with the ordinary acid diluted with water. The most dilute pure acid used contained 94·6 per cent. of H_2SO_4 (estimated from the density). The quality of the iron used also affects the reaction. In this work the following kinds of iron were employed.

A. Steel plate which gave the following analysis: carbon 0·35 (per cent.), manganese 0·61, phosphorus 0·06, silicon 0·01, sulphur 0·07.

B. Steel cut from a sulphuric acid drum. This, as well as steels A and C, was kindly analysed for us by Messrs. Eastaugh and Burrows, of the University of Sydney, and came out as follows: carbon 0·045 per cent., manganese 0·375 per cent. phosphorus 0·004 per cent., sulphur 0·015 per cent., silicon 0·007 per cent., nickel 0·46 per cent.

C. Steel wire analysed as follows: carbon 0·51 per cent., manganese 0·48 per cent., phosphorus 0·046 per cent., silicon 0·083 per cent., sulphur 0·058 per cent.

D. Wrought iron.

E. British pig iron, No. 1 Foundry (soft, gray).

F. White cast iron (British).

G. Cast iron from Lithgow, N.S.W. Cast in sand. Analysis kindly supplied to us by Mr. B. Smart, as follows: Carbon, graphite, 3·16 per cent.; carbon, combined, 0·57 per cent.; silicon, 3·27 per cent.; sulphur, 0·019 per cent.; phosphorus, 0·792 per cent.; manganese, 1·51 per cent.

H. Cast iron from Lithgow, N.S.W. (per Mr. B. Smart). Cast in chill. Analysis: carbon, graphite, 2·88 per cent.; carbon, combined, 0·53 per cent.; silicon, 3·46 per cent.; sulphur, 0·024 per cent.; phosphorus, 0·789 per cent.; manganese, 1·52 per cent.

I. Iron powder obtained by reduction of ferric oxide with hydrogen.

Nature of the action of sulphuric acid on iron.

When iron or steel is plunged into concentrated sulphuric acid there is an initial evolution of gas which usually falls off rapidly.

It lasts at most a few minutes and is probably due to the special condition of the surface of the iron. The gas given off is mostly hydrogen. There are doubtless usually traces of hydrocarbons present, but no sulphur dioxide could be detected in the gas. It is highly probable that the first evolution of gas is due to there being a small quantity of moisture on the surface of the iron as it comes from its condition of exposure to the atmosphere. After some time has elapsed a more or less steady current of gas is in most cases evolved from the iron. It is this action that we have more closely investigated.

It has already been pointed out by one of us (Powell, Proc. Roy. Soc. N.S.W., 1913, 47, 59) that cold concentrated sulphuric acid acts slowly on iron to produce ferrous sulphate and hydrogen. There is also a very small proportion, 1·3 per cent., of sulphur dioxide in the gas produced. The effect of temperature, acid, and metal on the reaction is next given.

Effect of temperature on the products.

As the temperature is increased the percentage of hydrogen decreases and that of the sulphur dioxide increases until at some particular temperature the gas evolved consists entirely of sulphur dioxide. This temperature was not the same for all the samples of iron worked on, and in some cases it was found that even if some hydrogen was being evolved at a particular high temperature, then after a few hours at that temperature the evolution of hydrogen had ceased and sulphur dioxide alone was being evolved.

Certain secondary reactions also seem to take place at high temperatures; sulphuretted hydrogen was detected by means of its reaction with lead acetate, although in most cases the gas reacted with the sulphur dioxide forming sulphur and water, before a test could be obtained: when the presence of sulphur in the reaction flask indicated that this was going on the surface of the mercury in the side tube leading to the measuring cylinder was invariably blackened owing, no doubt, to the formation of mercury sulphide.

In some cases (iron powder) sulphuretted hydrogen was evolved at 30° C. in sufficient quantity to be detected by the smell.

With steel wire (C) and concentrated sulphuric acid the following results were obtained:—

Table I.

Temperature.	Time from start of experiment till taking of sample.	H_2	SO_2
25°C.	8 days	96·8	3·2
30° C.	18 days	98·0	2·0
30° C.	54 days	95·1	4·9
35° C.	3 days	92·5	7·5
35° C.	6 days	92·0	8·0
35° C.	8 days	93·2	6·8
160° C.	½ hour	55·2	44·8
160° C.	2 hours	54·5	45·5
160° C.	4 hours	57·8	42·2
160° C.	7 hours	61·0	39·0
160° C.	16 hours	17·9	82·0
160° C.	30 hours	8·4	91·6
180° C.	1 hour	—	100·0
200° C.	1 hour	—	100·0

Effect of composition of metal on the nature of the reaction

The composition of the iron or steel employed considerably affects the analysis of gases evolved. Lithgow pi iron cast in chill (H) yielded gas containing 92 per cent of sulphur dioxide immediately on heating to 150° C whereas the steel wire of previous experiments required t be heated to 160° C. for 30 hours before the percentage sulphur dioxide was reached. The following table illustrates the nature of the reaction at 150° C. and 165° C.

TABLE II.

Temperature.	Time.	H_2	SO_2
150° C.	4 hours	7·7	92·3
150° C.	6 ,,	3·9	96·1
165° C.	1 ,,	—	100·0
165° C.	3 ,,	—	100·0

In this case at 165° C. the amount of hydrogen present, if any, had become too small to be detected by the ordinary methods of analysis. Nickel steel (B) yielded immediately on heating to 150° C. a mixture of gases containing 98 per cent. sulphur dioxide and 2 per cent. of hydrogen.

English No. 1. foundry iron behaved as follows :—

TABLE III.

Temperature.	Time in hours.	H_2	SO_2
100	5	35·0	65·0
150	3	—	100·0
165	3	—	100·0

The action of English white cast iron was very different, the percentage of sulphur dioxide being 100 at 100° C.

TABLE IV.

Temperature.	Time.	H_2	SO_2
30	12 days	35·0	65·0
50	24 hours	1·0	99·0
100	1 hour	—	100·0

Steel of composition (A) gave the following results :—

TABLE V.

Temperature.	Time.	H_2	SO_2
30	14 days	97·0	3·0
30	50 ,,	94·7	5·3

This is very similar to what was obtained with the steel wire already experimented on.

Influence of the acid on the action.

In the following table are shown the results obtained fter a week's run by the use of the ordinary "pure" acid 97·5 per cent.) and with this diluted with water to 94·6 er cent., and with commercial acid which contained 4·6 per cent. H_2SO_4.

TABLE VI.

Acid.	Temperature.	Iron used.	H_2	SO_2
per cent.				
97·5	30° C.	Steel wire	96·5	3·5
94·6	30° C.	,,	96·2	3·8
94·6 (commercial)	26° C.	B	98·8	1·2

The results of these experiments show that the products btained from the dilute acid do not differ greatly from ose with the most concentrated acid (97·5 per cent.). Further, the impurities present in the "commercial" id used were evidently of such a nature as not to disturb e reaction greatly.

Experiments on the rate of reaction.

Exact measurements on the rate of reaction between a etal surface and an acid are difficult to carry out, as the tent of the surface of the metal and its condition vary in te of all precautions.

Most of the experiments in this paper have been repeated two, and in some cases, three or four times : the results of these several experiments agreed fairly well.

Any general conclusions arrived at here in regard to temperature effect, effect of metal composition, and effect of acid are considered to be valid, inasmuch as other factors were kept constant while the one was varied, and because the results obtained could be repeated with very similar results.

The experiments were conducted in round bottom Jena distilling flasks. After introducing the iron and sulphuric acid the neck was sealed with a paraffined rubber stopper and the side tube led to a measuring cylinder inverted in a mercury trough. In some cases after filling the flask, the neck was fused and drawn out, thus avoiding the use of anything but glass in the apparatus. The volume of gas evolved was taken as a measure of the rate of the reaction. The volume was corrected for temperature and pressure, all volumes being calculated to 0° C. and 760 mm.

Experiment with steel (C).

Steel wire (19·4 grms.) having a surface of 143 square cms. and freshly polished with emery cloth, was immersed in 60 c.c. of concentrated sulphuric acid and placed in a thermostat maintained at a temperature of 30° C. (Table VII.). After 23 days the temperature was allowed to fall to room temperature for 10 days (generally about 25° C.). The rate of reaction after the first day at 25° C. had fallen from 0·14 c.c. per hour to 0·05 c.c. per hour. It then continued to fall until on the 10th day it had ceased altogether. On again raising the temperature to 30° C. the rate rose to a value slightly higher than its former value at 30° C. On again lowering the temperature to 25° C. the rate gradually decreased.

TABLE VII.

Time in days.	Temperature °C.	c.c. evolved per hour.

57	25	0·02
59	25	0·05
60	25	0·02
64	25	0·02
72	25	0·00

It was found that as the result of four experiments, the average rate of gas evolution at 30° C. from 20 grms. of steel wire during the first twenty days was 0·12 c.c. per hour. For each square decimetre of surface the rate was 0·08 c.c. per hour.

Variation of rate of reaction with iron used.

With steel (A) the rate remained constant for 10 weeks at 30° C. at 0·05 c.c. per hour per square decimetre. With steel (B) the average rate for twenty days was the same as for steel (A), but the action began more slowly. With cast iron (G) (Lithgow) an entirely different result was obtained. This sample of cast iron proved resistant to the action of sulphuric acid at 30° C. After four weeks at this temperature no gas had been evolved and even when the temperature was raised to 100° C. the iron still remained "passive." After removal from the acid the iron presented a very different appearance to that of the steels used in previous experiments. All the steels became coated with white anhydrous ferrous sulphate, which sometimes clung to the metal and sometimes fell to the bottom of the flask. In this case, however, the iron had a dull dark grey surface, which looked black while still immersed in the acid. This was probably due to a film of ferrous sulphide, the formation of which would also account for the darkening of the acid. (cf. Ditte, An. Ph. Ch., 1890, **19**, 68.)

Sample E. (*British foundry iron*).—This iron gave off no gas at 30° C. and indeed liberated no gas even after remaining at 50° C. for seven days.

Sample F. White cast iron (*British*).—The iron was too hard to cut into pieces without altering the temper. Turnings had therefore to be taken, and were used of such a size that they were retained by a mesh of 24 to one inch and passed through a mesh of 10 to one inch. 37 grms. were immersed in 120 c.c. of sulphuric acid. Gas was evolved in this case at a rate comparable with the rates found for steels, when equal surfaces are considered.

Sample D.—Wrought iron was cut into pieces having a surface area of 61·8 square cms.; 30 grms. were immersed in 120 c.c. of sulphuric acid. During the first seven days at 30° C. about 1·5 c.c. of gas were evolved, but after that no gas was evolved up to twenty-five days when the temperature was raised to 50° C.

The results of the various samples of iron are shown in the following table (Table VIII.).

TABLE VIII.

Average rate of gas evolution during the first twenty days at 30° C. (86° F.).

Iron used.	Weight of iron.	Surface of iron.	Quantity of acid.	c.c. per hour per sq. dcm.
	grms.	sq. cm.	c.c.	
A.	37	60	120	0·05
B.	40	60	120	0·05
C.	20	143	60	0·08
D.	30	62	120	0·005

F.	37	170	120	0·035
G.	37	68	130	0
H.	38	67	120	0

The results for iron powder are given separately, as this is hardly comparable with the other more compact forms of iron.

I. *Iron powder.*—Obtained by reducing pure ferric oxide. On mixing 20 grms. of the powder with 50 c.c. of sulphuric acid a very vigorous action ensued. Hydrogen, sulphuretted hydrogen and sulphur dioxide were liberated with the evolution of much heat. This violent action gradually eased off, but even after ten days was still very much greater than with other samples. On first mixing, the rate of evolution was very high, but was not measured exactly. This settled down in half an hour to about the rate shown in Table IX.

TABLE IX.

Time.	Temperature.	Rate.
4 days	30° C.	9·5
5 ,,	30° C.	6·95
6 ,,	30° C.	2·78
8 ,,	30° C.	2·15
11 ,,	30° C.	1·46

Effect of temperature on rate.

While the rate of gas evolution at 25°, 30°, and 35° C. was found for each temperature to be fairly constant, this cannot be said for temperatures above 35° C. Above this temperature the rate may vary considerably according to the time that the experiments have been in progress. In comparing the results of one temperature with another it was considered desirable to use the maximum rates observed. Different results are also obtained when fresh iron and acid are used for each temperature from those with the same materials heated to the higher temperatures.

In Table X the "Time" given in the second column is the time that has elapsed since the iron has been in contact with the acid at the particular temperature.

* Same reacting substances heated first at 30° and temperature then raised.

† Fresh iron and acid used for high temperatures.

With the exception of B (nickel steel), which gave off no gas at 100° C. for one day, all the specimens showed increased rate of gas evolution with rise of temperature. This rise of temperature did not cause a steady rise in the velocity; the temperature coefficient for increase of velocity per 10° C. usually fell as the temperature was raised. The average value, however, as calculated from these numbers is 3·1, which is very similar to the usual value obtained for temperature on reaction velocities.

Effect of concentration on rate.

The dilution of the acid was not carried very far, the most dilute acid used having a content of 94·6 per cent. sulphuric acid.

The results of experiments are shown in the following table (Table XI.)

TABLE XI.

Used 20 grms. of steel (C) having a surface of 143 sq. cm. Temperature 30° C.

Acid used.	Time from first contact in days.	Rate in c.c. per hou per sq. dcm.
per cent. 97·5 by analysis	6	0·07
97·5 by analysis	12	0·08
96·0 by density	2	0·03
	3	0·16
	6	0·37
	10	0·37
94·6 by density	1	1·0
	8	1·5
	12	2·37

The effect of diluting the acid increased the rate co siderably, and this effect became more pronounced aft the first few days had elapsed.

Effect of impurities on the rate of reaction.

The effect of rust was found to be such that when the steel was already rusted at the time of introduction to the acid the rate was increased considerably for the first two or three days at 30° and then fell to its normal value.

Effect of shaking.

In certain of these experiments which had been evolving gas for some time, the reaction gradually fell away and in some cases ceased altogether. This was particularly so when the temperature was high. An experiment carried out at 40° C. will serve as an example.

Time.	Rate.
1	1·00
7	0·90
8	0·80
9	0·07

The reaction began at the rate of 1·00 c.c. of gas per hour and fell away until on the ninth day 0·07 c.c. per hour were being evolved. The flask was shaken and then allowed to remain undisturbed and in a few hours the rate had again risen to 0·80 c.c. per hour.

In such cases as this, shaking had an effect on the rate of reaction, but the effect could hardly be called an accelerative one, since the rate was only raised to a value it had reached earlier in the experiment. The retardation was obviously due to the coating of anhydrous ferrous sulphate, which at 40° C. and higher very quickly accumulated. In other cases, however, where no such coating had been received by the iron, shaking had little effect.

PART II.

Experiments with a steel drum containing concentrated commercial sulphuric acid.

The drum used was composed of Mannesman steel (B). It measured 42 inches in length and 25 inches in diameter. The ends were curved inwards considerably. We were told that similar drums had been found to resist a pressure of ninety pounds to the square inch before bursting.

The drum was not quite full, the level of the acid being three inches from the bung hole. The volume of the acid was approximately ten cubic feet, and the gas space one foot. The area of the steel in contact with the acid was aken as twenty-four square feet. The acid was dark in olour and contained 94·6 per cent. of sulphuric acid (by ensity determination).

The drum had been welded along the side. By special xperiment on a part cut from the weld it was shown that he rate of evolution of gas at this place was not greater than t other parts of the drum. The drum was left in a yard nder cover. The temperature inside the drum was not ecorded, but a thermometer was placed beside it, and ver long periods of time it may be assumed that the verage temperature was similar to that recorded by the hermometer.

A mercury pressure gauge was inserted in the bung ole in August, 1912, but the pressure recorded after allowg the drum to stand for several weeks was very small, eing scarcely more than that due to the direct effect of an teration in atmospheric pressure and temperature on the essure of the gas in the drum.

This result was surprising as the laboratory experiments d led us to expect considerable pressure. On Nov. 12th, 12, the drum was shaken by rocking and hammering. e pressure immediately rose, and in a few days was so eat that the mercury gauge had to be abandoned. On v. 16th, a new gauge was kindly placed at our disposal Mr. S. H. Barraclough, of the Engineering Department the University of Sydney, and this was securely fixed in e bung of the drum. The rocking was carried on for a tnight to the extent of one to two hours rocking per day en the pressure reached 14 lb. to the square inch. The m was then left alone but the pressure rose in another tnight to 37 lb. to the square inch. The accumulated gas was then allowed to escape. Once the gas evolution had started it never completely ceased throughout the year 1912–1913.

The rate appeared to be controlled almost entirely by the temperature, and was little, if any, affected by further shaking, once the first evolution of gas had been started. Further, the rate of evolution was not affected by the pressure of the gas already in the drum, as was indeed the result to be expected.

In the table given below is a record of the rate of evolution of gas, expressed as pressure of pounds to the square inch. The average temperatures are also given during the time.

Table XII.

Period.	Aver. temp.	Extra pressure in lb. to the sq. inch produced by one day's evolution of gas.
1912.		
Nov. 16th—Dec. 10th	20° C.	1·5
Dec. 10th—Jan. 2nd	21° C.	1·7
1913.		
Jan. 2nd—Jan. 31st	23° C.	2·1
Jan. 31st—Feb. 25th	24° C.	2·6
Feb. 25th—Mar. 25th	22° C.	2·4
Mar. 25th—April 25th	18° C.	1·9
April 25th—May 19th	14° C.	1·6
May 19th—July 8th	12° C.	0·44
July 8th—Aug. 14th	12° C.	0·49
Aug. 26th—Sept. 27th	15° C.	1·4
Sept. 27th—Oct. 24th	17° C.	2·1
Oct. 24th—Nov. 10th	18° C.	2·3

The last velocity is greater than the velocity at the same time a year previously, but it was not increased by agitation and so for practical purposes may be taken as being the maximum.

To increase the pressure by 2·3 lb. to the square inch at 18° C. means that 0·15 cb. ft. of gas was produced per day. This means that the production of gas in c.c. per hour per square decimetre is 0·8 at 18° C.

The laboratory experiments for 94·6 per cent. acid gave a value 2·4 c.c. at 30° C. for steel (C). Inasmuch as laboratory experiments showed that there was little difference as a rule between steel (B) and (C), and as the temperature coefficient is 3 for 10° C., the correspondence obtained is satisfactory.

The safety of the carriage of sulphuric acid in iron drums will depend on the quality of the acid, the size of the air space left when filling, the temperature, and the time that elapses before the pressure is released.

Summary.

1. Concentrated sulphuric acid acts at the ordinary temperature on steel and on some kinds of cast iron, the products being ferrous sulphate and hydrogen with a small quantity of sulphur dioxide.

2. The reaction proceeds more rapidly with rise of temperature, and the gaseous products at 180° C. are sulphur dioxide with occasional small quantities of sulphuretted hydrogen, but no hydrogen.

3. The rate is increased on the average about three times for each 10° C. rise of temperature.

4. The rate of reaction depends on the concentration of the acid, but for small dilutions the ratio of hydrogen to sulphur dioxide in the mixture of gases evolved remains almost unchanged.

5. Although the rate of reaction depends to a certain extent on the composition of the sample of iron, as indicated by the large difference between steel wire and pig iron, an important factor governing the reaction with any one sample appears to be the condition of the surface of the iron.

6. Laboratory experiments on the rate of reaction were found to give results similar to those obtained on the large scale.

7. For the carriage of iron drums containing sulphuric acid, it is possible to calculate the conditions for safe carriage in any particular instance.

Our thanks are due to the British Australian Oil Company for placing a drum of acid at our disposal.

DETERMINATION OF THE VISCOSITY OF REFINED SYRUPS AND MOLASSES.

BY CHARLES W. R. POWELL.

Many methods have from time to time been suggested for the determination of the viscosity coefficients of liquids, and for liquids of low viscosity this determination can be made with a very high degree of accuracy. For instance, the viscosity coefficient of pure water has been determined at various times to several places of decimals, and even in ordinary laboratory work the error in such determinations may be restricted to 1 in 1000 without any difficulty. When, however, it is necessary to deal with very viscous liquids, the same degree of accuracy could hardly be expected and is certainly not obtained.

For dilute aqueous solutions or liquids of low viscosity the most convenient method of determination of the viscosity coefficient is that which involves the use of Poiseuille's capillary tube; but this method does not seem to have been very largely employed for very viscous liquids such as heavy oils and syrups. The glass capillary has been used for the determination of the viscosity of fused salts[1] and a platinum capillary has been used for similar work at high temperatures.[2] Other methods that have been tried are those depending on the rate at which a platinum wire sinks in the liquid[3] and upon the rate at which a platinum cylinder falls in the liquid.[4]

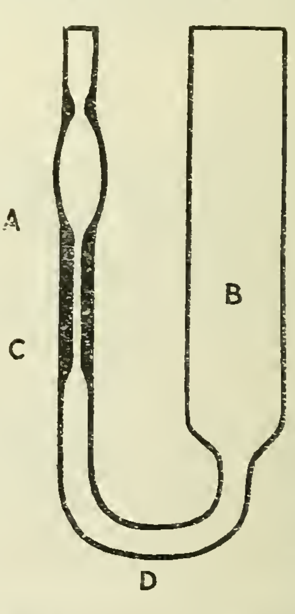
These last two methods were designed for very viscous liquids—liquids 1000 times more viscous than water—but similar methods applied to the class of liquids here experimented on, have been found to give unsatisfactory results. Fawsitt[5] has described a method by means of which the viscosity is calculated from the logarithmic decrement of a metal disc suspended in the liquid. This method, however, was designed for liquids that are not more than, say, 50 times as viscous as water, and would therefore be hardly suitable for heavy syrups which have a viscosity, in some cases, 1000 times greater than that of water. The viscosity of certain syrups has been determined by Pellet and Fribourg[6] by observing the time of flow of a definite volume of the syrup through an ordinary glass funnel, the stem of which was 10 cm. long and had an internal diameter of about 2 mm., the apparatus being maintained at a constant temperature by means of a water jacket. This method has the disadvantage of involving the use of a large amount of syrup, if good results are to be obtained, and this considerably increases the chance of error through variation of temperature, which has a large influence upon the viscosity.

The forms of apparatus in most general use for the determination of high viscosities are those of Redwood[7] and Engler.[8] These are fully described by Benedikt and Lewkowitsch.[9] Traube[10] condemns these viscosimeters because on theoretical grounds it is not permissible to compare directly the respective times of delivery of light and heavy oils, and still less the times of delivery of oils and water observed in one and the same apparatus (Engler's method involved the use of water as a liquid of standard viscosity, while Redwood employed refined rape oil for the same purpose). Traube thinks that the most satisfactory results can be achieved by approximating closely to Poiseuille's method, and considers the use of tubes of different diameters necessary for heavy and light oils if Hagenbach's correction to Poiseuille's formula is to become negligible.

More recently Dunstan and Strevens[11] have employed Ostwald's modification of Poiseuille's tube for the determination of the viscosity of lubricating oils and obtained good results. The dimensions of their apparatus were, capillary 6 cm. × 1 mm.; small bulb above capillary, 4 c.c.; bulb below capillary in other limb, 8 c.c.; length over all 15 cm. For the lubricating oils worked on these dimensions were very suitable, but for more viscous liquids such as syrups and molasses, it seemed to the author desirable to enlarge further the capillary and to decrease the size of the small bulb.

In the present paper the apparatus employed by the author is described, and the results obtained justify the use of such apparatus for the liquids dealt with. Furthermore it becomes unnecessary to adhere strictly to any particular dimensions in the construction of the viscosity tube, whereas with Redwood's viscosimeter it is most important that the orifice in the agate should be of standard size,[12] since slight variations in the size give discordant results. Similarly Engler[13] lays the greatest possible stress on the necessity of adhering strictly to the measures given in his apparatus, if correct results are to be obtained.

Form and dimensions of apparatus used.—Three tubes were used in the determinations, each having slightly different dimensions. The volume of the bulb, A (Fig. 1), varied from 1—1·5 c.c. The diameter of the capillary, C, which constitutes the essential difference from the ordinary tubes, was 2 mm., and the length of the capillary was varied from 6—7 cm. Owing to the increased size of the capillary, a general increase in the dimensions of the tube resulted, so that about 12 c.c. of liquid were necessary to fill the bulb, A, and the limb containing the capillary and still leave a small amount in the bottom of the wider limb, B. The following figures will supply all further information needed for a description of the apparatus.



Constriction above A: diameter 2 mm.

Bulb A: diameter 10 mm; volume 1—1·5 c.c.

Capillary C: outside diameter 7·5 mm.; inside diameter 2 mm.; length 6—7 cm.

U piece D (ordinary glass tubing): diameter 9 mm.

Limb B: diameter 2 cm.; length 23—25 cm.

The tube was so constructed that the height of the liquid in B was still a couple of centimetres below the bottom of the capillary, C, whe the bulb, A, was empty

As the use of 12 c.c might have proved a objection in some case a tube was made in whic very small thin-walle tubing of 2 mm. diamete was used instead the heavy capillar described above. Th considerably reduced the other dimensions of the apparatus, so that a mu smaller volume could be worked with.

Good results were obtained with this tube, but figures given here were obtained by use of the heav and larger tube, which besides being stronger, could cleaned very much more rapidly

Determination of the viscosity.—It was first of all nec sary to compare the times of flow in consecutive exp ments with the same syrup, in order to ascertain w degree of accuracy might be expected from this meth The following figures are the times of flow for "gol syrup," of which 12 c.c. were run into the wider limb. The same 12 c.c. of syrup were used throughout. viscosimeter was immersed in a large beaker of wa which was very accurately maintained at the temperature of the experiment.

[12] This J., 1886, 126.

[13] This J., 1893, 292.

The densities of the different syrups were not determined and therefore values of the viscosity are not given. However, this is only necessary if the actual viscosities are required, but as the object of this investigation was rather to illustrate the degree of accuracy that could be attained by employment of the method described, than to determine the viscosity, the time of flow is the only figure necessary in this case.

Table 1.

Time of flow in seconds at various temperatures.

50° C.		40° C.	30° C.	25° C.
76·6	76·5	213·1	702·3	1370·8
76·5	76·6	212·7	702·5	1371·4
76·6	77·2	212·8	703·4	
76·4	76·8	213·1		
76·4	76·4	213·1		

According to these figures the error at 50° C. averages 0·16 second in 76·6 seconds or about 1 in 500. At 25° C. the mean error has decreased to 0·3 in 1371·1 or 1 in 4500. It must be borne in mind, however, that a determination at 25° C. is much more tedious than one performed at 50° C., owing to the greater difficulty in maintaining the temperature constant over the much longer period. These figures were borne out by later experiments, a similar degree of accuracy being obtained in all cases. One more series of figures is added to illustrate this.

Table 2.

Time of flow at various temperatures.

50° C.		40° C.	30° C.
77·8	77·5	214·1	704·3
77·6	77·7	214·3	705·0
77·7	77·9	214·5	
78·0	7··7	213·9	
77·6		214·5	

Having seen that a close agreement would be obtained between the times of flow for different experiments with the same filling of syrup, experiments were next conducted in which the tube was washed out after each reading and a fresh volume of syrup used for the next reading. It was found that small differences in the volume of syrup in the viscosimeter made appreciable differences in the time of flow, so that it became necessary to determine the weight of 12 c.c. and weigh in this amount each time.

Table 3.

Times of flow for different fillings of the viscosimeter at 40° C.

Syrup No. 1.	No. 2.	No. 3.
204·8	126·6	213·1
203·8	126·5	214·3
204·5	126·5	
203·8	126·7	

Table 4.

Times of flow for different fillings of the viscosimeter at various temperatures.

Syrup No.	40° C.		30° C.	25° C.
4	181·6 182·0 182·0	182·0 181·7 182·1	552·1 550·0	
5	150·0 150·2 150·2	150·2 150·3 149·7	457·4 459·0	856·6 854·0
6	223·0 224·0	222·6 224·0	705·0 703·0	

At 40° C. the mean difference between the times of flow obtained for different fillings is fairly small, being for the different syrups 1 in 500, 1 in 1300, 1 in 200, 1 in 1000, 1 in 750, and 1 in 400. Also at this temperature the time of flow is conveniently short, so that the temperature can very readily be kept constant throughout the experiment. At lower temperatures, the temperature of the bath has a much larger chance of fluctuating owing to the much longer time of flow, and the greater differences obtained at 25° C. and 30 C. are thus accounted for. The most convenient method, then, of determining the viscosity of such syrups as these would be to make the determinations at about 40° C. and calculate by means of a predetermined temperature coefficient the viscosity at any required temperature. If the temperature coefficient for any range of temperature can be shown to be the same for all syrups of the same class, one determination of this coefficient would suffice for all such samples. Tables 5a, 6a, and 7a give values of temperature coefficients of the time of flow for golden syrup, treacle, and molasses, and show that these values remain fairly constant for different samples.

Table 5.

Time of flow in seconds of golden syrup at various temperatures.

40° C.	205	74	113	180
50° C.	96	37	53	90

TABLE 7A.

Temperature coefficients for different samples of molasses calculated from figures in Table 7.

	A	B	C	D
30—40° C.	2·35	2·20	2·44	2·27
40—50° C.	2·14	2·00	2·13	2·00

Comparison of the viscosity of the same sample determined in two different tubes.—In order to obtain a relative value for the viscosity of these syrups, the time of flow at any temperature was divided by the time of flow of pure glycerin at the same temperature. This gave a value of the viscosity (uncorrected for differences in density) relative to that of glycerin, which was taken as being the most convenient liquid to use as a standard.

The determination of the time of flow and temperature coefficients for glycerin, using three different tubes, resulted as follows:—

TABLE 8.

Time of flow in seconds for glycerin in different tubes and at different temperatures.

	Tube A.	Tube B.	Tube C.
20° C.	115·3	107·6	—
30° C.	49·55	46·4	34·0
40° C.	23·5	22·1	16·1

TABLE 8A.

Temperatures coefficients as calculated from the figures in Table 8.

	Tube A.	Tube B.	Tube C.
20—30° C. ..	2·33	2·32	—
30—40° C. ..	2·11	2·10	2·11

Tubes B and C, having rather different dimensions, were used in the next experiment with golden syrup: 15 grms. (the weight of 12 c.c.) of the syrup were weighed into each of the tubes and the time of flow in each tube observed at 30° C. and 40° C.

TABLE 9.

Times of flow in seconds of the same golden syrup in different tubes and at different temperatures.

	Tube B.	Tube C.
30° C.	632·5	456·0
40° C.	199·0	145·0
Temp. Coeff.	3·18	3·16

TABLE 9A.

Values of the time of flow of golden syrup relative to that of glycerin, as determined in two different tubes and at different temperatures.

	30° C.	40° C.
Tube B.	13·6	9·0
Tube C.	13·4	9·0

From these results it will be seen that no standard dimensions of the apparatus are necessary, as is the case with some other viscosimeters, it being necessary only to have an easily accessible standard liquid of constant viscosity. Various liquids have been suggested for this purpose, but glycerin was found to be very suitable when dealing with such heavy liquids as those here experimented on. Moreover the purity of the glycerin can very readily be determined by means of the refractometer.

CONCLUSIONS.

(1) An apparatus similar to Ostwald's viscosity tube appears to be very suitable for the determination of the viscosity of very viscous liquids.

(2) Consecutive observations of the time of flow for golden syrup, treacle, or molasses, for the same filling of the tube and for repeated fresh fillings, agree very closely.

(3) The temperature coefficients (for 10° C.) for times of flow, remain fairly constant for any particular class of liquid, thus enabling one to work at the most convenient temperature, and then to calculate the viscosity at any desired temperature by means of predetermined coefficients.

(4) Glycerin appears to be very suitable as a standard with which to compare the viscosities of such liquids as those mentioned.

(5) With the form of apparatus described the need for standard dimensions is done away with, a liquid of constant viscosity as a standard being all that is necessary.

Journal and Patent Literature.

PATENT SPECIFICATIONS may be obtained by post by remitting as follows:—

English.—8*d.* each, to the Comptroller of the Patent Office, W. Temple Franks, Esq., Southampton Buildings, Chancery Lan London, W.C.

United States.—1*s.* each, to the Secretary of the Society.

French.—1 fr. 05 c. each, as follows; Patents dated 1902 to 1907 inclusive, Belin et Cie., 56, Rue des Francs Bourgeoi Paris 3e.); Patents from 1908 to date, L'Imprimerie Nationale, 87, Rue Vieille du Temple, Paris.

German.—1 mark each (with full particulars) to Kaiserlich Patentamt, Berlin, Germany.

I.—GENERAL PLANT; MACHINERY.

Explosions in liquid air plants. W. Bramkamp. Chem. Ind., 1914, 37, 81—84.

Two out of three explosions in plants for the fractional separation of oxygen from nitrogen, were due to the unauthorised attempt to remove ice from the fractionating column by means of a blast-lamp and a red-hot spanner, respectively: the cork or silk lagging, saturated with oxygen, burnt explosively. The third was ascribed to an accumulation in the receiver of the oxygen fraction—of acetylene, partly as acetylide of copper, which had escaped from a neighbouring works. The author suggests as possible causes of explosions: stoppage of the tubes by solid argon; explosive vaporisation of solid argon warming; or accumulation of lubricant, or its decompo tion products, or even methane from the air, which mig become ignited on contact with ozone produced by electrification by friction of the non-conducting liqu oxygen.—O. E. M.

PATENTS.

Furnaces or kilns; Gas-fired ——. L. F. Tooth, Lond Eng. Pat. 1772, Jan. 22, 1913.

A HEATING chamber is formed above a combustion cham into which the gas jets project. Heated secondary ai supplied to the combustion chamber, which has a slo floor and side wall and is provided with baffles to direct the hot products of combustion into flues constructed in the sides of the furnace, by which they pass to the heating chamber above, entering at the sides. The gases then pass upwards to the vaulted roof of the heating chamber, by which they are deflected downwards to the centre of the hearth and thence rise again and escape through an opening in the centre of the roof.—W. H. C.

Furnace roofs and walls built of brickwork liable to shrink in heat; Construction and treatment of ——. E. C. R. Marks, London. From Veitscher Magnesitwerke-A.-G., Vienna. Eng. Pat. 8959, April 16, 1913.

Iron rods, sheets, etc., are embedded in the mortar between the magnesite bricks. The iron combines with the material of the bricks to form a slag, with increase of volume, thus compensating for the shrinkage. The walls may also be protected by a coating formed of a mixture of mortar and finely-divided iron.—W. H. C.

Grinding, crushing, pulverising and the like; Roller and ring mills for ——. J. Y. Johnson, London. From Gebr. Pfeiffer, Kaiserlautern, Germany. Eng. Pat. 10,883, May 8, 1913.

The ends of the grinding rolls are supported by plate springs fixed at one end to the casing. If several springs are employed the free ends of the springs overlap.—W. H. C.

Spraying viscous materials such as tar, molasses, heavy oils, and the like; Apparatus for ——. C. L. de W. Reader, Winchester. Eng. Pat. 20,036, Sept. 4, 1913.

The supply pipes by which the liquid is conveyed from the store tank to the spraying device are provided with internal steam pipes which pass through stuffing-boxes at the ends of the supply pipes.—W. H. C.

Washing, purifying and cooling gases; Atomising apparatus for ——. H. E. Theisen, Munich, Germany. Eng. Pat. 21,427, Sept. 23, 1913.

In the atomising gas washers described in Eng. Pats. 27,696 of 1911 and 27,417 of 1912 (this J., 1912, 1020; 1913, 820) additional water injectors are provided which give lateral and central supplies of water spray to prevent the treated gas from escaping past the beater-bars. Further, the water-supply channels in the rotary discs are so arranged that the beaters and discs can be lifted out through the top of the casing when necessary.—W. H. C.

Packing for machinery [*working at low temperatures*]. L'Air Liquide (Soc. Anon. pour l'Etude et l'Exploit. des Proc. G. Claude), Paris. Eng. Pat. 23,564, Oct. 17, 1913. Under Int. Conv., Oct. 17, 1912.

Leather, freed from fatty material by treatment with any of the usual fat solvents and afterwards dried to remove moisture, forms a pliant material for cupped or semi-cupped packing for pump plungers in machines working at low temperatures such as in apparatus for the manufacture of liquid air, and is stated to give satisfactory results without the use of lubricants —N. C. A.

Mixing machine with revolving drum and material elevation. E. Gauhe, Oberlahnstein, Germany. Eng. Pat. 23,919, Oct. 22, 1913.

The machine is portable, the revolving mixing drum, mounted on tubular trunnions, easily and cheaply replaced. ies transversely on the carriage whereby a larger drum can e used than when mounted longitudinally. The drum is itted with a single aperture in the cylindrical portion for illing and discharging and the extra weight of the cover f the aperture is counterbalanced. An automatic djustment is fitted for checking the drum when the pening is directly beneath the discharge-bucket of the aterial-elevator which is mounted on the carriage along-de the drum.—N. C. A.

Filling material for absorption, reaction, mixing and cooling towers. Nitrogen Products and Carbide Co., Ltd., and H. Nielsen, London. Eng. Pat. 26,269, Nov. 15, 1913.

The filling material consists of pieces comprising three or more arms or blades radiating from a central boss. The blades may be either straight or helical and smooth or corrugated, and the central boss may be either with or without a central hole. It is claimed that filling material of this shape combines a large surface area with a minimum displacement and that the pieces may be made cheaply by pressing a plastic material through a die.—N. C. A.

Gaseous mixtures; Apparatus for separating ——. Genevet et Cie. Fr. Pat. 462,202, Nov. 16, 1912.

The claims are for the use of an appropriate jet to impart a constant acceleration to the current of gas; of a settling chamber provided with transverse baffles and of a separator formed of a jet which is shaped partly circular and partly of a form appropriate to the stream of fluid.
—W. H. C.

Filters; Vacuum —— *of the drum type, as used in beneficiating precious metals and for other industrial purposes.* G. Spence, Mexico City. Eng. Pat. 18,333, Aug. 12, 1913. Under Int. Conv., Aug. 31, 1912.

See Fr. Pat. 461,346 of 1913; this J., 1914, 187.—T. F. B.

Air and gases; Means for removing moisture from ——. P. Schou, Copenhagen. U.S. Pat. 1,086,089, Feb. 3, 1914.

See Eng. Pat. 16,510 of 1912; this J., 1913, 275.—T. F. B.

Vessels in which materials are treated with an inflammable liquid in presence of a protective gas; Process and apparatus for safe working in closed ——. Martini und Hüneke Maschinenbau Akt.-Ges. Fr. Pat. 462,332, July 3, 1913. Under Int. Conv., July 3, 1912.

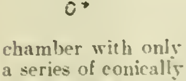
Disintegrating, separating, and mixing artificial fertilisers, ores, clay, chemical products, etc.; Apparatus for ——. G. M. Tyler. Fr. Pat. 462,736, Sept. 18, 1913. Under Int. Conv., March 8, 1913.

See Eng. Pat. 5760 of 1913; this J., 1913, 934.—T. F. B.

IIa.—FUEL; GAS; MINERAL OILS AND WAXES.

Coal; New process for the washing of ——. L. D. Ford. Trans. N. Engl. Inst. Min. and Mech. Eng., 1914, **64**, 91—106. (See also this J., 1911, 662.)

The construction of the *Rhéolaveur* which is the central device of the new method is illustrated diagrammatically in the figure. The coal is carried by a current of water, *c*, down the inclined plane, and another current entering at *a* prevents all but the heavier particles from falling through the opening. These heavier particles are carried away at the orifice, *o*. To save water, a number of such elements are combined, and arranged to discharge into a common chamber with only one discharge opening. By means of a series of conically bored discs this orifice can be made of such a size that it just allows the particles to pass without blocking the chamber. The author describes the working conditions and the union of several of the combined "Rhéolaveurs" into a continuous working plant. It is



found that the method is quite as efficient as the use of jigs, more compact and adaptable, also the working costs are reduced. The paper also contains a description of the *Controlavoir*, an apparatus for fractionating the coal on a small scale and obtaining information as to its behaviour on washing. The sample is placed in a U-tube and a water current turned on which will just keep in suspension the finest grains. The strength of the current is noted and the suspended matter is carried over into a specimen glass where it is collected and analysed. This process is continued till all the material has been carried over.—W. H. P.

Methane; Enrichment of gases with ——, and the production of coal-gas free from carbon monoxide. P. Jochum. J. Gasbeleucht., 1914, **57**, 73—80, 103—111, 124—131.

EXPERIMENTS were made with mixtures of carbon monoxide and hydrogen, ethylene and hydrogen, and with a mixture of carbon monoxide, hydrogen, methane and nitrogen of a composition similar to that of coal-gas, in order to ascertain the best conditions for carrying out the reactions (1) $CO+3H_2=CH_4+H_2O$; (2) $C_2H_4+H_2=C_2H_6$, in the presence of finely-divided nickel. The best temperature for the reduction of carbon monoxide was 270°—280° C. and for the catalyser to retain its activity as long as possible, the best proportion of gases in the mixture was 1 vol. of carbon monoxide to 5 vols. of hydrogen. When a mixture of equal volumes of ethylene and hydrogen was passed over the catalyser at 300° C., the ethane produced at first was almost all decomposed, forming methane, hydrogen and carbon. The maximum yield of methane from the coal-gas mixture was obtained at 260°—270° C. The gas used contained CO, 9·3; H_2, 50·0; CH_4 37·8 and N_2 2·9, and the resulting gas contained CO_2, 0·6; H_2, 4·1; CH_4, 89·1; and N_2, 6·2 per cent. Experiments were also made with purified lighting gas. It was not possible to purify the gas sufficiently to prevent deterioration of the catalyser: complete removal of sulphur was insufficient and the complete removal of aromatic hydrocarbons appeared to be necessary.—A. T. L.

Coal-gas; Analysis of ——, with the Bunte burette. E. Czakó. J. Gasbeleucht., 1914, **57**, 169—172.

IN accordance with some recent results obtained by C. Ab-der-Halden (J. des Usines à Gas, 1913, **19**, 296) it is shown that methane is appreciably soluble in aqueous reagents, including the cuprous chloride absorbent used in gas analysis. The consequent error is negligible, however, if the determinations are carried out in the manner outlined below. The perfectly colourless solution of cuprous chloride in hydrochloric acid is prepared according to the original method of Winkler. Three successive portions of 5 c.c. are introduced into the Bunte burette and in each case left in contact with the gas for 2 minutes, the burette being meanwhile tilted backwards and forwards very gently. Each portion of the reagent is withdrawn before the introduction of the next. The burette is then washed out by successive admission from the upper end of two portions of from 2 to 3 c.c. of concentrated hydrochloric acid, followed by the same amounts of distilled water; and before the final adjustment about 2 c.c. of potash solution are introduced at the lower end, after which the pressure is also equalised from below in the usual way. Especial importance is attached to the observance of the following points, viz., use of the smallest possible quantity of reagent; avoidance of violent shaking; careful and economical washing; and adjustment of pressure from below. Similar conditions hold for the estimation of other gases by absorption. The greater solubility of the homologues of methane in aqueous reagents is not important in the case of coal-gas, owing to their low partial pressures. The author considers that the absorption method cannot be bettered for the determination of carbon monoxide when the only other constituents to be determined are carbon dioxide and oxygen, as *e.g.*, in producer gas and furnace gases; but in cases involving the additional determination of hydrogen, methane and nitrogen, as *e.g.*, in coal-gas, a slow combustion method is recommended as preferable.—J. R.

Mahone petroleum. Its recent origin and the origin of petroleum in general. C. F. Mabery. J. Ind. Eng. Chem., 1914, **6**, 101—107.

MAHONE (Ohio) petroleum is obtained from a depth of 115—150 ft. and associated with the oil deposit are extensive beds of bituminous coal. The crude oil is nearly black, very viscous, optically inactive, sp. gr. 0·9036—0·9057 at 20° C., refractive index 1·4878—1·4822 at 26° C.; it is free from nitrogen and contains less than 0·01 per cent. S. It begins to distil at 230° C. and to decompose at 250° C., yielding less viscous oils. It was fractionated by distillation at 30 mm. pressure: at about 350° C. or somewhat lower decomposition occurred. Examination of the distillates showed that paraffins, C_nH_{2n} hydrocarbons, and asphaltic constituents were absent, the products consisting entirely of C_nH_{2n-2} and C_nH_{2n-4} hydrocarbons, the latter greatly predominating. The following hydrocarbons were isolated in a practically pure condition:

	B.pt.	Sp. gr. at 20° C.		B.pt.	Sp. gr. at 20° C.
	° C.			° C.	
$C_{11}H_{20}$	97—98	0·8549	$C_{15}H_{28}$	138—139	0·8662
$C_{12}H_{22}$	109—110	0·8576	$C_{16}H_{26}$	151—152	0·8692
$C_{13}H_{24}$	120—121	0·8614	$C_{17}H_{30}$	171—172	0·8716
$C_{14}H_{28}$	130—131	0·8654	$C_{19}H_{34}$	212—214	0·8790

Mahone petroleum is especially adapted for the preparation of high-grade lubricants, the C_nH_{2n-4} hydrocarbons and the lighter C_nH_{2-2} hydrocarbons, with viscosities of 100—125, being superior to any other petroleum products for lubricating purposes. The problem of the origin of petroleum is briefly discussed.—A. S.

Lubricating oils for motors; Testing ——. G. Lumet. Comptes rend., 1914, **158**, 172—175.

THE author describes apparatus designed for the Testing Laboratory of the Technical Commission of the Automobile Club of France, for the determination of the coefficient of friction under practical conditions. A rotatable metal cylinder is mounted horizontally. Against its interior surface four pieces of metal ("rubbers") are pressed by means of pistons mounted radially on a shaft which passes axially through the cylinder. The pistons are acted on by a cushion of oil (that to be tested) which, communicating with a pump by a channel along the shaft, can be maintained at any desired pressure. A small quantity of oil escapes from behind the pistons and this drops on the interior surface of the cylinder in the path of the "rubbers" and effects lubrication. The contact between the rotating cylinder and the "rubbers" tends to rotate the central shaft, and this tendency, which measures the friction, is exactly compensated by means of a weight movable on an arm attached to the shaft. The cylinder can be heated by Bunsen burners if necessary. The apparatus is adapted for linear velocities of 0—20 metres (0—65 feet) per sec., pressures of 0—5 kilos. per sq. cm. (0—70 lb. per sq. in.) and temperatures of 0°—300° C. The coefficient of friction, ϕ, is equal to KV^{β}/p^{a}, in which K is a viscosity constant, V is the linear velocity, p the pressure per unit area, and a and β are constants of which both are positive and neither is greater than unity. A large number of tests gave the average value 0·75 for a. With rise in temperature the value of β diminishes, and the coefficient of friction also diminishe in accordance with the expression $\phi=a/t^2+b/t+c$, in which a, b, and c are characteristic of the lubricant and the metal surfaces and dependent on the pressure and th velocity.—J. H. L

Paraffin waxes; Refractometric examination of —— D. Holde and H. Franck. Petroleum, 1914, **9**, 669—674

ONE grm. of the sample is dissolved in 50 c c. of chloroform the solution treated with 60 c.c. of 96 per cent. (by vol alcohol at 20° C., the precipitate separated (by suction the filtrate evaporated, the residue dissolved in 5 c.c. chloroform, and the solution treated with 15 c.c. of 96 p cent. alcohol. The second precipitate is separated as before, and the final filtrate evaporated to obtain the unprecipitated residue. The refractometer reading (Zeiss), *R*, at 90° C. of each of these fractions is determined. The following results are typical of those obtained :—

	1st precipitate.		2nd precipitate.		Un rec pitated residue.	
	R	Amount.	*R*	Amount.	*R*	Amount.
		per cent.		per cent.		per cent.
Ceresin 1, yellow soft	15·4	79·2	8·0	6·7	28·3	10·8
do. wth 10 per cent. paraffin wax m. pt. 50°—51° C.	14·5	75·3	4·6	7·5	23·0 (freed from oil + 0·6)	12·4
do. with 15 per cent. paraffin wax m. pt. 50°—51° C.	14·6	75·9	2·8	7·5	17·2 (freed from oil + 1·0)	13·0
Ceresin 2, white	13·8	81·3	5·7	8·6	12·3	8·2
do. with 10 per cent. paraffin wax	11·9	74·6	2·5	7·5	7·1 (freed from oil − 1·0)	11·0

On expressing the oil from the unprecipitated residue from ceresins the solid portion invariably gave a low refractometer reading (0·6—2·5). Paraffin waxes of various origin contained about 0·1 to 0·2 per cent. of oil showing refractometer readings of 22 to 48 at 90° C. Four samples of pure ceresin (m. pt 68° to 71° C.) gave refractometer readings of 11·5 to 13 at 90° C., whilst the readings given by 4 samples of hard paraffin wax, of different origin ranged from —2·6 to +1·5, and that of a sample of soft paraffin wax (m. pt. 41·5° to 42° C.) was —7·2. On fractional precipitation, as described, the hard paraffin waxes yielded first fractions of higher m. pt. than the original wax, but with refractometer readings not exceeding the limits of —1·2 and +1·7 at 90° C. The following fractions melted below 50° to 44° C., and had correspondingly low refractometer readings (—1 2 to —5), whilst the second fraction from the soft paraffin wax (m. pt. 36·5° to 38° C.) gave a reading of —8·5. The test is thus more sensitive for soft than for hard paraffin waxes. Certain commercial paraffin waxes (m. pt. up to 70° C.), prepared by distillation *in vacuo* and fractional "sweating," showed refractometer readings approximating the lower limit for ceresin (+10), and there was also less difference than with ordinary hard paraffin waxes in the readings given by the fractions. But such waxes are of higher price than normal paraffin waxes and are seldom on the market. In deciding whether a sample of ceresin contains added paraffin wax it must not be overlooked that ceresin-like products occur in petroleum. For example, by extracting a cylinder oil with alcohol-ether a wax was separated, which resembled ceresin in appearance, and had m. pt. 70° C. and a refractometer reading of 17·3 at 90° C.—C. A. M.

PATENTS.

Briquetting ; Apparatus and process for preparing pulverulent materials for moulding or ——. E. B. A. Zwoyer, Hoboken and R. A. Zwoyer, Perth Amboy, N.J., Assignors to The Zwoyer Fuel Co., New York. U.S. Pats. 1,084,919 and 1,084,920, Jan. 20, 1914.

HE material is passed first through a horizontal chamber here it is dried by a current of hot air or gas, then rough a second horizontal chamber at a lower level, here it is intimately mixed with a binding agent, and ally through a third similar chamber at a still lower vel where it is showered or tossed about in a current of to cool the mixture to the point at which the binder comes plastic.—W. H. C.

Fuel ; Process for converting coal dust into a commercial ——. J. Evans. Fr. Pat. 461,400, Aug. 14, 1913. Under Int. Conv., Aug. 19, 1912.

COAL dust, etc., is mixed with from 2 to 5 per cent. of starch, flour, or similar paste, and the mixture compressed into blocks which are dried at 100° C., and dipped in tar or tar containing a small proportion of pitch or resin. The blocks are then heated sufficiently to volatilise part of the tar, and are finally cooled in a current of air, so that the surface of each block receives a hard protective coating.—H. H.

Combustibles ; Process for obtaining agglomerates of finely divided materials for ——. Soc. Houillère du Nord d'Alais. Fr. Pat. 461,855, Nov. 7, 1912.

FINELY divided coal, anthracite, lignite, peat, sawdust, oil-cake, etc., is mixed with a small proportion, *e.g.*, 2·5 per cent., of colloidal material such as starch, or wheat, rice, or cassava flour, the mixture being worked into a paste and then dried for 3 or 4 hours at a temperature of 100° to 200° C.—H. H.

Quenching coke ; Apparatus for ——. Berlin-Anhaltische Maschinenbau-Akt.-Ges., Berlin. Eng. Pat. 23,555, Oct. 17, 1913. Under Int. Conv., Oct. 6, 1913. Addition to Eng. Pat. 9269 of 1912, dated Nov. 25, 1911.

THE incandescent coke is introduced into a dipping tank having a water-tight horizontal bottom with a perforated bottom arranged a small distance above. The tank slowly becomes immersed in quenching liquid as the charge of coke increases, and during the early portion of the descent cooling is effected by contact between the quenching liquid and the outside walls of the tank only. As soon as the tank reaches a certain depth, however, sliding valves arranged at the bottom of the side walls are opened by contact with stops situated in the quenching tank, and liquid enters the double bottom of the tank so as to quench the coke by direct contact. The valves remain open when the tank is raised after quenching is complete, and thus allow water to drain away.—H. H.

Carbonising ; Method of —— and superheating gas. A. Berglof, Chicago, Ill. U.S. Pat. 1,085,096, Jan. 20, 1914.

A MASS of coke in a vertical chamber is heated by independent electric currents so as to maintain two zones at different temperatures. Preheated gas is passed first through the zone at the lower temperature and then through the zone at the higher temperature and finally through a mass of coal above the coke and with which the chamber is fed. The gas leaving the chamber passes through a heat interchanger and serves to preheat the incoming gas.—W. H. C.

Gas producer with temperature regulator and recovery of distillation products such as acetic acid, methyl alcohol, etc. G. Felizat. Fr. Pat. 461,314, Aug. 11, 1913. Under Int. Conv., Aug. 29, 1912.

THE hopper supplying waste vegetable materials to a gas producer is made in the form of a tube dipping into the upper portion of the producer. From the centre portion of this tube a mixture of distillation products and part of the producer gas is withdrawn through a side tube leading to a condenser coil and gasometer. The temperature of the distillation zone in the fuel-supply tube is regulated by varying the pressure in the gasometer, whereby a greater or smaller volume of hot producer gas is drawn through the tube.—H. H.

Inflammable gases in the air; Process for detecting and determining ——. Akkumulatorenfabrik A.-G. Ger. Pat. 269,131, April 24, 1913.

The testing apparatus contains two wires both of which can be heated electrically, but only one of which acts catalytically. The non-catalytic wire is first heated, the air to be tested is allowed to enter, then the apparatus is closed, and the catalytic wire is heated.—A. S.

Gas manufacture; Process and apparatus for obtaining a useful by-product [ammonium nitrate or nitrite] from —— and for the recovery of ammonia from gas manufacture. A. H. Lymn, London. Eng. Pat. 1851, Jan. 22, 1913.

The ammonia contained in coal-gas, producer gas, or the like, is brought into contact with nitrogen oxides or oxy-acids, obtained by the combustion (under pressure in a suitable furnace) of gas, which has already been freed from ammonia, with nitrogen and oxygen.—O. R.

Gas for lighting or heating; Separation and utilisation of carbon dioxide contained in ——. Athion Ges. m. b. H. Fr. Pat. 461,107, Aug. 4, 1913. Under Int. Conv., Aug. 7, 1912.

Carbon dioxide is completely extracted from coal gas by means of a solution of an alkali carbonate, and is recovered in the well-known manner by heating the solution. After the separation of carbon dioxide, the gas can be treated successfully for the removal of carbon bisulphide (see Eng. Pat. 3043 of 1912; this J., 1912, 526; also this J., 1913, 743, 818).—H. H.

Peat; Extracting liquid hydrocarbons and halogen derivatives thereof from ——. G. Tischenko and H. Plauson, St. Petersburg. Eng. Pat. 27,428, Nov. 28, 1912.

Moist peat is mixed with salts, oxides, or hydroxides of alkali or alkaline earth metals, or of aluminium, zinc, copper, lead, tin, iron, etc., or with the metals in the form of powder, the mixture is heated in retorts in an arc furnace at a temperature at which metallic carbides are formed, and the gases and vapours produced are washed with water, cooled, freed from water and led through heated tubes packed with a catalytic agent, whereby liquid hydrocarbons are obtained. If halogen salts are used, halogen derivatives of the hydrocarbons are obtained. Examples: (1) 100 kilos. of peat containing 35—50 per cent. H_2O, and 50 kilos. of sodium carbonate yield benzene 25, naphthalene 25, anthracene 1·5, benzenoid residues 5, paraffins 30, paraffin oil compounds 12, and gases and residues 10 kilos. (2) 100 kilos. of dry brown peat and 100 kilos. of unslaked lime yield benzene 36, paraffin hydrocarbons 30, and various volatile paraffin hydrocarbons 18 kilos.—A. T. L.

Hydrocarbons; Producing —— from carbides. G. Tischenko and H. Plauson, St. Petersburg. Eng. Pat. 27,429, Nov. 28, 1912.

Carbides which react with water in the cold yielding acetylene, methane, ethylene, hydrogen, etc. are heated above 500° C. and submitted to the action of steam, or of water, at various pressures. For example, superheated steam is passed through calcium carbide at 600°—700° C. "under a vacuum of 30—50 mm." forming a mixture containing 60 per cent. of benzene, together with other aromatic hydrocarbons, acetylene and ethylene. A mixture of 4 parts of calcium carbide and 3 parts of aluminium carbide, heated to 600° C. and treated with steam "under a vacuum of 8—10 mm." yields "pentine" according to the equation $2C_2H_2+CH_4=C_5H_8$; at atmospheric or higher pressure, terpenes are formed. Calcium and aluminium carbides mixed so as to yield equal volumes of acetylene and methane, and treated as in the first example, yield propylene and its polymers. Cerium carbide, CeC_2, under the same conditions yields pentane:—$C_2H_2+C_2H_4+CH_4+H_2=C_5H_{12}$.—A. T. L.

Combustible oils, tar, and pitch; Process for treating ——. W. M. Steadman, Bracebridge, Lincoln. Eng. Pat. 711, Jan. 9, 1913.

Crude oil, tar, etc., of sp. gr. not below 0·86, is introduced into a closed and preferably heated chamber where it is thoroughly agitated with water, naphtha, and air, or air and steam, so as to produce an emulsion which can be utilised as a fuel either for internal combustion engines or for general heating purposes. The preferred proportions of naphtha and water are 2 and 10 per cent. respectively.—H. H.

Oil-gas or vapour for heating or firing purposes; Method of and means for producing ——. W. M. and M. M. Burdon, Bellshill, Lanarkshire. Eng. Pat. 1766, Jan. 22, 1913.

Improvements in the process and apparatus described in Eng. Pats. 27,348 and 29,522 of 1910 and 14,657 of 1911, whereby a gyratory motion is imparted to the primary air before mixing it with the oil. After mixing the oil and air are passed through a heating chamber, then mixed with a suitable quantity of preheated secondary air and burned.—W. H. C.

Mineral oil; Manufacturing a new product from ——. The New Oil Refining Process, Ltd. and J. L. Rossini, London. Eng. Pat. 2672, Feb. 1, 1913.

The oil obtained by the processes described in Eng. Pats. 13,675 of 1908 and 28,460 of 1911 (this J., 1909, 133) is distilled and the fraction passing over below 390°F. (199° C.) is washed with sulphuric, phosphoric, or other oxyacid, then with ammonia, soda or other alkali, and distilled up to 390° F. (199° C.). The residue remaining in the still consists of polymerised substances and has drying properties which make it suitable for use as a varnish or lacquer, or as a binding material for paint.
—A. T. L.

Fuel for internal combustion engines and process of making same. W. R. Gulick, Jersey City, N.J., U.S.A. Eng. Pat. 18,681, Aug. 16, 1913.

A fine spray of crude petroleum or its non-volatile liquid by-products is injected into a closed chamber containing gasoline, which is agitated vigorously during the mixing operation and for about 2 hours afterwards. The mixtur is allowed to stand for several hours, and is then ready fo use. The proportion of gasoline to crude oil may be a low as 25 per cent., and may vary widely above tha limit. The product may be mixed with fresh gasolir in the fuel tanks of internal combustion engines, and stated to prevent the formation of hard carbon in tl cylinders.—H. H.

Paraffin compositions; Process for expressing fluid fro ——. J. Hansen, Texas City, Tex. U.S. Pat. 1,084,7 Jan. 20, 1914.

The paraffin composition is forced in succession throu two filters. Whilst passing through the first filter t material is cooled and whilst passing through the seco at a reduced speed, it is heated and subjected to increa pressure.—W. H. C.

Coke ovens; Process for the continuous working of vert —— and furnace for use therein. J. Lütz. Fr. P 461,843, Aug. 5, 1913. Under Int. Conv., Aug. 5, 19

IIb.—DESTRUCTIVE DISTILLATION; HEATING; LIGHTING.

Tungsten lamp; Uses of the concentrated filament —— in the laboratory. F. A. McDermott. J. Amer. Chem. Soc., 1914, 36, 454—455.

THE author recommends for laboratory purposes the Mazda stereopticon lamp (concentrated filament) rated at 100 watts on a 110-volt circuit, and giving about 60 candle-power. The round bulb is about 7·5 cm. diam., and the filament is formed into a close coil looped over supports about 1 cm. apart, the loops forming an open cylinder about 1 cm. in diam.; as viewed from one side the entire light-giving element is concentrated in a space about 1 cm. square. The lamp has proved specially useful for microscopic work and for the polarimetric examination of solutions too highly coloured or turbid to give satisfactory results with light from ordinary sources.—A.S.

Nitrogen; Disappearance of —— in a tungsten lamp. Chemical reactions at very low pressures. II. I. Langmuir. J. Amer. Chem. Soc., 1913, 35, 931—943. Z. anorg. Chem., 1914, 85, 261—278. (See also this J., 1913, 1099.)

NITROGEN is consumed in a tungsten lamp in three ways: chemical, electrochemical and electrical. The chemical effect is caused by the direct union of tungsten vapour with nitrogen to form the nitride WN_2. At pressures up to 0·001 mm. the velocity of this change is proportional to the product of the rate of volatilisation of the tungsten and the pressure of the nitrogen. From about 0·003 to 1 mm. the velocity is dependent on the rate of volatilisation of the metal and independent of the pressure. At pressures over 2 mm. the velocity is still dependent on the rate of volatilisation but the latter is greatly diminished by the presence of nitrogen at this pressure. Nitrogen does not react under any conditions with solid tungsten. The velocity of evaporation of tungsten *in vacuo* at a emperature T on the thermodynamic scale is given by

$$\log_{10}M = 15{\cdot}402 - \frac{47444}{T} - 1{\cdot}4 \log_{10}T$$

where M is expressed in grms. of tungsten per second per q. cm. of surface; and the vapour pressure in mm. of nercury is given by

$$\log_{10}p = 15{\cdot}502 - \frac{47444}{T} - 0{\cdot}9 \log_{10}T$$

he latent heat being 218000—1·8T cals. per grm.-atom. he vapour pressure at the m. pt. (3270° C.) is about ·08 m.m., and the b. pt. is near 5000° C. The nitride WN_2 a clear brown substance when seen in thin layers, easily istinguishable from finely divided tungsten. It is deomposed by water, yielding ammonia and probably the ioxide WO_3. The electrochemical removal of nitrogen kes place at much lower temperatures (1600° C.) if otentials of over 40 volts are used, so that a perceptible scharge takes place through the gas. In this case so the nitride is formed. The purely electrical process curs at pressures below 0·005 mm. with 250 volts and ry high filament temperatures. It is very irregular and part at least of the nitrogen is easily recoverable by heating the bulb. The behaviour of nitrogen towards solid tungsten and tungsten vapour is very similar to that of oxygen towards platinum.—W. H. P.

PATENTS.

Distillation of carbonaceous material. H. G. Hills, Manchester, and R. W. Thom, Southport. Eng. Pat. 3284, Feb. 8, 1913.

THE material is placed in thin layers on trays in an externally heated oven from which the air is exhausted, and the distillation is carried out in stages at successively higher temperatures, the distillates being received in separate tar tanks. The process is intermittent, the trays being removed for recharging. The successive stages of the distillation may be effected in successive ovens of a series.—A. T. L.

Distillation gases; Process and apparatus for removing tar from warm ——, utilising tar, tar oils, or similar products as washing agents. Berlin-Anhaltische Maschinenbau-Act.-Ges. Abteilung Köln-Bayenthal. Fr. Pat. 461,956, Aug. 28, 1913. Under Int. Conv., Sept. 28, 1912.

THE gas is introduced beneath a flat plate perforated with holes of say 1 cm. diam. and immersed in a layer of tar, tar oil, or similar washing agent, so that large bubbles of the gas rise in a steady stream through the tar, the surface of which remains comparatively calm. Owing to surface tension, the bubbles become flattened as they reach the surface, and the tar, etc., contained in the gas is effectively removed as the bubbles escape from the surface.—H. H.

Heating material containing liquid; Processes and apparatus for ——. T. O. Franke, London. Eng. Pat. 12,232, May 26, 1913. Under Int. Conv, Jan. 27, 1913. Addition to Eng. Pat. 12,231 of 1913 (see U.S. Pat. 1,083,879 of 1914; following).

THE material (peat, ooze, wood pulp, etc.) is agitated by stirrers, knives or mixers during the heating by steam and the direction of the steam is reversed from time to time.
—W. H. C.

Heating material containing liquid; Apparatus for ——. J. Franke, London. U.S. Pat. 1,083,879, Jan. 6, 1914.

THE material is contained in a vessel which is revolved upon horizontal hollow trunnions through which the heating agent enters and leaves. By means of suitable automatic valves the direction of the flow of the heating agent through the vessel is reversed at every revolution of the vessel.—W. H. C.

Heating material containing liquid; Process and apparatus for ——. T. O. Franke, London. Eng. Pat. 12,231, May 26, 1913. Under Int. Conv., Aug. 26, 1912.

SEE U.S. Pat. 1,083,879 of 1914; preceding.—T. F. B.

Heating substances containing liquid; Process and apparatus for ——. T. O. Franke. Fr. Pat. 461,776, Aug. 25, 1913. Under Int. Conv., Aug. 26, 1912, and Jan. 27, 1913.

SEE Eng. Pat. 12,232 of 1913 and U.S. Pat. 1,083,879 of 1914; preceding.—T. F. B.

Heating air or gases; Heat-regenerator for ——. O. Gobbe, Jumet, Belgium. U.S. Pat. 1,086,322, Feb. 3, 1914.

SEE Eng. Pat. 5034 of 1913; this J., 1913, 903.—T. F. B.

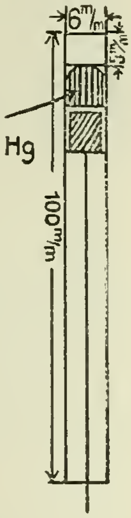
III.—TAR AND TAR PRODUCTS.

Peat tar; The phenols of ——. E. Börnstein and F. Bernstein. Z. angew. Chem., 1914, 27, 71—72.

A SAMPLE of tar obtained in the manufacture of coke from peat contained 18 per cent. of phenolic substances. Some of these were apparently methylated, so after a preliminary fractionation the methyl groups were first removed and the product further fractionated. In this way the presence in the tar of phenol, *o*-, *m*-, and *p*-cresol, 1.2.3- and 1.2.4-xylenol, catechol, homocatechol, and pyrogallol was demonstrated.—W. H. P.

Pitch ; Determination of the temperature of softening of ——. V. Abeles. Chem.-Zeit., 1914, **38**, 249.

A modification of Klinger's method (this J., 1914, 130) whereby the thickness of the layer of pitch is yet more rigorously defined. The mercury (5 grms.), supported in the tube by a movable cork or wad (see fig.), is adjusted so that the meniscus coincides with a mark on the tube 5 mm. from the end. The space above the mercury is then filled with molten pitch at 150° C., and after cooling in ice the wad is removed and the determination continued as described by Klinger. Böhm's method, in which weighed pieces of brass are used in place of the mercury, yields higher values and consequently greater differences in the case of high-melting asphaltums.
—J. R.



Patents.

Coal tar and the like hydrocarbon distillation. J. Rosen, London. Eng. Pat. 28,972, Dec. 16, 1912.

A volatile solvent which has a boiling point at least 80° C. below that of the product to be distilled, is introduced progressively into the heated tar or other mineral oil. The solvent is introduced at a considerably lower temperature than that to which the tar is heated, and its effect is to carry over the heavy constituents of the tar. The products are condensed separately, and the condensed solvent is led back to the still for a subsequent operation. The light oils of coal tar may be used as solvents in coal tar distillation, whilst for distilling a petroleum tar of b. pt. 330° C., light petroleum oils of b. pt. 170° C. are suitable. (Reference is directed in pursuance of Sect. 7, Sub-sect. 4, of the Patents and Designs Act, 1907, to Eng. Pats. 1980 of 1880 and 1411 of 1898.)
—T. F. B.

Coal tar, petroleum residues, creosote, schist oils and the like ; Conversion of —— *into pitch.* J. Rosen, London. Eng. Pat. 28,973, Dec. 16, 1912.

In carrying out the process described in Fr. Pat. 443,207 of 1911 (see this J., 1912, 978) it may be desirable to convert only part of the constituents of the coal tar, petroleum residues, etc., into pitch, and to recover the other constituents. In such a case, a current of air under pressure is introduced into the heated tar, etc., in a series of column-like or other stills, the constituents to be saved being removed and condensed separately, whilst the other vapours evolved are passed into the succeeding columns to be converted into pitch. The process is preferably carried out in columns from 6 to 10 metres high and 2 to 3 metres in diameter.—T. F. B.

Alpha-arylides of beta-naphthisatin ; Process for producing ——. Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. Eng. Pat. 30,072, Dec. 31, 1913. Under Int. Conv., May 2, 1913.

β-Hydrocyanocarbodinaphthylimine or the mixed hydrocyanocarbo-β-naphthylarylimines can be converted into α-arylides of β-naphthisatin by treatment with aluminium chloride in absence of water. Intermediate products containing aluminium are formed during the reaction, but they can be easily converted into the free arylides, *e.g.*, by treatment with cold concentrated hydrochloric acid.—T. F. B.

Cresol ; Process for separating m- and p- ——. Schülke und Mayr. Ger. Pat. 268,780, Dec. 24, 1911.

A mixture of *m*- and *p*-cresol is allowed to stand for a long time at the ordinary temperature with about its own weight of 80—90 per cent. sulphuric acid, whereupon the greater part of the *m*-cresol is sulphonated, whilst the *p*-compound is unchanged. The *p*-cresol is separated from the mixture either by pouring into water or by extraction with ether or other organic solvent. The sulphonic group is removed from the *m*-cresolsulphonic acid by known methods.—T. F. B

α-Nitro compounds of acylated diaminoanthraquinones ; Process for preparing ——. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 268,984, Oct. 17, 1912.

When an acyl derivative of 1.4-diaminoanthraquinone is treated with a nitrating agent in concentrated sulphuric acid solution, the nitro group enters an α-position in the nucleus not containing the amino groups. By eliminating the acyl group, a new compound, 5-nitro-1.4-diaminoanthraquinone, is obtained.—T. F. B.

Hydrochlorides of primary aromatic amines and their derivatives ; Process for isolating the —— *from the reduction products of the corresponding nitro-, amino-nitro-, nitroso-, azoxy-, azo-, oxyazo-, and aminoazo-compounds.* H. Pomeranz. Ger. Pat. 269,542, Jan. 9, 1912.

The compounds mentioned in the title are reduced by means of hydrochloric acid and iron, the quantity of the latter being such that only ferrous chloride and no ferric chloride is formed, whilst the excess of hydrochloric acid is so regulated that the whole of the ferrous chloride formed remains in solution : by this means, the hydrochloride of the amino-compound is obtained in a pure condition.—T. F. B.

Phenols and their substitution products ; Process for preparing di- and polyhydric ——. C. F. Boehringer und Söhne. Ger. Pat. 269,544, Dec. 15, 1911.

Mono- or polyhalogenated phenols or their substitution products are heated under pressure with aqueous solutions of alkali hydroxides or carbonates, or mixtures of the two, in presence of copper or a copper salt. The yields are said to be very high ; for instance, the yield of catechol from *o*-chlorophenol was 83 per cent. —T. F. B.

Distilling hydrocarbons ; Process for ——. Soc. Anon. des Combustibles Industriels. Fr. Pat. 462,952, Dec. 4 1912.

See Eng. Pat. 28,972 of 1912 ; preceding.—T. F. B.

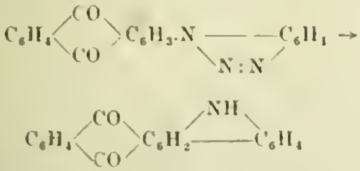
IV.—COLOURING MATTERS AND DYES.

Purpurogallin ; Preparation of ——. C. Graebe. Ber 1914, **47**, 337—338.

By oxidising pyrogallol with sodium nitrite and formi acid in the absence of air, 30—31 per cent. of the theoretic yield of purpurogallin is obtained, whereas by the usu method, using acetic acid in the presence of air, tl highest yield obtainable is 20 per cent. The product obtained quite pure without recrystallisation.—J. B.

Carbazole derivatives of the anthraquinone series. Ullmann and E. Illgen. Ber., 1914, **47**, 380—383.

The carbazoles of the α-aminoanthraquinone series for leuco-compounds which dye cotton, though faintly, shades fast to alkalis, in which respect they differ from t condensation product prepared from carbazole and phthalic anhydride (this J., 1911, 738) which, like the acridone derived from β-aminoanthraquinone, is not resistant to alkalis. The new compounds are prepared from azimino derivatives of α-aminoanthraquinone by heating, preferably in diphenylamine solution, *e.g.* :—



$$C_6H_4\langle{}^{CO}_{CO}\rangle C_6H_3.N\langle{}^{\quad\longrightarrow\quad}_{N:N}\rangle C_6H_4 \rightarrow$$

$$C_6H_4\langle{}^{CO}_{CO}\rangle C_6H_2\langle{}^{NH}_{\longrightarrow}\rangle C_6H_4$$

The azimides are obtained either by treating 1-anilino-2-aminoanthraquinones with nitrous acid, or by a new method according to which a 1-chloroanthraquinone is condensed with aziminobenzene.—J.B.

Diazotisation of various amines; Velocity of ——. E. Tassilly. Comptes rend., 1914, **158**, 489—491.

THE velocity of diazotisation of aniline, *o*- and *p*-toluidines, *m*-xylidine, *p*-anisidine and tolidine may be represented by the equation $\frac{dx}{dt}=K\ (100\text{-}x)^2$. The three nitranilines react very rapidly, but it is probable that they also follow the same course.—W. H. P.

Definition and testing of the fastness of dyestuffs. See VI.

PATENTS.

Triazoles of the aromatic series; Manufacture of ——. A. G. Bloxam, London. From Chem. Fabr. Griesheim-Elektron, Frankfort on Maine, Germany. Eng. Pat. 29,224, Dec. 18, 1913.

o-AMINOAZO dyestuffs of the benzene, naphthalene, or anthracene series can be converted easily, and with good yields, into the corresponding triazoles (*pseudo*-azimines) by heating with metals acting as catalysts, in presence of organic solvents of high boiling-point. *Example.* Benzene-azo-β-naphthylamine (100 parts) and finely divided copper (1 part) are heated for five hours to boiling in nitrobenzene (1000 parts); the 2.1-naphtho-N-phenyl-triazole is isolated by filtering the solution and expelling the solvent by means of steam.—T. F. B.

[Indigoid] colouring matters; Treatment of insoluble ——. J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. Eng. Pats. 29,583, Dec. 23, 1912, and 10,583, May 5, 1913.

SEE Ger. Pat. 265,536 of 1912; this J., 1913, 1101. The sulphite-cellulose lye may be replaced by aromatic sulphonic or carboxylic acids, especially benzylated amino-sulphonic acids, phenolsulphonic acids, and condensation products of phenolsulphonic acids with formaldehyde. —T. F. B.

Vat dyestuffs; Process for making ——. Farbwerke vorm. Meister, Lucius, und Brüning. First Addition, dated Sept. 24, 1913, to Fr. Pat. 447,592, Aug. 23, 1912. Under Int. Conv., Nov. 14, 1912, March 20 and Sept. 1, 1913.

THE dyestuffs described in the principal patent (this J., 1913, 226) can be obtained by treating arylido-halogen-quinones with derivatives of thiocarbonic acid, such as he xanthates or trithiocarbonates. Further, when the reaction is carried out under pressure, preferably in presence of water, alcohol, or other diluent, and using any of the ulphur compounds mentioned, the reaction is accelerated without diminution of the yield. If higher temperatures re employed (*e.g.*, 180°—185° C.), products of somewhat ifferent shade are obtained. Again, in place of using ulphydrates as described in the principal patent, hydrogen ulphide may be used, preferably in a closed vessel under ressure, and in presence of a diluent.—T. F. B.

Dyestuffs soluble in sodium sulphide; Process for preparing ——. Farbwerke vorm. Meister, Lucius, und Bruning. Ger. Pat. 268,891, Jan. 14, 1912. Addition to Ger. Pat. 264,044 (see this J., 1913, 1005).

INSTEAD of treating the substances mentioned in the chief patent with sulphuric acid, an alkali sulphide, particularly a sulphydrate, is used.—T. F. B.

Sulphide dyestuffs of the carbazole series; Process for producing blue ——. L. Cassella und Co. G. m. b. H. Fr. Pat. 462,316, Nov. 19, 1912.

MONOSULPHONIC acids of carbazole or of its N-alkyl derivatives are condensed with *p*-nitrosophenol in presence of concentrated sulphuric acid, forming soluble blue indophenolsulphonic acids. These can also be obtained by treating with normal or acid sulphites the indophenols formed by condensing *p*-nitrosophenol with carbazole or its N-alkyl or N-aryl derivatives. On heating these indophenolsulphonic acids or their leuco compounds for prolonged times with alkali polysulphides, sulphide dyestuffs are produced which dye cotton blue shades very fast to light and to chlorine.—T. F. B.

Anthraquinone derivatives; Process for preparing ——. K. Brass. Ger. Pat. 268,646, Feb. 20, 1912.

ARYL-1-AMINOANTHRAQUINONES or their homologues or substitution products, in which the *p*-position to the imino group in the aryl nucleus is unoccupied, whilst the *o*-position to the imino group in the aryl or anthraquinonyl nucleus contains a carboxyl group, are treated with oxidising agents. When treated with condensing agents, the products are converted into vat dyestuffs of the anthraquinone-acridone type.—T. F. B.

Vat dyestuffs; Process for preparing ——. Kalle und Co., A.-G. Ger. Pat. 269,123, Nov. 15, 1912. Addition to Ger. Pat. 241,997 (see this J., 1912, 223).

PHENO-OXYNAPHTHOCARBAZOLES which are derived from β-naphthylamine, or their homologues or analogues, are condensed with reactive isatin-α-derivatives or their homologues or analogues, and the products are treated with halogens. The resulting dyestuffs give blue to violet-black dyeings from the vat.—T. F. B.

Azo dyestuffs; Process for preparing ——. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 269,213, Nov. 6, 1912.

A DIAZOTISED aminobenzoylamine of the formula, $R.R'N.CO.C_6H_4.NH_2$ (where R and R′ may be aromatic radicals, or R an aromatic and R′ an aliphatic radical) is combined with an azo dyestuff component. The products dye wool from acid baths greenish-yellow to bluish-red shades fast to light.—T. F. B.

Vat [anthracene] dyestuffs; Process for preparing fast ——. R. Wedekind und Co. m. b. H. Ger. Pat. 269,215, Dec. 19, 1912.

THE yellow dyestuff containing bromine, obtained from dibromo-2-hydroxyanthraquinone according to Ger. Pat. 265,647 (see this J., 1913, 1101), is condensed with a primary aromatic amine. The products dye cotton from the alkaline vat, fast bright shades.—T. F. B.

Indigo dyestuffs; Mode of preparing finely-divided or colloid ——. A. Schmidt and A. Steindorff, Assignors to Farbwerke vorm. Meister, Lucius, und Brüning, Höchst on Maine, Germany. U.S. Pat. 1,085,361, Jan. 27, 1914.

SEE Ger. Pat. 242,532 of 1910; this J., 1912, 278.—T. F. B.

Azo dyes; Yellow ——. H. Geldermann, Berlin-Lichterfelde, and F. Ackermann, Berlin-Freidenau, Assignors to Act.-Ges. f. Anilinfabr., Berlin. U.S. Pat. 1,086,155, Feb. 3, 1914.

SEE Eng. Pat. 6779 of 1913 this J., 1913 905.—T. F. B.

Vat dyestuffs of the benzanthrone series. Badische Anilin und Soda Fabrik. Fr. Pat. 462,576. Nov. 25, 1912.

See Eng. Pat. 26,551 of 1912; this J., 1913, 1004.—T. F. B.

Production of fast shades on vegetable fibres and dyestuffs therefor. Eng. Pat. 1435. *See* VI.

V.—FIBRES; TEXTILES; CELLULOSE; PAPER.

Esparto grass; The commercial importance of ——. C. J. Koch. Tropenpflanzer. 1914, **18**, 59—79.

The esparto plant grows best on mixed limestone and gravel soils; its natural region lies between 32° and 41° N. latitude, but it is capable of resisting considerable variations in temperature and is found at altitudes up to 3000 ft. The leaf ranges in length from 30 to 70 cm., attaining I m. under exceptional circumstances. It is pale green when growing but becomes yellow on drying; it rolls up under the influence of dryness, attaining its cylindrical form at the ripening stage. About 200,000 tons of the grass are imported almost exclusively by England; the quantity has remained stationary for 15 years, a decline from one source being made up by increased importations from other sources. If the leaf is harvested before maturity the quality of the fibre is very inferior, yielding a semi-transparent paper. In most districts the use of the knife is forbidden; a tuft of grass requires 8—15 years before it becomes productive, and may then be "pulled" annually for 30—50 years. The best time for pulling is the autumn; in most countries a close-season is fixed by regulation during the earlier months of the year. The harvested grass is stored and dried for a considerable time before packing for shipment; the hydraulic-pressed bales weigh about 22½ lb. per cub. ft. The majority of German papermakers are not interested in the grass, partly through unfamiliarity, partly owing to difficulties in procuring freights. Freights from Algiers and Oran run about 28s. per ton for Hamburg and 24s. for English ports. The area under esparto in Algeria is about 2,800,000 acres, of which about three-fourths are in the department of Oran. Regulations as to season of cropping are in force, also certain zones are reserved as a protection against sand-troubles. Exports from Algeria were 100,788 tons in 1911 and 116,632 tons in 1912, average price 52s. per ton; exports from Tunisia were 50,797 tons in 1911, average price 57s. per ton. Increases from these countries in recent years have taken place at the expense of the Tripoli trade, now practically ruined by war and scarcity of labour. The Spanish variety of esparto is still the most valuable although high prices and careless industrial habits have led to wasteful methods of cropping. Exports have declined from about 60,000 tons in 1897 to 41,000 in 1912, but the fluctuations since 1904 show a fairly steady average; the price runs about 95s. per ton and has fallen from more than double this figure since 1883. —J. F. B.

Patents.

Retting plants; Process for chemically ——. V. N. F. Lombard, Paris, and G. A. F. Lasègue, Alfortville, France. Eng. Pat. 23,355, Oct. 15, 1913. Under Int. Conv., July 19, 1913.

The plant is heated in an autoclave with a halogen derivative of a hydrocarbon mixed or emulsified with water, an alkali being added to neutralise any acid formed. The solvents preferred are the chlorine derivatives of acetylene, particularly trichloroethylene (b.pt. 85°—88° C.).—J. B.

Cotton resembling silk; Manufacture of ——. L. Hermsdorf and B. Teufer. Fr. Pat. 463,073, Sept. 29, 1913. Under Int. Conv., June 20, 1913.

Cotton, whether mercerised or not, is treated in a bath of soap solution and then dipped, without washing, into a solution of an acid, *e.g.*, acetic, sulphuric formic, lactic, or boric acid, etc. This imparts a silky "touch" to the cotton, which is subsequently calendered under heavy pressure between rolls engraved with numerous very fine lines, whereby a silky lustre is produced.—J. F. B.

Cellulose ethers and their transformation products; Manufacture of ——. H. Dreyfus. Fr. Pat. 462,274, Nov. 18, 1912.

Alkyl ethers of cellulose are prepared by steeping cellulose in a solution of caustic soda or potash sufficiently dilute to permit of the uniform distribution of 2—4 mols. of alkali per mol. of cellulose. The water is then more or less completely removed by evaporation *in vacuo*, preferably under a very high vacuum. The mass of alkali cellulose is treated with methyl or ethyl sulphate or chloride, which may be employed alone or diluted with a neutral solvent such as benzene to ensure uniform distribution, at a temperature preferably not exceeding 50°—60° C. The solubility of the products may be modified by subsequent treatment with mineral or organic acids, the action being interrupted at any stage when the desired solubility is attained.—J. F. B.

Cellulose from resinous woods; Manufacture of —— with recovery of oil of turpentine and resin oil. Soc. Anon. Le Camphre. Fr. Pat. 462,681, Nov. 27, 1912.

Resinous wood is digested in the form of small chips with a solution of caustic soda to which salts, such as sodium carbonate or sulphate, may be added. When the temperature and pressure in the digester have reached a suitable point, a cock in the upper portion of the vessel is slightly opened and the vapours of oil of turpentine are distilled off, condensed in a cooling worm and the distillate separated from the water. The digestion of the charge of wood is continued until complete, and the lye is separated from the cellulose. The liquid is concentrated and calcined in a closed vessel with the production of resin oils and tars. The latter are separated by treatment with soda and the resin oils purified by rectification; phenolic by-products are obtained by acidifying the alkaline solution of the tars.—J. F. B.

Sulphite pulp spent lyes; Preparation and utilisation of binding and impregnating substance from ——. E. Pollacsek. Fr. Pat. 462,429, Sept. 10, 1913. Under Int. Conv., Sept. 16, 1912.

The spent lyes are treated with a slight excess of lime and evaporated until a scum begins to form, a certain quantity of heavy mineral oil is then added drop by drop, which enables the compounds of lime to be skimmed off. The clarified liquid is further evaporated until it is just fluid and about 5 per cent. of heavy mineral oil is worked into the hot thickened mass. After cooling, the mass is mixed with a further quantity of heavy oil in the proportion of 5 parts of oil to 4 parts of the product; the whole is mixed with 1·5 part of lime paste and boiled up again. This product serves as a basis for binding and impregnating compounds by mixing with lime, heavy oil or water according to the purpose in view.—J. F. B.

Flax; Process of preparing ——. G. H. Campbell, Toronto. U.S. Pats. 1,086,270, 1,086,271, 1,086,272, and 1,086,273, Feb. 3, 1914.

See Eng. Pats. 14,715, 14,716, 14,717, and 14,718 of 1911; this J., 1912, 583, 714, 769.—T. F. B.

VI.—BLEACHING; DYEING; PRINTING; FINISHING.

Fastness of dyestuffs; The definition and testing of the ——. Report of the "Echtheitskommission" (Ver. Deutscher Chemiker). Z. angew. Chem., 1914, **27**, 57—63. Chem.-Zeit., 1914. **38**, 154—158.

The report of a committee appointed by the *Verein Deutscher Chemiker* to establish standard fastness tests and standard definitions of fastness. The standards of fastness or norms are identified by numbers, the lowest number indicating the least degree of fastness, the highest number the greatest degree of fastness. The norms are prepared with well-known dyestuffs, dyed according to given methods. The numbers in brackets after the names of dyestuffs refer to Schultz's Farbstofftabellen, 5th Ed. 1. *Fastness to light.* The standards are: *Cotton:* I. 5·5 per cent. Chicago Blue 6B (424), first bath. II. 1 per cent. Methylene Blue BG (659). III. 1 per cent. Indoin Blue R (126). IV. 20 per cent. Kyrogene Violet 3R, first bath. V. 2·5 per cent. Benzo Fast Red 8BL, first bath. VI. 9 per cent. Hydron Blue G in paste (748), first bath. VII. 8 per cent. Kyrogene Black, first bath. VIII. 25 per cent. Indanthrene Blue GC in paste (843), first bath. *Wool:* I. 3·15 per cent. Indigotine I (877). II. 3 per cent. Patent Blue A (545). III. 3·25 per cent. Amarant (168). IV. 4·4 per cent. Azo Acid Red B (64). V. 5 per cent. Acid Violet 4 RN. VI. 2·5 per cent. Diamine Fast Red F (343) after-chromed. VII. 4 per cent. Anthraquinone Green GXN (864). VIII. Indigo pure, dyed to the same strengths as the above seven standards. 2*a*. *Fastness to washing and to boiling of dyed cotton in contact with white cotton.* Two tests are used. (A) The sample is plaited with an equal weight of white cotton and treated with a solution of 2 grms. of Marseilles soap per litre for ½ hour at 40° C. in a 40 volumes bath, then alternately kneaded with the fingers and returned to the bath ten times and finally rinsed and dried. (B) The plait is boiled for ½ hour in a solution of 5 grms. of Marseilles soap and 3 grms. of soda ash per litre, cooled to 40° C. during ½ hour, and then worked with the fingers as in A. I. (Test A: shade only a little lighter, white stained). 3 per cent. Benzopurpurin 4B (363), dyed at the boil with 20 grms. of Glauber's salt per litre, evaporation being compensated. After 1 hour a further 20 grms. of Glauber's salt per litre is added and boiling continued for ¼ hour. II. (Test A: shade unchanged, white unstained or nearly so). 5 per cent. Primuline (616). dyed as under I., then diazotised and developed with β-naphthol, the dyed material being finally soaped at 35° C. for 5 minutes with a solution of 2 grms. of Marseilles soap per litre. III. (Test B: shade decidedly lighter, white only slightly stained). 2·5 per cent. Indoin Blue BB (126) on yarn mordanted with 6 per cent. of tannin and 3 per cent of antimony salt, dyeing with 5 per cent. of acetic acid. first ½ hour cold, then raising to the boil during ½ hour and boiling ¼ hour. IV. (Test B: shade unchanged, white only slightly stained). 12 per cent. Immedial Indone R conc. (733) dyed with 1½ times the dyestuff weight of sodium sulphide crystals, 3 grms. of soda and 20 grms. of salt per litre, evaporation being compensated. After 1 hour at the boil a further 20 grms. of salt per litre is added and boiling continued ¼ hour. Alternative standard: Indigo dyed to the same strength in a hydrosulphite vat containing 10 grms. of Indigo (20 per cent. paste) per litre, giving three dips with 10 minutes oxidation between. V. (Test B: shade unchanged, white unstained or nearly so). Alizarin Red ("Old Red"). 2*b*. *Fastness to washing of dyed wool plaited with white wool and cotton.* Two tests are used. A. The dyed material is plaited with equal weights of washed white wool and boiled out cotton and treated for ¼ hour at 40° C. in a 50 volume bath containing 10 grms. of Marseilles soap (free from caustic soda) and 0·5 grm. of soda ash per litre, then kneaded well by hand five times, squeezed, rinsed and dried. B. The plait is treated in the above solution at 0° C., removed, allowed to cool for ¼ hour, then worked by hand as before. *Fastness with regard to white wool.* I. (Test A: great change of shade, much bleeding into the white material). 2 per cent. Orange II (145) dyed 1 hour at the boil with 10 per cent. of Glauber's salt nd 10 per cent. of sodium bisulphate. III. (Test A: o change in shade or only a trace, no bleeding into the hite). 2 per cent. of Patent Blue A (545) dyed with 10 per ent. of Glauber's salt and 3 per cent. of acetic acid. aising from 40° C. to the boil in 20 minutes and oiling lightly for 1 hour, the bath being exhausted by dding 2 per cent. of sulphuric acid after ½ hour's boiling. . (Test B: no change in shade or only a trace, no bleeding to white). 7 per cent. of Palatine Chrome Black 6 B (181) dyed with 10 per cent. of Glauber's salt and 3 per cent. of acetic acid, raising from 60° C. to the boil in ¼ hour, boiling ½ hour, exhausting gradually with 2 per cent. of sulphuric acid, cooling to 70° C., adding 2·5 per cent. of potassium bichromate and boiling lightly for 40 minutes. *Fastness with regard to white cotton.* I. (Test A: much bleeding into white). 2 per cent. Chrysophenine G (304). dyed with 10 per cent. of Glauber's salt, raising to the boil from 40° C. in 20 minutes, boiling for 1 hour and exhausting with 2 per cent. of acetic acid after boiling ¾ hour. III. (Test A: no bleeding into white). 2 per cent. Patent Blue (545) dyed as before. V. (Test B: no bleeding into white). 7 per cent. Palatine Chrome Black 6 B (181) dyed as before. 3*a*. *Fastness to water of dyed cotton.* The dyed material is plaited with white cotton, silk and wool in the proportion of two parts of dyed material to one part of white, steeped for 1 hour in a 40 volume bath of distilled water at about 20° C. and dried at the ordinary temperature. I. (After one steeping shade somewhat lighter, white stained). 2 per cent. Chrysophenine G (304) dyed as under 2a I. III. (After one steeping shade unchanged and white not stained). 2 per cent. Chloramine Yellow C (617) dyed as the foregoing. V. (After three steepings, each with fresh water, no change and no staining). 8 per cent. Immedial Carbon B (720) dyed as under 2*a* IV. 3*b*. *Fastness to water of dyed wool.* The sample is treated for 12 hours as under 3*a*. I. (After one steeping shade changed or lighter, white stained). 2 per cent. Azo Yellow (141) dyed with 10 per cent. of Glauber's salt and 10 per cent. of sodium bisulphate, 1 hour at the boil. III. (After one steeping shade unchanged, no bleeding). 2 per cent. Patent Blue A (545) dyed as under 2*b*. V. (After three steepings, each with fresh water, shade unchanged, no bleeding or only a trace). 7 per cent. Palatine Chrome Black 6B (181) dyed as under 2*b*. 4. *Fastness to rubbing.* A piece of unfinished white cotton is stretched over the index finger and rubbed backwards and forwards over the dyed material ten times with a stroke 10 cm. long. No types given. 5*a*. *Fastness to hot ironing of dyed cotton.* The dyed material is wrapped in thin, white, unfinished cotton which has been moistened with distilled water and pressed with an iron, so hot that a woollen thread pressed by it begins to be singed, until the damp wrapper has become quite dry. The shade of the ironed part is compared with the neighbouring unironed parts, while it is still hot. I. (Shade much changed, colour bleeds into the white cotton). 1·5 per cent. Methylene Blue B (659) dyed after the usual method for basic dyestuffs during 1½ hours in 20 parts of distilled water with 2 per cent. of acetic acid on material mordanted with 6 per cent. of tannin and 3 per cent. of antimony salt. III. (Shade somewhat changed, no bleeding). 1 per cent. Benzopurpurin 4B (363) dyed as under 2*a*. V. (No change, no bleeding). 1 per cent. Chloramine Yellow C (617) dyed as under 2*a* I. 5*b*. *Fastness to hot ironing of dyed wool.* The dyed material is pressed for 10 seconds with an iron so hot that it just fails to scorch a white wool thread. I. (Shade greatly changed, the original tone returning very slowly or incompletely on cooling). 2 per cent. Fuchsin S (524) dyed with 10 per cent. of Glauber's salt and 10 per cent. of sodium bisulphate, 1 hour at the boil. III. (Shade rather strongly changed, returning quickly). 2 per cent. Amarant (168) dyed with 10 per cent. of Glauber's salt and 10 per cent. of sodium bisulphate. heating from 60 C. to the boil in 20 minutes and boiling 1 hour. V. (No change). 2 per cent. Tartrazine (23) dyed as I. 6. *Fastness to storing of dyed wool and cotton.* The sample is plaited with an equal weight of white wool, steeped in a solution of 5 grms. of Marseilles soap per litre at the ordinary temperature, wrung out, kept in an atmosphere of sulphur dioxide for 12 hours, rinsed and dried. *Dyed cotton.* I. (Shade changed, white wool stained). 1 per cent. Diamond Fuchsin (512) dyed as for Methylene Blue under 5*a*. III. (Shade very slightly changed, no staining). 1 per cent. Columbia Blsck F extra (463) dyed as under 2*a* I. V. (No change). 1 per cent. Diamine Black BH (333) developed with β-naphthol as for Primuline under 2*a*. *Dyed wool.* I. (Shade somewhat strongly changed, no bleeding into white or very little). 2 per cent. Diamine Scarlet B (319) dyed as under 2*b* I. III. (Slight change in shade, no bleeding or only a trace). 2 per cent. Milling Red G (293) dyed with 10 per cent. of Glauber's salt and 2 per cent. of acetic acid, heating from 30° C. to the boil in 20—30 minutes, boiling lightly 1 hour and exhausting with 3 per cent. of acetic acid after boiling for ¾ hour. V. (No change in shade, no bleeding or only a trace). 2 per cent. Palatine Scarlet A (81) dyed with 10 per cent. of Glauber's salt and 10 per cent. of sodium bisulphate, raising from 60° C. to the boil in 20 minutes and boiling 1 hour. 7*a*. *Fastness to perspiration of dyed cotton.* The sample, plaited with an equal weight of white cotton, is steeped for 10 minutes at 80° C. in a solution containing 5 c.c. of neutral ammonium acetate (7·5 Bé.=30 per cent.) per litre of distilled water and then dried without rinsing. I. (Shade becomes lighter, white cotton strongly stained). 1 per cent. Chrysophenine G (304) dyed as under 2*a* I. III. (Shade unchanged, white stained). 1 per cent. Diamine Black BH (333) dyed as I. V. (No change, white not stained). 20 per cent. Indanthrene Blue RS in paste (638). 7*b*. *Fastness to perspiration of dyed wool.* The dyeing is spotted with a 10 per cent. salt solution, dried at the ordinary temperature and brushed. I. (Great change in shade). 2 per cent. Amarant (168) dyed as under 5*b* III. III. (Moderate change in shade). 2 per cent. Wool Green S (566) dyed with 10 per cent. of Glauber's salt and 10 per cent. of sodium bisulphate for 1 hour at the boil. V. (No change), 2 per cent. Brilliant Crocein 3B (227) dyed as under I. Alternative test: The sample, plaited with white wool and cotton is treated with ammonium acetate as for cotton. I. (Shade unchanged or very slightly changed, white wool and cotton stained). 2 per cent. Azo Yellow (141) dyed as under 3*b*. III. (No change in shade, cotton not stained, wool only a little). 2 per cent. Amarant (168) dyed as under 5*b*. V. (No change, no staining). 7 per cent. Palatine Chrome Black 6B (181) dyed as under 2*b*. 8. *Fastness to alkali* (*and to street mud and dust*). The sample is spotted with a mixture containing 10 grms. of lime and 10 grms. of ammonia (24 per cent.) in a litre of water, pressed, allowed to dry at the ordinary temperature and brushed. *Wool.* I. (Strong change in shade). 2 per cent. Water Blue (539) dyed with 10 per cent. sodium bisulphate, raising from 60° C. to the boil in 20 minutes and boiling ¾ hour. III. (Moderate change). 2 per cent. Amarant (168) dyed as under 5*b*. V. (No change). 7 per cent. Palatine Chrome Black 6 B (181) dyed as under 2*b*. *Cotton.* I. (Great change). 1·5 per cent. Malachite Green conc. (495) dyed on tannin-antimony mordant as under 5*a* I. III. (Moderate change). 1 per cent. Direct Deep Black E extra (463) dyed as under 2*a* I. V. (No change). 8 per cent. Diamine Black BH (333) dyed as under 2*a* II. 9*a*. *Fastness of dyed cotton to cross-dyeing.* The dyed material, plaited with an equal weight of white wool and of white cotton, is boiled in a 40 volume bath with 10 per cent. of sodium bisulphate on the weight of the material. I. (Shade a little lighter, white wool stained). 2 per cent. Chloramine Yellow C (617) dyed as under 2*a* I. III. (Shade not affected or only slightly, white wool only slightly stained). 3 per cent. Primuline developed as under 2*a*. V. (No change, no staining). 8 per cent. Immedial Carbon B (720) dyed as under 2*a* IV. 9*b*. *Fastness to cross-dyeing of dyed wool.* The dyed material, plaited with white wool, is treated in a 70 volume bath with a solution containing 2·5 grms. of sodium bisulphate per litre for 1½ hour at 90—92° C. I. (Shade only a little changed, white wool stained). 2 per cent. Chrome Yellow D (177) dyed with 10 per cent. of Glauber's salt and 3 per cent. of acetic acid, raising from 60° C. to the boil in ¼ hour, exhausting after boiling ½ hour with 2 per cent. of sulphuric acid, cooling to 70° C., adding 1·25 per cent. of potassium bichromate and boiling lightly for ½ hour. III. (Shade unchanged, white only slightly stained). 2 per cent. Diamine Scarlet B (319) dyed as under 2*b* I. V. (Shade unchanged, white not stained or only slightly), 6 per cent. Alizarin Black WX extra in paste (774) dyed with 10 per cent. of Glauber's salt and 5 per cent. of acetic acid, raising from 60° C. to the boil in 20 minutes, boiling ½ hour, then exhausting with 5 per cent. of acetic acid, boiling a further 20 minutes, cooling to 70° C., adding 2 per cent. of potassium bichromate, and boiling lightly for 40 minutes. 10. *Fastness to acid of dyed cotton.* The material is spotted with 10 per cent. sulphuric acid and with 30 per cent. acetic acid and the spots compared with a plain water spot. I. (Mineral acid: great change; organic acid: little change). 3 per cent. Diamine Scarlet B (319). III. (Mineral acid: great change. Organic acid: unchanged). 0·5 per cent. Chrysophenine G (304). V. (No change with either acid). 20 per cent. Indanthrene Blue RS in paste (838). 11. *Fastness to kier boiling of dyed cotton.* The sample is tested in two ways: A, boiling for 6 hours along with white unbleached cotton in a circulating kier together with 7·5 per cent. of soda ash, 0·5 per cent. of Marseilles soap and 1 per cent. of "Ludigol"; liquor to cloth ratio, 5:1. B, boiling as above without the "Ludigol." I. (Test A: completely destroyed). Congo Red. II. (Test A: almost completely destroyed). Methylene Blue B. III. (Test A: rather changed but not spoiled). Indigo. IV. (Test A: no change). Helindone Orange R (913). V. (Test B: no change). Turkey Red ("Old Red"). 12. *Fastness to chlorine of dyed cotton.* The sample is plaited with an equal weight of white cotton, wetted out and treated for 1 hour at 15° C. in bleaching powder solution containing 1 grm. active chlorine per litre (a 5° Bé., sp. gr. 1·037, liquor diluted 1:20 and checked by titration) or in a sodium hypochlorite solution, prepared from bleaching powder and sodium carbonate, containing 1 grm. active chlorine per litre and not more than 0·3 grm. of sodium carbonate per litre. The sample is afterwards rinsed, soured, rinsed and dried. I. (Sodium hypochlorite: shade lighter, white stained. Bleaching powder: shade much lighter, white stained). I per cent. Methylene Blue B (659) dyed as under 5*a*. II. (Sodium hypochlorite: shade changed, white not stained. Bleaching powder: shade much changed, white not stained). 6 per cent. Indanthrene Olive G in powder (791) dyed ½ hour at 60° C. in a 20 volume bath of distilled water made up with 5 parts of caustic soda of 40 Bé. (sp. gr. 1·383) and 2½ parts of hydrosulphite on the weight of the dyestuff. III. (Sodium hypochlorite: only a little lighter, white not stained. Bleaching powder: shade much lighter, white not stained). Indigo dyed to the strength of 3 per cent. Diamine Fast Blue FFB dyed as under 2*a* I. IV. (Sodium hypochlorite: no change, no staining. Bleaching powder: shade distinctly lighter, white not stained). 10 per cent. Hydron Blue G 20 per cent. paste (748) dyed as under II., but with ½ part of caustic soda of 40 Bé. (sp. gr. 1·383) and ½ part of hydrosulphite on the weight of dyestuff. V. (No change and no staining with either sodium hypochlorite or bleaching powder). Turkey Red ("Old Red"). 13. *Fastness to mercerising of dyed cotton.* The dyed material is stitched into bleached, unfinished cotton cloth and steeped for 5 minutes in cold caustic soda of 30 Bé. (sp. gr. 1·263), pressed, rinsed, soured, rinsed and dried. I. (Shade the least changed, white cotton somewhat stained). 4 per cent. Primuline (616) dyed as under 2*a*. III. (Shade unchanged, white only very slightly stained). 1 per cent. Chloramine Yellow C (617) dyed as under 2*a* I. V. (Shade unchanged, no staining). 8 per cent. Immedial Carbon B (720) dyed as under 2*a* IV. 14. *Fastness to bleaching of dyed wool.* The dyed woollen cloth is stitched with white wool, cotton and silk and bleached with a solution of 100 parts of distilled water and 20 parts of hydrogen peroxide (10—12 vol. per cent.), maintained slightly alkaline with ammonia. The sample is entered at 50° C. in a 40—50 volume bath, which is allowed to cool gradually during 12 hours. I. (No change in shade, or very little, but silk, wool and cotton stained). 2 per cent. Azo Yellow (141) dyed as under 3*b*. II. (Shade lighter, little bleeding). 2 per cent. Patent Blue A (545) dyed as under 2*b*. III. (Shade lighter, no bleeding). 2 per cent. Fast Yellow S (137) dyed as for Azo Yellow under 3*b*. IV. (Shade not changed or only slightly, some bleeding into silk and cotton but none into wool). 2 per cent. Chrysophenine G (304) dyed as under 2*b*. V. (No change in shade or bleeding, or only a trace). 2 per cent. Sulfoncyanin GR extra (257) dyed with 20 per cent. of Glauber's salt and 5 per cent. of ammonium acetate, raising from 40° C. in ½ hour and dyeing at 80°—90° C. for ¾ hour. 15. *Fastness to milling of dyed wool.* Two tests: A. Neutral milling. The dyed material, plaited with equal weights of wool and cotton, is treated at 30° C. in a 40 volume bath of 20 grms. of Marseilles soap per litre of distilled water. The sample is first milled by hand, then allowed to stand two hours, again milled and finally washed and dried. B. Alkaline milling. Same treatment as in A but at 40° C. and with the addition of 5 grms. of soda ash to the soap solution. *Fastness with white wool.* I. (Test A: decided change in shade, strong bleeding into white). 2 per cent. Azo Yellow (141) dyed as in 3*b*. II. (Test A: little change in shade, little bleeding). 2 per cent. Ponceau RR (82) dyed as for Orange II under 2*b*. III. (Test A: No change or only a trace, no bleeding). 6 per cent. Sulfoncyanin Black 2B (265) dyed as under 14 IV. IV. (Test B: no change or only a trace, little bleeding). 2 per cent. Chrome Yellow D (177) dyed as under 9*b*. V. (Test B: No change or only a trace, no bleeding). 7 per cent. Anthracene Chrome Black P extra (185) dyed as under 2*b* V. *Fastness with white cotton.* I. (Strong bleeding into white cotton). 2 per cent. Diamine Scarlet B (319) dyed as under 2*b* I. II. (Little bleeding). 2 per cent. Ponceau RR (82) dyed as for Orange II. under 2*b*. III. (No bleeding). 6 per cent. Sulfoncyanin Black 2B (265) dyed as under 14 IV. IV. (Little bleeding). 5 per cent. Diamond Black F (277) after-chromed with 1·5 per cent. of potassium bichromate, otherwise dyed as under 2*b* V. V. (No bleeding). 7 per cent. Diamond Black PV (157) dyed as under 2*b* V. 16. *Fastness to carbonising.* The sample is steeped in sulphuric acid of 5° Bé. (sp. gr. 1·037) for ½ hour, squeezed so as to retain 100 per cent. of moisture, dried at 80° C. for 1 hour, washed for ¼ hour with 200 parts of distilled water, squeezed, neutralised in 200 parts of sodium carbonate solution (2 per 1000), washed till neutral to litmus and dried. I. (Great change in shade). 2 per cent. Alizarin Red W (780) dyed with 2 per cent. of acetic acid, raising from 30° C. to the boil in ½ hour and boiling 1½ hour, on wool previously mordanted with 3 per cent. of potassium bichromate and 2½ per cent. of sodium bisulphate 1¼ hour at the boil. III. (Little change). 2 per cent. Orange IV (139) dyed with 10 per cent. of Glauber's salt and 10 per cent. of sodium bisulphate 1 hour at the boil. V. (No change or only a trace). 2 per cent. Palatine Scarlet A (81) dyed with 10 per cent. of Glauber's salt and 10 per cent. of sodium bisulphate, raising from 60° C. to the boil in 20 minutes and boiling 1 hour. 17. *Fastness to potting of dyed wool.* Two tests: A. The dyed material, plaited with equal weights of white wool and cotton, is treated with 60 parts of distilled water at 90° C., washed and dried. B. As in A with the addition of 1 grm. of Marseilles soap per litre. I. (Test A: shade changed, white wool or cotton strongly stained). 2 per cent. Patent Blue A (545) dyed as under 2*b*. III. (Test A: No change or only a trace, wool and cotton somewhat stained). 5 per cent. Diamond Black F (277) dyed as under 15 IV. V. (Test B: no change or only a trace, no bleeding). 7 per cent. Alizarin Black WX extra, dyed as under 2*b* V. 18. *Fastness to decatising of dyed wool.* Two tests: A. The material is wound on a decatising cylinder and steamed in a closed apparatus for 5 minutes at a pressure of 1 atmosphere. B. The same but at 2·5 atmospheres pressure for 10 minutes. I. (Test A: rather great change in shade). 2 per cent. Sulfoncyanin GR extra (257) dyed as under 14 V. III. (Test A: no change). 2 per cent. Crocein AZ (225) dyed as Brilliant-Crocein 3B under 7*b*. V. (Test B: no change). 9 per cent. Naphthol Black 6B (269) dyed with 10 per cent. of sodium bisulphate, raising from 40° C. to the boil in ½ hour and boiling lightly 1 hour. 19. *Fastness to sea water of dyed wool.* The dyed material, plaited with an equal weight of white wool, is treated for 24 hours with 40 parts of a cold solution containing 30 grms. of salt and 6 grms. of calcium chloride per litre and dried without rinsing. I. (Shade only slightly changed, white wool strongly stained). 2 per cent. Chrysoin (143) dyed as under 3*b* I. III. (Shade not changed or only very slightly, white somewhat strongly stained). 2 per cent. Cyanol extra (546) dyed as under 2*b* III. V. (No change, no staining). 6 per cent. Sulfoncyanin Black (265) dyed as under 14 V.—J. B.

Adsorption in solutions. II. G. von Georgievics. Kolloid-Zeits., 1914, **14**, 69—74.

The author has shown previously (this J., 1912, 68) that in the absorption of acids by wool there is first solution of the acid by the wool, followed by adsorption. In Boedecker's distribution formula: $\frac{\sqrt[x]{C_{\text{liquor}}}}{C_{\text{fibre}}} = K$, if $x = 1$, the process is one of solution, and in cases of solution plus adsorption, the value of x is greater than 1 and increases with the amount of adsorption. The values of x for the absorption of thirteen different acids by wool are tabulated. They follow the same order as the relative "strengths" of the acids, and the author draws the conclusion that the adsorption as distinct from the solution of the acids is due to the chemical affinity of the acids for wool substance. Evidence is cited in favour of the view that this hypothesis of adsorption is of general application.
—A. S.

Wool; The action of formaldehyde on ——, and a note on the constitution of wool. A. Kann. Färber-Zeit., 1914, **25**, 73—75.

When treated with formaldehyde solution of about 4 per cent. concentration wool becomes resistant to the action of alkali and at the same time loses its affinity for dyestuffs. The author has found that by the use of very weak formaldehyde (solutions containing 0·25 or as low as 0·10 per cent. of commercial formaldehyde) the wool can be protected against the tendering action of alkali without loss of affinity for dyestuffs. The reaction between wool and formaldehyde takes place with great ease in slightly alkaline solution and much less advantageously in acid or neutral solution. Wool thus treated can be dyed with sulphide dyestuffs, it shrinks less on steaming and it can be scoured with caustic alkali, using very little soap. The treated wool reacts with nitrous acid just like untreated wool. This shows that wool does not contain an amino group, for such a group would have been rendered inactive by the formaldehyde. It is concluded that wool contains the imino group, and the product of reaction with nitrous acid is a nitrosamine. Wool treated with nitrous acid retains its power of reacting with formaldehyde so that the condensation must be of the aldol type and takes place with the carboxyl groups of the wool. These facts support the view that wool contains imino and carboxyl groups and not amino and ketonic groups.
—J. B.

Patents.

[Scouring] Textile piece goods, warp yarns and the like; Machines for treating —— with liquids. J. S. Ainley, Huddersfield. Eng. Pat. 6970, March 22, 1913.

In a machine of the usual type for scouring warps or fabrics in rope form, the sloping side on which the material falls from the taking-off roller is provided with an endless apron between which and another endless apron the fabric is grouped in folds, in which form emerging from beneath the upper apron it comes under a "possing" or squeezing plate. The two aprons and the squeezing plate are all driven intermittently.—J. B.

Ozone: Treating [bleaching] fibrous materials with ——. E. Gminder, Reutlingen, Germany. Eng. Pat. 28,763. Dec. 12, 1913. Under Int. Conv., Dec. 14, 1912.

The goods, more especially laundry goods, are treated in a hydro-extractor with a spray produced by atomising water with ozonised air.—J. B.

Fast shades on vegetable fibres; Production of —— and dyestuffs therefor. H. Levinstein, J. Baddiley and Levinstein, Ltd., Manchester. Eng. Pat. 1435, Jan. 17, 1913.

The new dyestuffs are produced by combining the tetrazo-compound of a diamine with 2 mols. of middle components capable of undergoing re-diazotisation after coupling, at least one of which is an extra-nuclear amino-derivative of an aminonaphtholsulphonic acid; tetrazotising the intermediate product thus obtained and combining with 2 mols. of resorcinol. The dyestuffs by after-treatment on the fibre with formaldehyde become fast to washing. Shades ranging from orange to purple and dark green are produced; for instance, tetrazotised *m*-azoxytoluidine combined with 1 mol. of *m*-aminobenzoyl-2-amino-5-naphthol-7-sulphonic acid and 1 mol. of 2-amino-5-naphthol-7-sulphonic acid, tetrazotised and combined with 2 mols. of resorcinol gives an orange colour.—J. B.

Dyeing textile fibres; Machines for ——. J. Fitton, Wakefield. Eng. Pat. 13,210, June 7, 1913.

The dye-vat is provided with an inner concentric vessel, the vertical sides of which are perforated. Inside this again is a movable vessel which also has its vertical sides perforated. The material is packed in the space between these two perforated walls and the dye-liquor is circulated horizontally through the material from the inside of the innermost vessel by means of a pump.—J. B.

Dyeing pelts, hairs, feathers, etc.; Process for ——. Act.-Ges. für Anilin-Fabr., Berlin. Eng. Pat. 61, Jan. 1, 1914. Under Int. Conv., June 14, 1913.

A clear greenish yellow shade is produced by treating the material, mordanted or not, with a solution of 2-hydroxy-3-methoxybenzaldehyde (a by-product in the manufacture of vanillin).—J. B.

Dry-dyeing of furs or fur goods; Process for the ——. O. Lange. Ger. Pat. 266,515, Feb. 2, 1913.

Compounds obtained by heating oxidisable organic bases, such as *p*-phenylenediamine, with olein, are dissolved in the baths, in which carbon tetrachloride, petroleum spirit, etc., is used as solvent.—T. F. B.

Dyeing [and impregnating] materials which are difficult to dye completely; Process for ——. J. Weller. Ger. Pat. 266,708, Jan. 24, 1913.

Hard substances, such as wood, stone, horn, etc., or densely packed textiles, such as cops, are treated with an easily volatile substance, such as ether, carbon tetrachloride, or petroleum spirit, and then immersed in hot dyestuff solutions. The preliminary treatment may also be applied before impregnating wood, horn, or stone with substances other than dyestuffs.—T. F. B.

Aniline Black; Process for producing ——. A. Ehrenzweig. Ger. Pat. 267,628, Jan. 13, 1912.

p-Phenylenediamine or its homologues, a copper salt, a chlorate, aluminium acetate, and lactic acid are used in the production of Aniline Black. The fibres are dried at temperatures up to 100° C. The following proportions are given:—For 100 litres of dyebath are added (*a*) 4000 grms. of aniline oil, 5200 grms. of 30 per cent. hydrochloric acid, and 2600 grms. of 50 per cent. lactic acid, (*b*) 320 grms. of powdered alumina and 1120 grms. of acetic acid of 8·5° B. (sp. gr. 1·064), (*c*) 350 grms. of *p*-phenylenediamine, 700 grms. of sodium chlorate and 840 grms. of copper sulphate.—T. F. B.

Dyeings on vegetable and animal fibres; Process for producing fast ——. Chem. Fabr. Griesheim-Elektron. Ger. Pat. 268,779, June 22, 1911.

A diazoamino compound of the anthraquinone series is converted into its leuco compound by treatment with an alkaline reducing agent, this is applied to unmordanted animal or vegetable fibre, and the dyestuff is developed by oxidation.—T. F. B.

Discharges on indigo or similar dischargeable dyestuffs; Process for producing white or coloured ——. C. Sunder, and Moritz Ribbert A.-G. Ger. Pat. 267,408, Feb. 1, 1913.

The dyed goods are printed with a paste containing glucose, zinc oxide, and stannous oxide, or a tin salt, with or without an undischargeable vat dyestuff; after drying, the goods are passed through a boiling bath of caustic soda or potash of 20° B. (sp. gr. 1·162), washed and dried.—T. F. B.

VII.—ACIDS; ALKALIS; SALTS; NON-METALLIC ELEMENTS.

Sulphur in pyrites; New method for the determination of ——. E. Martin. Monit. Scient., 1914, **4**, 86.

Details are given of certain precautions necessary in the volumetric method described recently (this J., 1913, 1065): to ensure complete precipitation of the barium carbonate it is essential to have present a considerable excess of sodium carbonate and to use only sufficient carbon dioxide just to discharge the pink colour of the phenolphthalein.—A. S.

Ammonia soda process; Another form of the ——. P. P. Fedotieff and J. Koltunoff. Z. anorg. Chem., 1914, **85**, 247—260.

In view of the advantages of carrying out the ammonia soda reaction with sodium nitrate as raw material (see Colson, this J., 1910, 190), the authors made a complete study of the reaction on the same lines as that of the ammonia soda reaction proper (this J., 1904, 865). Working in the same way as with sodium chloride (*i.e.*, by passing carbon dioxide into an ammoniacal solution of the nitrate) the results are similar to those obtained in the ordinary process. The mother liquor may be treated with lime and a residue of calcium and sodium nitrates obtained, valuable for manurial purposes; or the liquor may be evaporated till all the dissolved sodium bicarbonate has reacted with ammonium nitrate, giving off carbon dioxide and ammonia, then further evaporated to about half the volume, when about half of the ammonium nitrate will crystallise out. On adding sodium nitrate, ammonia and water in quantities sufficient to bring the solution back to its original composition, and carbonating, all the newly added sodium nitrate will be converted into bicarbonate and 87 per cent. of the ammonia into ammonium nitrate, while the remaining 12 per cent. of ammonia can be recovered on evaporation.—W. H. P.

Calcium hydroxide. T. Seliwanow. Z. anorg. Chem., 1914, **85**, 329—352.

Amorphous calcium hydroxide usually yields more water than corresponds with the formula $Ca(OH)_2$, but it reaches this composition on drying at 110° C., or in a desiccator at ordinary temperatures. The excess water is greater in specimens of the hydroxide obtained by precipitation of calcium chloride with sodium hydroxide, than in specimens obtained by slaking the oxide, although the latter on being kept under water for a long time approach the former in moisture content. The precipitated hydroxide absorbs water vapour more readily than the slaked hydroxide, the absorption being similar to that for other colloidal substances, with no definite hydrate formation. A crystalline hydroxide can be obtained from supersaturated solutions by evaporation at 28°—30° C. under reduced pressure. It has the formula $Ca(OH)_2$ and is less soluble than the amorphous product. Supersaturated solutions which readily deposit crystalline hydroxide on warming, are indifferent to the solid hydroxide and do not deposit their excess at ordinary temperatures. The cryohydrate obtained by freezing lime water is a mixture of ice with $2Ca(OH)_2,H_2O$. The latter is less soluble than, and has a characteristic crystalline form quite different from, that of the hydroxide; it is unstable, readily passing into the amorphous hydroxide. The author concludes that the amorphous hydroxide is a polymeride of $Ca(OH)_2$, containing not less than four atoms of calcium in its molecule. The crystalline product is probably not less complicated, and this view is supported by its polymorphism.—W. H. P.

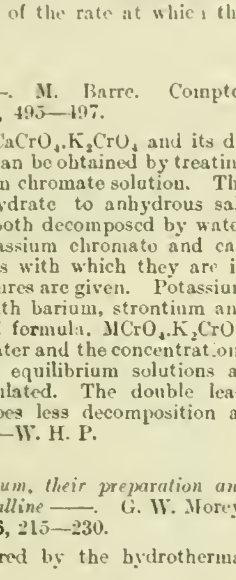
Sulphates; Physico-chemical determination of ——. A. Kling and A. Lassieur. Comptes rend., 1914, **158**, 487—489.

The criticisms advanced by Bruno and d'Auzay (this J., 1912, 506 and 742) against Dutoit's method of determining sulphates (this J., 1908, 871 and 912) are endorsed by the authors, who used barium acetate as precipitant. The low results obtained are attributed to the removal of soluble sulphate by the earlier portions of the barium sulphate precipitate. This removal is most pronounced in the more concentrated solutions at low temperatures, and in the presence of alcohol. It is more marked with potassium and rubidium sulphates than with those of the other alkali metals. It only takes place when the barium sulphate is precipitated *in situ*; a potassium sulphate solution suffers no fall in concentration on being left in contact with previously precipitated barium sulphate. In alkaline solutions the alkali is absorbed and the sulphate left in solution, and a precipitate containing absorbed sulphate may have this partially displaced on treatment with alkali. The actual extent of the absorption is a function of the rate at which the precipitant is added.—W. H. P.

Double chromates; Some ——. M. Barre. Comptes rend., 1914, **158**, 495—497.

Calcium potassium chromate, $CaCrO_4.K_2CrO_4$ and its dihydrate, $CaCrO_4.K_2CrO_4.2H_2O$ can be obtained by treating calcium chromate with potassium chromate solution. The transition temperature from hydrate to anhydrous salt is about 45° C. The salts are both decomposed by water and the concentrations in potassium chromate and calcium chromate of the solutions with which they are in equilibrium at various temperatures are given. Potassium chromate forms double salts with barium, strontium and lead chromates of the general formula, $MCrO_4.K_2CrO_4$. These also are decomposed by water and the concentrations of potassium chromate in the equilibrium solutions at various temperatures are tabulated. The double lead salt unlike the others undergoes less decomposition at high than at low temperatures.—W. H. P.

Silicates of potassium and sodium, their preparation and general properties; New crystalline ——. G. W. Morey. J. Amer. Chem. Soc., 1914, **36**, 215—230.



The new silicates were prepared by the hydrothermal method, the reacting substances being heated in presence of water in a closed bomb at a high temperature and consequent high pressure. The bomb used, made of tool steel, consisted of a cylinder, E, 3 ins. diam. and 8 ins. long, in which was bored a hole of 1¼ in. diam. enlarged at the top to receive the plug, B, which was screwed down hard by means of a wrench; between the plug and the plunger was a steel washer to ensure that the latter did not rotate when the plug was screwed down. The ½-in. rod, C, of the plunger passed through the washer and the plug with a clearance of about $\frac{1}{32}$ in. The plunger fitted tightly into the bomb just above and below the shoulder and the joint was sealed by a flat copper washer, D, $\frac{1}{16}$ in. thick, which was softened by annealing in a flame just before use. A bomb of this type was used in 200 experiments without a leak being observed. It was heated in an electric furnace, and the temperature measured by a thermo-element inserted in the hole, F, ¼ in. diam. The reacting substances, usually water and finely powdered glasses (made from quartz and alkali carbonate), were placed in the gold crucible, G. The products obtained varied according to the temperature, composition of the original glass (ratio of alkali oxide: silica) and concentration of the water (pressure) Four new crystalline silicates, namely $K_2Si_2O_5$, $KHSi_2O_5$, $Na_2Si_2O_5$ and Na_2SiO_3, were obtained, all in the form of orthorhombic crystals. $K_2Si_2O_5$ and Na_2SiO_3 were readily attacked by water, $Na_2Si_2O_5$ less readily, whilst $KHSi_2O_5$ was not appreciably decomposed even when left in contact with water for some hours at 100 C. A series of hydrous glasses was also obtained representing supercooled solutions unsaturated under the experimental conditions. They were quite hard though containing up to 25 per cent. of water. When heated in the air they lost water, and swelled up to a sponge-like mass often with extremely thin vesicular walls. In most of the experiments the bomb after being heated was plunged into cold water: when the crucible was supported in the upper part of the bomb, so that on cooling, the vapour space, below the crucible, was cooled more rapidly than the reaction-mixture, the resulting rapid diminution of pressure caused the water in the mixture to vaporise suddenly and a nearly anhydrous, light, porous pumice-like product was obtained.—A. S.

Persilicates; The possible existence of ——. E. Jordis. Chem.-Zeit., 1914, **38**, 221—222.

When a solution of an alkali silicate is electrolysed, a portion of the oxygen set free at the anode is absorbed; the same takes place in the case of sulphuric acid solutions of silicates where the dilution is such as to prohibit the formation of persulphates. These facts afford some support for the assumption that persilicates are capable of existing (see also this J., 1914, 199). Solutions of alkali silicates absorb oxygen when exposed to the air for about 12 months; on acidifying such solutions with hydrochloric acid, chlorine is evolved together with large quantities of carbon dioxide.—W. P. S.

Molybdenum; Preparation of a metaphosphate of tervalent ——. A. Colani. Comptes rend., 1914, **158**, 499—501.

Molybdic acid can be reduced in the presence of phosphoric acid at a high temperature by a variety of methods with the formation of a yellowish crystalline substance of the formula, $Mo(PO_3)_3$. The most convenient reducing agent is molybdenum sulphide, and the reaction is carried out in a gold Rose crucible in a current of carbon dioxide. The phosphate has the sp. gr. 3·28 at 0 C. and remains unaltered in dry air. It only oxidises slightly on being heated and is practically unaffected by mineral acids at 100° C. It is slowly attacked by boiling sulphuric acid or cold *aqua regia*, and it dissolves completely in a sealed tube at 200° C. in a slightly acid solution of bichromate or iodic acid. Heated with water alone in the absence of air to 250°—300° C., it gives phosphoric acid and a small quantity of hydrogen.—W. H. P.

Oxides of cobalt. H. T. Kalmus. J. Ind. Eng. Chem., 1914, **6**, 115—116.

Many oxides of cobalt have been described in the literature, but the existence of several of them is doubtful and only the three oxides, Co_3O_4, Co_6O_7 and CoO, are of special concern to the manufacturer of commercial cobalt oxide. When cobalt hydroxide produced by precipitating a chloride or sulphate solution with bleaching powder, is calcined at 105° C., a chocolate brown powder, $Co_2O_3.H_2O$, is produced, which on heating at a higher temperature (385°—910° C., preferably about 750° C.) is converted into a black oxide consisting, like the commercial black oxide, of Co_3O_4, mixed with a small proportion of Co_6O_7. Above 910° C. the black oxide loses oxygen and changes gradually into the gray monoxide, CoO, which can be reduced to metal by carbon monoxide above 450° C. or by hydrogen above 250 C. The monoxide also exists as a yellow-green modification, which can be obtained by heating Co_3O_4 with 2—3 per cent. of carbon at about 900° C. The monoxide is oxidised to Co_3O_4, or Co_3O_4 plus Co_6O_7, when heated in air at 385°—910° C. The oxides mentioned are all non-magnetic.—A. S.

Lead chloride and potassium chloride in aqueous solution; Equilibrium between ——. Demassieux. Comptes rend., 1914, **158**, 183—184.

Isothermals at 14°, 50° and 100° C. are represented graphically. The three curves are of the same general form, and show branches corresponding to the existence of two double salts, $2PbCl_2,KCl$ and $PbCl_2,KCl,\frac{1}{3}H_2O$.
—J. H. L.

Sulphur dioxide with ammonia; Products of the reaction of ——. M. Ogawa and S. Aoyama. Science Rep. Tôhoku Imp. Univ., Ser. I., 1913, II, 121—129.

With ammonia in excess, and in ethereal solution at the temperature of a mixture of ice and salt, under the conditions given by Divers and Ogawa (this J., 1900, 245) sulphur and ammonia give the white ammonium aminosulphite, $NH_2SO_2NH_4$; with sulphur dioxide in excess, the pale-yellow aminosulphurous acid, NH_2SO_2H, is formed. At ordinary temperatures, if the excess of ammonia is removed, the ammonium salt decomposes to a red mass containing sulphite, sulphate, trithionate, and sulphamide; the acid decomposes on slight warming to a similar mass. The red substance is not a compound of the formula $N_4H_{12}S_5O_{10}$, as supposed by Divers and Ogawa, but is principally ammonium trithionate. Ephraim and Piotrowiski (this J., 1911, 358) have denied that the red substance is a decomposition-product, on the ground that they obtained it directly at —38° C.; but this was because the reacting gases were imperfectly controlled, and the heat of the reaction dissipated with insufficient rapidity.—O. E. M.

Colloidal solutions; Preparation of —— by mechanical subdivision. G. Wegelin. Kolloid-Zeits., 1914, **14**, 65—69.

The author has succeeded in converting a number of substances into the colloidal condition by more or less prolonged grinding in an agate mortar, preferably with addition of a little water. Colloidal solutions of vanadium pentoxide and trioxide, silicon, antimony, and tungstic, titanic and molybdic acids were prepared in this way, but negative results were obtained with the ductile metals, copper and bismuth, and with selenium, tellurium, graphite, sulphur, violet chromium chloride, calcium fluoride, oxides of copper, iron, cobalt, and zinc, and lead dioxide. The properties of the vanadium pentoxide and trioxide sols are described in detail. A colloidal solution of vanadium pentoxide in alcohol was prepared in a similar manner, but negative results were obtained with petroleum coagulation. Starch after being ground in an agate mortar benzine and addition of the latter to the alcohosol caused swelled immediately when treated with cold water, and on further grinding, a solution was obtained which could be filtered clear and gave an intense blue colour with iodine.—A. S.

Iodine; Solubility of —— in sodium iodide solution. H. W. Gill. J. Chem., Met. and Min. Soc., S. Africa, 1913, **14**, 290—292.

By substituting sodium iodide for the potassium salt in iodometric analysis, the iodine can be recovered from waste solutions (this J., 1913, 961). The solubility of iodine in sodium iodide was found to be directly proportional to the concentration of the iodide; each 1 per cent. of iodide brings about the solution of 1 per cent. of iodine, from which it would seem that a compound $NaI_2,2H_2O$ exists in solution.—W. R. S.

Kaolin; Catalytic effect of —— on the union of hydrogen and oxygen. J. Joannis. Comptes rend., 1914, **158**, 501—504.

The presence of kaolin favours the combination of hydrogen and oxygen at temperatures from 230° C. upwards, *i.e.*, considerably below the temperature (above 350° C.) at which is can be observed in absence of kaolin. The amount of water formed appears to be proportional to the time of contact between the gases and the catalyst. The activity of the kaolin depends greatly upon the temperature at which it has previously been heated, and the extent to which it has lost its water of constitution. The lower the water content the smaller is the activity.
—W. H. P.

Oxygen and nitrogen; The Plumboxan process for the decomposition of atmospheric air into ——. G. Kassner. Arch. Pharm., 1913, **251**, 596—609. (See also this J., 1911, 621.)

Steam is passed over a mixture of an alkali metaplumbate and an alkali manganate (Plumboxan), at a temperature of 400°—500° C., when oxygen is evolved. The mixture can be regenerated by passing dry air over it at the same temperature. Under suitable conditions the absorption of oxygen is complete and pure nitrogen is obtained. The mechanism of the reaction is discussed in detail and evidence brought forward in support of the view that the evolution of oxygen is due to the alternate formation and decomposition of a perplumbate. Using 1 kilo of Plumboxan, a litre of oxygen can be obtained in 5 minutes by treatment with steam at 400° C., whilst at temperatures of 450°—500° C., the rate of production is doubled or trebled.
—F. Shdn.

Active nitrogen. E. Tiede and E. Domcke. Ber., 1914, **47**, 420—425. (See also this J., 1913, 232; 1914, 76.)

By means of a jointless glass apparatus in which commercial nitrogen (Linde) was passed over copper heated electrically to a temperature measured by a thermocouple, it was shown that the after-glow was suppressed unless the nitrogen was purposely contaminated with oxygen, provided that the temperature and pressure were such that no dissociation of copper oxide took place. On raising the temperature beyond a limit depending on the pressure, the glow was restored. The phosphorescence of sulphur, iodine, sodium, and thallium chloride, observed on heating them in nitrogen which has been subjected to the action of the electric discharge, and attributed by Strutt to the presence of active nitrogen, was similarly suppressed in the absence of oxygen.—O. E. M.

Ozone, nitrogen peroxide and hydrogen peroxide; Determination and distinction of ——, at high dilutions. J. N. Pring. Chem. News, 1914, **109**, 73—75.

Potassium iodide dissolved in its own weight of water was used as the reagent. In the case of ozone the ratio of free iodine (plus hypoiodite) to iodate (plus periodate) decreased with the total amount of ozone passed and also with the concentration of the ozone. The ratio was determined by successive titration with sodium thiosulphate in neutral and acid solution. With very dilute ozone mixtures the former products were formed exclusively and the amount of alkali produced was too small to be detected with phenolphthalein or litmus. The alkalinity test was therefore inconclusive in the case of highly diluted ozone. The iodine test failed when the dilution was greater than one part of ozone per million parts of gaseous mixture; at twice this concentration ozone still had a decided odour. Below the cryoscopic point of the reagent (—24° C.) iodate always predominated. Nitrogen peroxide differed from ozone in always yielding iodate as the main product in neutral solution. With an acid solution of the reagent in contact with atmospheric oxygen even minute quantities of nitrogen peroxide could be detected through a characteristic catalytic process, whereby iodine was continuously liberated. Very dilute gaseous mixtures of hydrogen peroxide behaved like similar mixtures of ozone; but with increasing concentration the final result was a catalytic decomposition of the peroxide:

$$KIO + H_2O_2 = KI + H_2O + O_2.$$

A solution of titanium sulphate in sulphuric acid turned yellow in presence of traces of hydrogen peroxide but was unaffected by ozone.—J. R.

Phosphorus; The modifications of ——. I. The transformations of phosphorus vapour by the silent electric discharge. V. Kohlschütter and A. Frumkin. Z. Elektrochem., 1914, 20, 110—123.

The action of the silent electric discharge on phosphorus vapour results in the formation of a layer of a homogeneous product of a high degree of dispersion. The degree of dispersion and consequently the appearance of the deposit vary considerably with the nature of the indifferent gas present in the tube, just as they do in the case of metals under somewhat similar circumstances (this J., 1912, 645). Argon and helium at 0·5 mm. pressure produce a kind of loosening of the deposit which is more marked in the case of argon than in that of helium. An excess of phosphorus vapour beyond the quantity transformed, which can be ensured by heating the tube, has also a similar effect. Argon and phosphorus vapour are absorbed by the deposit and can be expelled by subsequent heating. Hydrogen and nitrogen unite with the phosphorus vapour under the influence of the discharge, forming solid compounds. These compounds may be deposited in the layer of transformed phosphorus without affecting its homogeneous appearance under the microscope. It is only at relatively high pressures that visible quantities of different solids are formed. On heating the homogeneous deposits obtained under various conditions they are all transformed into ordinary red phosphorus, and the differences in colour caused by differences in the conditions of deposition entirely disappear. The process and the structural forms observed appear to be very similar to those observed in the case of silver (this J., 1912, 188). The original deposits are related to Hittorf's phosphorus, in the same way as mirror silver to the crystalline metal. Just as the degree of dispersion of the mirror silver decreases on heating so does that of the phosphorus, the somewhat sintered red phosphorus being formed. This is a disperse form analogous to anhydrous stannic oxide gel, and in suitable "mineralising" melts may be converted into Hittorf's crystalline phosphorus just as the stannic oxide can be converted into cassiterite.—W. H. P.

Artificial graphite; Sulphuretted hydrogen from ——. W. H. Woodcock and B. Blount. Analyst, 1914, 39, 67—69.

A sample of Acheson's massive graphite emitted hydrogen sulphide when broken or scraped. It contained 0·11 per cent. S. and 0·20 per cent. of ash consisting of:—Si 0·052, Al 0·014, Fe 0·012, Ca 0·029, and Mg 0·008 per cent. Experiments showed that hydrogen sulphide was not occluded by the material, but that the gas was derived from an unstable sulphide of the type Al_2S_3, which is decomposed by moist air, when not protected by the graphite. It was pointed out by W. J. A. Butterfield that minute traces of hydrogen sulphide could be detected by the odour with more certainty than by means of lead acetate paper as ordinarily used.—C. A. M.

Esters of chromic acid. Wienhaus. *See* XX.

Solubility of silica in hydrochloric, nitric, and sulphuric acids. Wunder and Suleimann. *See* XXIII.

Analysis of nitrates, chlorates and peroxides by reduction. Russo and Sensi. *See* XXIII.

Patents.

Phosphoric acid; Method of manufacturing ——. M. M. Haff, Assignor to T. L. Willson, Ottawa, Canada. U.S. Pat. 1,084,856, Jan. 20, 1914.

A charge of phosphatic and silicious material is fused in an electric furnace, broken carbon is placed on the bath to form a conducting path of increased current density, and air is mixed with the furnace gases to re-oxidise any reduced phosphorus oxides.—O. R.

Boron nitride; Manufacture of stable ——. The British Thomson-Houston Co., Ltd., London. From General Electric Co., Schenectady, N.Y., U.S.A. Eng. Pat. 12,377, May 27, 1913.

Boron nitride is stabilised by heating to 2000° C. or more in an electric resistance furnace, preferably in the presence of about 20 per cent. of a boron compound, which is volatile at the temperature of treatment, the resulting atmosphere of boron compounds serving to prevent oxidation of boron nitride.—O. R.

Nitrides; Process of manufacture of ——. G. Coutagne. First Addition, dated Nov. 8, 1912, to Fr. Pat. 457,992, July 25, 1912 (this J., 1913, 1010).

When the second electrode is constituted as described in the chief patent, either by one of the agglomerated carbon rings of the furnace lining, or by a carbon bar encased in one of these rings, the arc is no longer caused to rotate rapidly but remains fixed; its point of attachment to the second electrode then either describes a circle or turns about its own axis, according as it is attached eccentrically or axially, its motion being imparted to it by the slow rotation of the furnace and being unaffected by the gaseous current.—O. R.

Chromic acid salts of the heavy metals and of the alkaline earth metals; Process for the manufacture of ——, and also of chromium colouring matter. J. Mühlbauer, Prague, Bohemia. Eng. Pat. 14,226, June 19, 1913. Under Int. Conv., June 19, 1912.

Alkaline-earth chromates are obtained by heating chromic oxide or hydroxide with alkaline-earth oxides or hydroxides to a red heat in an oxygen-containing gas under pressure; by the similar treatment of chromic oxide or hydroxide, alone or together with oxides or hydroxides of the heavy metals, intensely coloured pigments are produced.—O. R.

Hydrocyanic acid [from residues of coal-gas purification]; Process for the manufacture of ——. Fabriques de Produits Chimiques de Thann et de Mulhouse, Thann, Germany, South Metropolitan Gas Co., London, and G. Freyss, Nancy, France. Eng. Pat. 18,168, Aug. 9, 1913.

The sludge obtained by washing crude coal-gas with ferrous sulphate solution, is boiled with slaked lime until free from ammonium compounds, and the resulting calcium ferrocyanide is treated with ammonium sulphate to form a precipitate of calcium-ammonium ferrocyanide and calcium sulphate, which is filtered off, washed, and boiled with dilute sulphuric acid with the formation of pure hydrocyanic acid and ammonium ferrous ferrocyanide, the latter compound yielding calcium ferrocyanide again when boiled with lime. The reactions are represented by the equations: (1), $Ca_2Fe(CN)_6 + (NH_4)_2SO_4 = Ca(NH_4)_2,Fe(CN)_6 + CaSO_4$; (2), $2Ca(NH_4)_2Fe(CN)_6 + 3H_2SO_4 = Fe(NH_4)_2Fe(CN)_6 + 2CaSO_4 + (NH_4)_2SO_4 + 6HCN$: (3), $Fe(NH_4)_2Fe(CN)_6 + 2Ca(OH)_2 = Ca_2Fe(CN)_4 + Fe(OH)_2 + 2(NH_4)OH$.—O. R.

Common salt; Manufacture of ——. International Salt Co., Ltd., London. Eng. Pat. 22,455, Oct. 6, 1913. Under Int. Conv., July 31, 1913.

Common salt is fused in a furnace, then run continuously into a revolving system of concentric pans, disposed one below the other; as the material cools and overflows from one pan into another, it is stirred by means of a pronged device, adapted to be lowered into each of the pans as required, the granulated salt being automatically discharged from the finishing pan by means of a tubular scoop.—O. R.

Phosphorus pentachloride; Manufacture of ——. S. Peacock, Philadelphia. Pa., U.S.A. Eng. Pat. 23.023. Oct. 11, 1913.

Tri-calcium phosphate is heated with potassium chloride in an atmosphere void of oxygen, in proportions corresponding with the equation: $Ca_3P_2O_8 + 10KCl = 3CaO + 5K_2O + 2PCl_5$. To obtain a high velocity of reaction and to minimise dissociation of the pentachloride, the gaseous products of the reaction are removed by suction, a yield of 97—98 per cent. being obtained at a temperature of about 1100° C. and a pressure of about 500 mm. If desired, the phosphorus pentachloride may be treated with hot water to form phosphoric and hydrochloric acids, and caustic potash may be recovered from the solid residue of the double decomposition.—O. R.

Calcium cyanamide; Process of producing ——. Dettifoss Power Co., Ltd., and J. H. Lidholm, London. Eng. Pat. 28.524, Dec. 10, 1913. Under Int. Conv., Feb 24, 1913.

Calcium carbide is introduced continuously but gradually into a furnace chamber, which is heated to a high temperature and supplied with nitrogen; owing to the small quantity of carbide fed into the furnace at a time, the material almost instantly acquires the reaction temperature, so that the fresh carbide is constantly being heated by the heat of reaction of cyanamide in the process of formation; the block of cyanamide, when complete, is removed all at once from the reaction chamber. to which end it is collected in a separate vessel, having perforated sides and resting on the furnace bottom; the latter is removable and quickly replaceable by another furnace bottom carrying an empty collector, so that no appreciable amount of heat is lost when changing collectors.—O. R.

Lead salts of acetic acid; Manufacture of ——. A. G. Bloxam, London. From Westdeutsche Bleifarbenwerke Kalkow G.m.b.H., Offenbach a/M., Germany. Eng. Pat. 29,048, Dec. 16, 1913.

A mass of lead rests inside a cylindrical vessel upon a grating, the space between which and the bottom of the vessel contains acetic acid or normal lead acetate solution; the level of the liquid reaches to just below the grating. Compressed air is forced through the liquid and raises it in the form of foam into intimate contact with the superposed lead, with the result that the lead is rapidly oxidised and dissolved.—O. R.

Radioactive matter in thorium-containing solutions; Method of obtaining the ——. F. Glaser, Wiesbaden, Germany, Assignor to C. Glaser, Baltimore, Md. U.S. Pat. 1,084,734, Jan. 20, 1914.

Solutions containing thorium, phosphoric acid, and radioactive matter, are diluted with water and heated, whereby thorium compounds and radioactive matter are deposited in a precipitate of relatively small bulk.—O. R.

Hydrogen; Purification of ——. J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen-on-Rhine, Germany. Eng. Pat. 14,509, June 23, 1913.

Hydrogen, or a gas containing it, is freed from sulphur and sulphur compounds by heating with a solution of caustic alkali under a pressure greater than 5 atmospheres. Thus, caustic soda of from 10 to 50 per cent. strength may be employed at a temperature of 150°—225° C. and a pressure of 50 atmospheres.—O. R.

Hydrogen from iron ore and steam; Reducing and oxidising apparatus for generating ——. Berlin-Anhaltische Maschinenbau-A.-G., Berlin. Eng. Pat. 28,390, Dec. 9, 1913. Under Int. Conv., Dec. 11, 1912.

A cylinder of refractory material is divided into separate shafts by means of refractory partitions, and is encased in a gas-tight, metal jacket. This subdivision of the cylinder ensures the uniform action of the reducing gases and steam on the whole charge of material in each shaft, and the temperature in the shafts can be regulated in such a manner that, whilst the whole column of ore is sufficiently heated, its partial fusion is avoided. Each shaft is provided with Morton closing devices at either end for the introduction and discharge of the iron ore. By a suitable arrangement of valve-controlled supply and discharge pipes, for reducing gases and steam, it is possible to cut out one of the shafts temporarily, so that its contents can be withdrawn and the shaft recharged, without interfering with the working of the adjoining shafts.—O. R.

Hydrogen and oxygen; Apparatus for the electrolytic production and collection of ——. E. Benker. Fr. Pat. 461,981, Aug. 29, 1913. Under Int. Conv., Sept. 7, 1912.

Hydrogen containing not more than 1 per cent. by vol. of oxygen, and oxygen containing not more than 3—4 per cent. by vol. of hydrogen, are prepared by electrolysis in an apparatus of the bell-collector type, in which the anode bell is submerged more deeply than the cathode bell, and in which the length of the cathode is about two-thirds of the length of the anode. Current leads extend to the bottom of each bell, and the relative dimensions given refer to the portions of the electrodes extending from the bottoms of the bells downwards.—O. R.

Nitrogen; Method of obtaining—and making compounds therefrom. T. L. Willson and M. M. Haff, Ottawa, Canada. U.S. Pat. 1,084,774. Jan. 20, 1914.

Sulphur is burnt in a confined body of air, and the mixture of nitrogen, sulphur dioxide, and oxygen is passed through a solution containing lime, to form a bisulphite liquor: the residual nitrogen, containing traces of oxygen, is then passed over heated sulphur, and the sulphur dioxide formed is absorbed as before.—O. R.

Bleaching and like fluids; Apparatus for preparing ——. C. A. M. Buckley, London. U.S. Pat. 1,085,718, Feb. 3, 1914.

See Eng. Pat. 18,600 of 1912; this J., 1913, 1007.—T.F.B.

Common salt; Manufacture of ——. A. W. Brown, Belfast, J. H. Webster, Carrickfergus, and A. G. Salamon, London. U.S. Pat. 1,086,020, Feb. 3, 1914.

See Eng. Pat. 17,300 of 1912; this J., 1913, 1107.—T.F.B.

Graphite; Method of purifying ——. A. Humann and F. Teisler, Dohna, Saxony. Eng. Pat. 10,547, May 5, 1913.

See Fr. Pat. 458,441 of 1913; this J., 1913, 1068.—T.F.B.

Hydrogen under pressure: Process of working with ——. C. Bosch, Assigner to Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. U.S. Pat. 1,086,130, Feb. 3, 1914.

See Eng. Pats. 29,260 of 1912 and 13,258 of 1913; this J., 1913, 1010.—T. F. B.

Hydrogen; Furnace for the manufacture of ——. A. Messerschmitt. Fr. Pat. 461,625, Aug. 4, 1913. Unde Int. Conv., Nov. 2, 1912.

See Ger. Pat. 268,062 of 1912; this J., 1914, 137.—T.F.B

Hydrogen; Apparatus for producing —— by successi oxidation and reduction of ferruginous contact masse A. Messerschmitt. Fr. Pat. 462.379, Aug. 27, 191 Under Int. Conv., Oct. 17, 1912.

See Ger. Pat. 268,339 of 1912; this J.. 1914, 137.—T.F.

Obtaining a useful by-product [ammonium nitrate or nitrite] from coal gas. Eng. Pat. 1851. *See* IIa.

VIII.—GLASS; CERAMICS.

British clays under the osmose purification process. W. R. Ormandy. Trans. Eng. Ceram. Soc., 1913—14, **13,** 35—48.

In a previous paper (see this J., 1913, 488) the osmose process as applied to various Continental clays was described. The purification of British clays is now described and illustrated. Coloured china clays may be induced to yield paper-white clays if previously green or bluish, as the impurity is here due to tourmaline or double silicates containing some iron, and either neutral or electro-positive, but it is more difficult to remove yellow or brown colouring matter due to the presence of iron phosphate and humic substances. The suitability of a china clay for the manufacture of hard porcelain depends on its contraction at 1500° C., which should be 17 per cent. English china clays show only 10—12 per cent. contraction, but after osmose treatment may give 16 per cent. A contraction of 19 per cent. is found to be accompanied by a percentage of alumina in excess of that required by theory for pure kaolinite. The colour of china clay is not essential in hard porcelain, as the iron exerts no colouring effect at the temperature employed. A new addition to the osmose plant, an electrical filter-press by which the most plastic clay can be filtered rapidly under a pressure of a few pounds, solves the topographical difficulty caused by the pits being a considerable distance from a railway station, as it can be erected close to the railway at the "dries," whither the clay has been sent through pipes as a 10 per cent. suspension. Ball and fire clays purified by the osmose process are more suitable for use in the manufacture of grey and brown paper than low-grade china clay or gypsum. The treatment of ball clays for pottery reduces their sintering temperature by 200°—300° C.; few clays in the natural state sinter below 1450° C. The peacock marl at Hanley, from which nothing but low-grade fire bricks had previously been made, is after purification now used for making sanitary ware. A yellow clay thrown out from an iron mine sintered and melted at practically the same temperature, but after treatment there was a margin of over 150° C. between the two temperatures, i.e., a margin wide enough to enable high-grade vitrified floor and roofing tiles to be made from a hitherto valueless product.
—H. H. S.

Iron; Extraction of — from potters' materials by means of magnets. H. H. Thompson. Trans. Eng. Ceram. Soc., 1913—14, **13,** 15—29.

The apparatus described consists primarily of an inclined trough having a series of electro-magnetic bars fixed laterally in the bottom, the magnet windings being housed underneath. Electro-magnets are said to be from 2·5 to 10 times as efficient as permanent magnets. The edge of each bar is magnetised along the whole of its length and width. The projections are curved like a fan facing the approach of the liquid slip which is broken against a number of vertical serrations on the curved faces. The trough is inclined at an angle of 50°, and the liquid flowing down it is throughout in actual contact with magnets, a condition which is necessary owing to the resistance offered by the slip to the passage through it of minute particles of iron. Moreover, minute particles possess only sufficient magnetic permeability to be held by a magnet when actually in contact with it; a magnet which attracted horizontally a 6-inch nail from a distance of 10 inches was able to attract a speck of iron from only 2¼ inches. In the event of the current failing a collapsible bridge is provided to prevent the iron accumulated on the magnets from being washed into the purified clay. The bridge is also used in cleaning the iron from the magnets by a hose, the current having been switched off.—H. H. S.

Magnetic pottery; A note on ——. J. W. Mellor. Trans. Eng. Ceram. Soc., 1913—14, **13,** 80—82.

Oxides of iron, practically always present in pottery materials, are converted into magnetite, the stable oxide, during firing. A photomicrograph of a bone china section is given illustrating the formation of magnetite crystals. Free metallic iron is absent from normal pottery. The magnetic qualities of clay wares are due to magnetic oxide of iron either free or dissolved in vitreous granules of ferrous silicate. Hopwood's supposition of a magnetic iron silicate (this J., 1913, 827) is regarded as unnecessary.
—H. H. S.

Fritted glazes for stoneware and fine earthenware, with special regard to leadless glazes. A. Berge. Sprechsaal, 1914, **47,** 97—101, 113—115.

The formulæ and mixings of twelve lead and ten leadless glazes which are fired at cone 010 and have all been found of commercial value are given, as illustrated in the following table. The constituents were fritted with the exception of additions in the mill of felspar, kaolin and sand.

	SiO_2	Al_2O_3	B_2O_3	K_2O	CaO	Na_2O	SrO	ZnO	MgO	BaO	PbO

The different behaviour of stains in different glazes is shown by the pink of composition: $1{\cdot}8\ SiO_2$, $0{\cdot}05\ Cr_2O_3$, $0{\cdot}95$ CaO, $0{\cdot}05\ K_2O$, which developed well under glaze 11 of the lead series but was quickly decomposed by glaze 4.—H. H. S.

Clays; The causes of plasticity, binding power, shrinkage and absorption of ——. P. Rohland. Sprechsaal, 1914, **47**, 129—130.

In reply to Keppeler's statement (see this J., 1913, 827) that plasticity depends on clay-substance, the author recounts his colloid theory (see J., 1909, 1250). So-called "zinc clays" produced by the action of hot water containing silicic acid on zinc blende, and of the composition ZnO 74·1, SiO_2 35·4, Al_2O_3 1·6, Na_2O 1·8, loss on ignition 8·0 per cent., are strongly plastic though devoid of "clay substance," but rich in colloids. The presence of colloids in clay explains its other properties, binding power, shrinkage and absorption of dyes.—H. H. S.

Crazing of lead glazes on earthenware bodies. J. A. Callcott. Trans. Eng. Ceram. Soc., 1913—14, **13**, 49—60.

Crazing may be caused by excess of some constituent in the glaze or body, by application of the glaze to too porous a body, or by incorrect firing. It is due generally to excess of soda in the glaze or of china clay in the body. Lime may be substituted for soda if opacity and dullness do not follow, a consequence which is avoided by rapid cooling through the temperature range, 1000°—500° C., in which crystallisation is most likely to take place. Cornish stone is also a useful substitute for soda. China clay in the body may be replaced by Cornish stone or flint or, if colour be no object, by ball clay. Substitution of buff for purple Cornish stone in the body may be a cause of crazing. The function of flint is to alter the coefficient of expansion and to promote chemical combination between clay and fluxes. Vitreous bodies, usually deficient in flint, are especially liable to exhibit crazing. If the mixings are unaltered, a higher temperature or more prolonged firing is required.—H. H. S.

Nickel in glaze colours. H. Wicks and J. W. Mellor. Trans. Eng. Ceram. Soc., 1913—14, **13**, 61—66.

Nickel oxide imparts a variety of tints in blue, green, yellow and brown, varying according to the composition of the glaze, but which in general can be better produced without the aid of nickel. Increase of alumina in the glaze formulæ renders the colour more stable with a wider margin of safety in firing. Silica and boric acid deepen the tint and augment the solubility of the oxide. The influence of the alkali, alkaline earth and magnesium-zinc groups of metals is in harmony with the respective positions of the individual elements in the periodic table. With the alkalis, nickel yields a brown tint which deepens in passing from lithium to potassium. The alkaline earths also cause deepening of brown from calcium to barium. Beryllium gives yellowish-brown, magnesium green and zinc blue. When used as underglaze, nickel colours are attacked by lead glazes forming the common brown of nickel-lead silicate, which bears a similar relation to nickel-zinc blue that violet cobalt silicate bears to Thenard's blue and Rinmann's green. The molecular formulæ used for the glazes in these experiments was PbO, $0{\cdot}15\ Al_2O_3$, $1{\cdot}75\ SiO_2$, the lead being replaced by another oxide to the extent of 0·3 equivalent and 2 per cent. of nickel oxide being added.—H. H. S.

Nickel underglaze colours. T. Perry. Trans. Eng. Ceram. Soc., 1913–14, **13**, 67—69.

Underglaze colouring agents were prepared by firing powdered mixtures of nickel oxide with various non-colouring acid and basic oxides in the first ring of a tile-biscuit oven, each of the stains thus produced being subsequently used under each of the glazes of general formula: 0·3 PbO, $0{\cdot}3\ Na_2O$, 0·4 RO, $0{\cdot}25\ Al_2O_3$, $2{\cdot}95\ SiO_2$, $0{\cdot}25\ B_2O_3$, where R in turn represented the alkali and alkaline earth metals and zinc, cadmium, lead and bismuth. Nickel oxide formed with basic oxides, alone or with silica, powders varying in colour from pale brown to dark olive green. Magnesia, however, produced a strong yellow green (NiO : MgO), and, with stannic oxide added, a brilliant light green. Zinc with silica and nickel oxide gave a dark blue powder. Whatever the basic oxide present, the introduction of alumina induced a light matt-blue. Titania and nickel oxide, with or without other basic oxides, produced yellow. Stannic and zirconium oxides gave buff or brownish colours. The behaviour of these stains when fired under glazes varied considerably. Colours made from nickel and another basic oxide gave straw browns. The higher the firing temperature and the more energetic the flux, the darker was the brown colour produced. Addition of silica to the powders lightened the colours and imparted a greenish tinge. Blues produced by addition of alumina were very unstable under the action of glazes. The zinc-silica dark blue was also unstable under glaze. A high content of zinc in the glaze tended to preserve the alumina and zinc blue stains, but as soon as action began the colour changed to grey and then brown. Magnesia greens were also readily destroyed. Titania yellows were fairly stable both as regards firing temperature and difference in glaze composition. The most stable colours were those produced by stannic and zirconium oxides. In all glazes of the earthenware type nickel tended to give a brown colouration and was only safe for underglaze use when brown tints were desired.—H. H. S.

Glazes; Behaviour of some —— in the glost oven (II.): Damp and dry spots. J. W. Mellor. Trans. Eng. Ceram. Soc., 1913–14, **13**, 30—34. (See this J., 1913, 488.)

Loss in manufacture occurs when the glaze accumulates on some parts of the ware and recedes from others, leaving patches. The fault is said to be more common in heavily fritted or leadless glazes, and more liable on overfired and vitreous ware than on more porous bodies. It is also seen on some underglaze colours such as matt blue and chrome-tin pinks. The fault may be due to the biscuit, the underglaze colour or the glaze. In the first instance, adherence of the unfired glaze to the body is prevented by damp patches, greasy or oily patches, accumulations of dust on the biscuit, or overfiring of the biscuit. Underglaze colours if overground produce the same effect as dust on the biscuit. They may be defective also in their composition, having too much or too little flux to hold the softening glaze; or they may be correct in composition but overfired in the hardening-on kiln. When the glaze itself is at fault, the cause is over-grinding, too much frit, or thick dipping, or excess of raw clay making the glaze too hard. The general causes of the defect are stated to be that the adhesive power of the softening glaze which holds it to the body is so equally balanced against the cohesive force which gives all glazes a tendency to crawl from free edges and roll into beads, that a slight disturbance, local or otherwise, may cause the glaze to leave the body in patches; and that the absorption of the glaze at local spots may produce patches more thinly dipped than the remainder. The latter modification does not show such thickened edges surrounding a bare patch as the former cause.—H. H. S.

PATENTS.

Refractory vitreous substances, such as quartz-glass, and the like; Manufacture of ——. H. J. S. Sand, Nottingham. Eng. Pat. 15,629, July 7, 1913.

In the manufacture of vitreous substances, which cannot be converted into mobile liquids by heat, the inclusion o air bubbles, dust, and the like is avoided by placing th refractory, vitreous material inside an envelope of suitabl shape, and preferably of the same material as that to b manufactured. The envelope is then exhausted, heated and collapsed on to the enclosed substance, which is thereb heated and converted into the required product.—O. R

Brick and similar kilns. J. C. Blythe, Birtley, Durham. Eng. Pat. 6895, Mar. 20, 1913.

In a kiln of the oven type, a fire-box, having a perforated roof and solid walls, is situated immediately below a combustion chamber, through which the products of combustion pass before entering the kiln; the perforated roof of the fire-box forms part of a partition of spaced bricks, which separates the fire-box from the combustion chamber, the walls of the latter being also in the form of spaced bricks, allowing free access to the kiln. Means are provided for supplying air and steam under pressure to the fire-box, to induce a forced draught, which ensures thorough combustion and admits of the employment of low-grade fuel.—O. R.

Kiln; Continuous —— for burning clay-ware. L. N. Legg, Calhoun, Ga. U.S. Pat. 1,085,448, Jan. 27, 1914.

A continuous down-draught kiln comprising a number of compartments arranged in a row, each having openings in both end walls for the introduction and removal of ware. Adjacent to the side walls of each compartment are combustion chambers, with fire-boxes in the end walls. Flues are arranged so that a suitable draught is maintained, the air from each compartment being supplied to the combustion chambers of the next compartment of the series, and the collection flue of the last compartment being in communication with the combustion chambers of the first compartment.—T. St.

Ceramic products; Process for avoiding efflorescence in the manufacture of ——. Soc. de Produits Céramiques de Massy. First Addition, dated Sept. 24, 1912, to Fr. Pat. 446,875, Oct. 13, 1911 (this J., 1913, 143).

The soluble metallic salts, especially chlorides and sulphates of iron or the like, added, according to the chief patent, to prevent efflorescence, may also be added for the purpose of colouring any ceramic products, such as biscuit ware, porcelain, fayence, terra-cotta, glazes, and enamels. —O. R.

White enamel; Process of producing ——. E. Heilmann, Güstrow, Germany. Eng. Pat. 26,498, Nov. 18, 1912. Under Int. Conv., Nov. 23, 1911.

As a clouding agent for white enamels, use is made of a mixture of magnesia or zinc oxide with alumina, previously calcined to temperatures sufficiently high to form a spinel, or instead of these a solid solution of magnesium spinel in magnesia or alumina, or of zinc spinel in zinc oxide or aluminia may be used. These mixtures or solid solutions may be admixed with white refractory materials, such as silicic acid, tin oxide, zirconium oxide or titanic acid, the ingredients being calcined at a high temperature after mixing.—W. C. H.

Vitreous substance. F. Wolf-Burckhardt, Biebrich, and W. Borchers, Aachen, Assignors to Zirkonglas Ges. m. b. H., Frankfort, Germany. U.S. Pat. 1,086,113, Feb. 3, 1914.

See Fr. Pat. 432,786 of 1911; this J., 1912, 130.—T. F. B.

IX.—BUILDING MATERIALS.

Firebricks; Action of flue dust on ——. J. W. Mellor. Trans. Eng. Ceram. Soc., 1913-14, **13**, 12—14.

A muffle built of good refractory material and heated by gas from a producer immediately below was stopped by the choking of the flues leading from the producer with a fusible ferruginous slag. Analysis of the slag showed it to consist of 95—99 per cent. of fuel ash from the producer mixed with a very small amount of the refractory material which it had attacked in the muffle or in the flues. The fuel ash contained 28 per cent. of iron oxide and the results show that ordinary fireclays are very sensitive to the presence of admixed iron compounds under reducing conditions which were here caused by the 10 per cent. of carbonaceous matter in the ash. The stream of producer gas would bring flue dust, probably fused beforehand, into contact with the muffle whereby a skin would be formed and chemical interaction would take place. Ultimately the glaze produced would begin to trickle down, carrying with it in solution some of the refractory material. A silica muffle would not overcome the difficulty; the natural remedy is to use a fuel with less fusible ash and to clean the producer gas free from dust before it reaches the muffle.—H. H. S.

Asphaltum penetrometer; A new electrically controlled and timed ——. Effect on penetrations of variations in standard needles. H. W. Mahr. J. Ind. Eng. Chem., 1914, **6**, 133—136.

The essential part of the new penetrometer consists of an electro-magnetic clutch timed and controlled by a Sieman's intermediate relay with time-limit, by which the penetrometer circuit is broken and automatically made at the end of five seconds. The brass-clad steel rod which holds the needle and can be weighted to the desired extent, moves up and down through openings in two thin German silver plates, and is partly enclosed by the concave poles of the electro-magnet. The rod is held by the electromagnet whilst the needle is being set on the surface of the asphaltum, then the circuit is broken by pressing a button. The depth of penetration is measured by means of a rack and pinion connected with an adjustable hand on a dial. The results obtained with the apparatus are accurate and concordant, and the personal error is entirely avoided. Comparative tests showed that errors due to variations in standard needles are negligible. (See also this J., 1909, 710.)—A. S.

Patents.

Acid-, fire-, and water-proof elastic material, and a process for the manufacture thereof. N. Magelssen, Christiania, Norway. Eng. Pat. 1703, Jan. 21, 1913.

The composition consists of a mixture of water-glass, containing an excess preferably of both sodium and potassium hydroxides, equivalent to at least 6 per cent. by weight of the water-glass, and filling materials, such as chalk or asbestos, to which an acid, or substance having an acid reaction, or a salt is added. The salts suggested are sulphates of iron, zinc or aluminium.—W. C. H.

Artificial stone, concrete and the like and materials therefor. R. Ettling, Swanscomb, and W. Chappell, Gravesend. Eng. Pat. 6697, March 18, 1913.

From 1 to 4 oz. of chrome alum mixed with ¼ to 1 oz. of "common soda" or sulphate of iron are dissolved in each gallon of water that is mixed with the aggregate, or the unmatured concrete or artificial stone may have applied to its surface, or be soaked in, a solution of chrome alum and common soda in water in the above proportions. —W. C. H.

Artificial stone, etc.; Process for treating ——. C. H. Seaman, Assignor to O. H. Foerster, Milwaukee, Wis. U.S. Pat. 1,085,227, Jan. 27, 1914.

A solution of 2 oz. of stearic acid in about 1 quart of alcohol is applied to the surface of stone-like bodies in order to render the latter non-porous, and to remove moisture.—T. St.

Mortar; Process and apparatus for the manufacture of dry, portable ——. J. Joachim. Fr. Pat. 461,129, Aug. 5, 1913. Under Int. Conv., Aug. 6, 1912, and May 14, 1913.

Sand and lime, suitably moistened, are passed through a rotating drum, divided into communicating compartments. The heat evolved by the hydration of the lime serves to heat fresh charges of raw material, and the mixture is crushed in the third and successive compartments by means of wooden balls, which travel with the material into the final compartment. The wall of the latter is perforated, and the mortar mixture passes through the perforations whilst the wooden balls, together with the coarse material, are retained; the balls, after being heated if necessary, are returned and used again. The mortar passes from the drum into a silo, where it is allowed to mature, and is afterwards prepared for transport by subjecting it to trituration in a conical grinding mill, inside which a sprinkling appliance admits the final quantities of water required. In a modified form of the apparatus, a number of rotating drums are mounted one inside the other, the combination being sealed from the air except as regards the inlet to the first drum and the outlet from the last. In this case the first drum, usually the central one, acts as a preliminary slaker and mixer, a portion only of the sand and water being admitted to it, and the remainder added in the second and succeeding drums.—O. R.

Quicklime; Process for the manufacture of —— in blocks. L. Negro and F. Neumerkel. Fr. Pat. 461,359, Aug. 13, 1913. Under Int. Conv., April 15, 1913.

Quicklime in lump form is cooled, pressed to the desired shape at 800—1000 atmospheres pressure, and allowed to expand freely immediately after compression has taken place, when the block becomes mechanically strong and durable. Powdered quicklime must first undergo a preliminary, moderate compression, the resulting block being reduced to pieces of appropriate size, and these fragments then treated like the first-mentioned material in lump form.—O. R.

Dyeing [and impregnating] materials which are difficult to dye completely. Ger. Pat. 266,708. *See* VI.

X.—METALS; METALLURGY, INCLUDING ELECTRO-METALLURGY.

Zinc industry of Upper Silesia. Board of Trade J., Feb. 12, 1914. [T.R.]

According to the "Börsen Zeitung" (Berlin) of 28th January, the production of raw zinc in Upper Silesia last year amounted to approximately the same as in 1912, which latter year's production showed an increase of 11·2 per cent. over 1911. For years the industry had been greatly retarded through manufacturers being able to dispose of their production of sulphuric acid only at considerable loss, on account of the abnormally high railway tariff on this commodity. The efforts which have been made during the past twelve months to lower the tariff on sulphuric acid have, however, been partially successful, which is all the more significant, inasmuch as the production of sulphuric acid in Upper Silesia is increasing rapidly from year to year, and with it the heavy demands which had resulted from the requirements of the blende-smelting trade. In 1900 the production of sulphuric acid per ton of raw zinc amounted only to 0·08 metric ton; in 1905 it had increased ten-fold to 0·85 metric ton, and last year it still further increased to 1·34 metric tons. The production of sheet zinc increased by about 5487 metric tons, or about 9·7 per cent. As far as prices were concerned the year was quite satisfactory, as the average value of a ton of raw zinc increased by 8·6 per cent., and of sheet zinc by 9·2 per cent.

Iron ore; Electric smelting of —— in Canada. T. R. Loudon. Appl. Sci. (Toronto), 1914, **8**, 219—223.

In the furnace used by the Moffat-Irving Steel Co., Toronto, a continuous shower of ore (fine magnetite) and limestone is passed from the upper stack, through the reduction chamber—wherein the ore is partly reduced by carbon monoxide—to the crucible in which the reduction is completed by means of finely powdered coke introduced at the top of the crucible arch. The furnace, of 300 kilowatt capacity and operated on three-phase current, has three electrodes arranged at equal intervals around the crucible, and dipping into the latter at about 60° to the horizontal. The electrodes are of 5⅛ in. graphite, water-cooled, and regulated by hand; the voltage employed ranges from 56 to 84. The steel produced in eight experimental smeltings contained 0·12—0·35 per cent. C and gave a percentage elongation (on 2 in.) of 10—17·5 before and 20—35 after, heat treatment.—W. E. F. P.

Rail steels for electric railways. Experiments on the Metropolitan Railway. W. Willcox. Inst. Civil Eng. Times Eng. Suppl., Feb. 25, 1914.

The results of some tests made to determine the most suitable rail to withstand the heavy wear of electric railway rolling stock, were given. For the last seven years high-silicon steel has been used and has proved more durable and considerably less liable to rusting than ordinary steel. It is made from basic open-hearth, basic Bessemer or acid Bessemer steels by the Sandberg process, in which during manufacture the whole of the silicon is extracted and a known quantity added. The rails are 45 ft. long and weigh 86 lb. per yard. The results as regards life were:—High-silicon basic open-hearth, over 23 months; high-silicon acid Bessemer, first lot of rails in the down road, 11 months, second lot of rails just over 15 months, and on the up road just over 15 months: basic open-hearth titanium, 9⅓ months; and ordinary basic open-hearth, 9⅓ months on the down road, and barely 11 months average on the up road. Silicon steel is specially suitable in tunnels, on account of its comparative freedom from rusting as compared with ordinary steel; moreover the price is not more than 10s. per ton in excess of the price of ordinary steel, whereas nickel-steel, chrome-steel, etc., cost much more. A test was made of rolled manganese-steel rails, containing C 1·20, Si 0·30, S 0·03, P 0·06, and Mn 12·00 per cent. Two pairs of 95 lb. rolled manganese rails of British standard section were placed near Moorgate Street on a 15-chain curve. After being there nine months, they were put in the curve between Farringdon Street and Aldersgate Street, on the down road just outside the tunnel part of the curve. The original weights when put in the road near Moorgate-street were No. 1 high rail, 1,425 lb.; No. 1 low rail, 1,427 lb.; No. 2 high rail, 1,428 lb.; and No. 2 low rail, 1,400 lb. When put in the curve at Farringdon Street on January 6, 1912, No. 1 high rail had lost 22 lb. in weight, No. 1 low rail 1 lb., No. 2 high rail 14 lb., and No. 2 low rail 17 lb. This gives an average loss of about 1·56 lb. per yard per annum. Weighed again on October 11, 1913, the weights were No. 1 high rail, 1,333 lb., No. 1 low rail, 1,393 lb., No. 2 high rail, 1,375 lb., and No. 2 low rail, 1,365 lb. The total loss in weight, therefore, is No. 1 high rail, 92 lb., No. 1 low rail, 34 lb., No. 2 high rail, 53 lb., and No. 2 low rail 35 lb., equal to an average of 1·43 lb. per yard per annum. After a period of two years and six months these rails, although wearing away, are wearing evenly, and show n signs of battering, as even the hardest of the other rail tested, did.

Nickel-chromium steels; Transformation points and struc ture of ——. L. Guillet. Comptes rend., 1914, 15 412—414.

The effect of chromium in lowering the transformatio temperature on cooling of a steel with a fixed percentage nickel is not proportional to the amount of chromiu present; beyond 3 to 5 per cent. (according to the nick content) the effect becomes more or less constant. Ste containing nickel and chromium divide themselves rough into three main classes. In the first the transformati on heating is not greatly different from that on coolin Such steels have usually a pearlitic structure. In t second class are those of martensitic structure, in which the chromium increases there is an increasing differer between the two points. In steels of the third class, containing carbides, the chromium is not all dissolved and its effect does not increase as more is added. The first class disappears when the amount of nickel present is sufficient in itself to produce a considerable difference in the transformation temperatures. The carbide steels are relatively very resistant to ammonia and nitric acid. The martensitic steels are produced when the transformation point on cooling falls to about 350° C.—W. H. P.

High-speed tool-steel ; The analysis of ——. F. Fettweis. Stahl u. Eisen, 1914, **34**, 274—275.

In the estimation of tungsten, chromium, molybdenum and vanadium, when these metals occur together in steel, *Vanadium* does not interfere with the usual volumetric chromium method, if the titration be carried out at 35° C., since at this temperature the vanadium is oxidised quickly and the chromium is not oxidised. In the estimation of vanadium, the greater part of the iron is first removed by ether, and the remainder, together with chromium, etc., by means of sodium hydroxide. Before the latter precipitation it is desirable to evaporate to dryness with sulphuric acid, dissolve in water, add hydrogen peroxide, and again evaporate to fuming. Loss of vanadium in the precipitation is thus avoided. *Molybdenum* is separated from vanadium, after removal of the iron by sodium hydroxide, by precipitation with hydrogen sulphide. Molybdenum does not interfere with the ordinary volumetric determinations of chromium and vanadium. *Cobalt* is best estimated electrolytically.—T. St.

Copper ; Influence of movement on the solution of —— *in nitric acid.* M. Drapier. Comptes rend., 1914, **158**, 338—340.

Copper dissolves rapidly in nitric acid when allowed to remain at rest, but the rate of solution diminishes and ceases almost entirely when the metal is kept moving, or the acid agitated. This is not due to local elevation of temperature, for a copper tube through which a current of cold water is passed, dissolves rapidly in nitric acid, but rather to the fact that agitation of the acid removes reduction products (nitrous acid) away from the metal. Nitric acid to which sodium nitrite has been added dissolves copper as rapidly when in movement as when at rest. If two copper electrodes be immersed in nitric acid, there is a difference of potential of 0·1 volt when one electrode is stationary and the other is rotated rapidly. (See also Stansbie, this J., 1913, 1135.)—W. P. S.

Titanium ; The influence of —— *on copper and some of its commercially important alloys.* F. O. Bensel. Metall u. Erz., 1914, **11**, 10—20, 46—60.

By electrolysis of copper-titanium fluoride in a bath of fused fluorspar an alloy containing : Cu 83·70, Ti 3·15, Ca 9·51, and Pb 1·79 per cent. was obtained, whilst by electrolysis of a mixture of titanic oxide and copper fluoride under similar conditions an alloy containing : Cu 58·67, Ti 26·51, Ca 11·74 per cent. was deposited. The electrolysis of cuprous chloride and calcium chloride in a bath of fluorspar and calcium chloride yielded an alloy containing Cu 70, and Ca 23 per cent. The reduction of titanic oxide by carbon in presence of cuprous sulphide always gave a product with over 5 per cent. S. The alumino-thermite treatment of mixtures of copper oxide and titanic oxide yielded always alloys containing 5 per cent. and upwards of aluminium. Nickel-titanium alloys with traces only of aluminium and manganese-titanium alloys with 5 to 6 per cent. Al were also prepared by the thermit reaction. These alloys were used to introduce small percentages of titanium into copper, copper-tin, copper-manganese, and copper-nickel. With the first three of these considerable loss of titanium always took place and the fluid alloys became very thick, so that a maximum titanium content of only 1 per cent. was obtained. Microscopic examination showed that with more than about 0·4 per cent. Ti, this latter separated as slag-like inclusions. The titanium had an injurious effect on the mechanical properties, but somewhat increased the resistance to the action of dilute solutions of nitric acid and sodium chloride at nearly 100° C. With copper-nickel up to 5 per cent. Ti was introduced : the tensile strength with 2 per cent. Ti was almost doubled, the elongation being diminished to about 6 per cent. This alloy (Cu 88, Ni 10, Ti 2 per cent.) might find technical application. The introduction of titanium into copper-nickel caused a slight diminution in the resistance to corrosion.—T. St.

Nickel-copper-gold alloys ; Ternary ——. P. De Cesaris. Gaz. chim. ital., 1914, **44**, I., 27—35.

Of the three pairs of metals of which the ternary alloys are composed, copper forms a continuous series of solid solutions with nickel and with gold, but nickel and gold are only partially miscible in the solid state, the two saturated solid solutions containing respectively 8 and 80 per cent. Ni. Fifty-six ternary alloys were studied by the method of thermal analysis and isotherms at intervals of 25° C., representing the temperature of initial solidification, are plotted in a triangular diagram. In order to fix approximately the region of limited miscibility in the ternary system (equilibrium was not attained in the thermal experiments), a series of the alloys was examined micrographically before and after annealing at 820° C. Of the alloys represented in the following table, Nos. 16, 22, 27, 31 and 48 belonged to the region of limited miscibility, whilst the others were outside this region : No. 48 was close to the border line between the two regions :—

No.	Ni	Cu	Au	No.	Ni.	Cu	Au
	%	%	%		%	%	%
2	10	20	70	31	60	10	30
10	20	20	60	42	10	25	65

—A. S.

Nickel arsenide ; Temiskamite, a new —— *from Ontario.* T. L. Walker. Amer. J. Sci., 1914, **37**, 170—172.

Temiskamite has a composition, apart from small proportions of isomorphous elements, corresponding to Ni_4As_3. The mineral occurs in calcite veins carrying niccolite and smaller amounts of native bismuth and silver. It is silver-white with a touch of red, tarnishing very quickly to madder grey. Hardness, 5·5 ; sp. gr., 7·901 ; fusibility, 2 ; lustre, metallic ; it is opaque and non-magnetic, and gives a brownish black streak.—T. St.

Cobalt ; Preparation of metallic —— *by reduction of the oxide, and preliminary experiments on cobalt and its alloys.* H. T. Kalmus. Report to Canadian Dept. Mines. J. Ind. Eng. Chem., 1914, **6**, 107—115. Trans. Canadian Min. Inst., 1913, **16**, 255—270.

Black cobalt oxide, Co_3O_4, is now produced on a fairly large scale in Canada. A sample contained Co 70·36, Ni 1·12, Fe 0·82, S 0·45 per cent. It was purified by precipitating a hydrochloric acid solution with marble to remove iron and arsenic ; fractionally precipitating a chloride solution with bleaching powder whereby practically all the cobalt was precipitated as hydroxide before any nickel ; and boiling with sodium carbonate and with hydrochloric acid to remove sulphur. A sample of the purified oxide contained : Co 71·99, Ni 0·04, Fe 0·11, S 0·02 per cent. For the production of moderate quantities of pure cobalt free from carbon, reduction with hydrogen proved satisfactory ; the rate of reduction increased rapidly between 700° and 1100° C. Reduction was effected more rapidly by carbon monoxide than by hydrogen, over 90 per cent. of the oxide being reduced in a few minutes between 500° and 750° C., whilst complete reduction was rapidly attained at 900° C. Between 350° and 450° C. finely divided cobalt decomposed carbon monoxide with liberation of carbon. Metallic cobalt prepared by the alumino-thermite reaction was free from carbon and frequently contained less than 1 per cent. Al. The cheapest method of reduction was by heating with powdered carbon for $1\frac{1}{2}$ hours at 900°—1200° C.; the metal contained 0·2—0·3 per cent. C.; powdered charcoal and lampblack gave somewhat better results than anthracite coal, and the rate of reduction was increased by briquetting the charges. In an electric furnace not specially designed for the purpose, 15 lb. of cobalt were produced in 1 hour with a consumption of 20 kilowatts. Metallic cobalt method at 1497° C. (2727° F.). When cast it had a marked tendency to occlude gases, but sound castings were obtained by adding a few tenths per cent. Mn. and heating at a little above the melting point for ½ hour before teeming. Cast cobalt was about as hard as wrought iron; tensile strength 61,000 lb. per sq. in., compressive strength 158,000 lb. per sq. in. Cobalt could be deposited electrolytically in a similar manner to nickel and gave somewhat tougher deposits. A brief account of some alloys of cobalt with other metals is given (see this J., 1910, 1253; 1911, 1318; 1913, 28; 1914, 203). An alloy containing: Co 45, Cr 15, and W 40 per cent. would drill glass dry and one containing Co 60, Cr 15, W 25 was equal to the best self-hardening tool steel. A cobalt bronze: Cu 66·66, Sn 12·13, Co 15·15, Cr 3·03, Al 3·03 per cent could be readily cast and turned; it was somewhat harder but of slightly lower tensile and compressive strength than the corresponding nickel alloy. Other possible applications of cobalt, which are still being investigated, are the production of non-corrosive Co-Sn and Co-Cu-Sn alloys, magnetic Co-Fe alloys, and the use of cobalt and cobalt oxide instead of nickel and nickel oxide in Edison storage cells.—A. S.

Tin ores and concentrates; The assay of ——. The Pearce-Low method. E. A. Wraight and P. L. Teed. Inst. Min. and Met., Feb. 19, 1914. [Advance proof.]

A series of tests in which various minerals were added to tin ores and concentrates of known tin content, and the mixtures then assayed for tin by the Pearce-Low method (Low, "Techn. Methods of Ore Analysis," Third Ed., 1908, p. 208) proved that the method is very accurate except when compounds of titanium, tungsten, or bismuth are present. The modification proposed when titanium is present, is to fuse the ore with potassium bisulphate, and treat the melt with dilute sulphuric acid, when all the titanium goes into solution, and the residue, containing all the tin, is fused with sodium peroxide in the usual way. Tungsten, if present with titanium, can be completely removed by treating the residue from the titanium solution with ammonium carbonate. Ores containing tungsten may also be digested, after finely powdering, with sodium hydroxide solution, when all the tungsten goes into solution. When tin ores contain bismuth, the bismuth is precipitated by the nickel. As the precipitate consumes iodine, it must be removed by filtration, and the solution again reduced before titration. In general, in carrying out the Pearce-Low assay, the authors recommend grinding the sample to 100-mesh at least; fusion in nickel crucibles, and reduction with nickel; the temperature of the solution at titration to be below 70° F. (21° C.); avoidance of large amounts of cuprous chloride and ferrous chloride; the bulk of the solution before reduction to be 400 c.c., containing 125 c.c. of hydrochloric acid.
—T. St.

Tin ores; The assay of ——. H. W. Hutchin. Inst. Min. and Met., Feb. 19, 1914. [Advance proof.]

Experiments in which tin ores and tailings were heated under various conditions with zinc oxide, lime, etc., showed that by heating with lime for 15 to 20 minutes over a large Teclu burner, it is possible to convert the whole of the tin into calcium stannate, which can then be dissolved in hydrochloric acid, and the tin estimated volumetrically in the usual way. The new process is a modification of the "Beranger" method.—T. St.

Antimony and arsenic; Determination of —— in lead-antimony alloys and anti-friction metals. L. Bertiaux. Ann. Chim. analyt., 1914, **19**, 49—51.

From 1 to 10 grms. of the metal are heated with 20—60 c.c. of sulphuric acid until any precipitated sulphur has redissolved and sulphur dioxide has been completely expelled, the solution is diluted with its own volume of water, and arsenic and antimony determined together by titrating the boiling solution with permanganate (the iron factor of the permanganate multiplied by 1·0714 gives the equivalent amount of antimony and arsenic in terms of antimony). Another portion of the metal is heated with ferrous sulphate and hydrochloric acid, and arsenic determined in the distillate with iodine solution as usual. If much iron be present, it must be determined separately and deducted from the antimony-arsenic result. Tin, bismuth, and zinc do not interfere with the determination, nor does copper unless present in such quantity that its colour affects the end point in the permanganate titration.—W. P. S.

Vanadium ores and their treatment. H. Manz. Metall u. Erz, 1913, **10**, 379—384. (See also this J., 1913, 90.)

The occurrence and composition of the chief vanadium ores, and statistics relating to production and value are given. Almost all extraction methods aim at the production of an alkali vanadate solution, from which either vanadium pentoxide or iron vanadate is obtained. Ferro-vanadium is produced either by reduction with carbon in the electric furnace, or by the alumino-thermit process. The former method has the disadvantage of yielding a product with from 1·5 to 6·0 per cent. C. The thermite process is carried out in sheet-iron vessels lined with magnesite. A mixture of vanadium pentoxide, hammer-scale and aluminium, sometimes with addition of iron turnings, is introduced in successive portions, a mass weighing about 35 kilos., and containing 30 to 40 per cent. V being thus obtainable in a single operation. The most useful commercial alloy contains about 30 per cent. V. It is hard, but not brittle, and is difficult to pulverise; sp. gr. 7·34, m. pt. 1340° to 1400° C.—T. St.

Tungsten and carbon. O. Ruff and R. Wunsch. Z. anorg. Chem., 1914, **85**, 292—328.

The melting points of tungsten-carbon alloys in a furnace with a reducing atmosphere (carbon monoxide) depend very greatly on the rate of heating and on the composition of the furnace gases. An outer layer rich in carbon is formed which has a high melting point, so that fusion takes place from within outwards. The rate of heating has thus a twofold effect on the temperature of visible fusion; it affects the degree of carbonisation of the outer layer and also the rate at which the carbon can diffuse to the interior. The carbides found by the authors were W_3C (m. pt. over 2700° C.), WC (decomposes on melting), and the metallographic observations suggested a third component, probably W_2C. Three eutectics were observed, composed of tungsten and WC (1·4 per cent. C., m. pt. 2690° C.), W_3C, WC, and another unidentified carbide (2·4 per cent. C, m. pt. 2660° C., probably metastable), and WC and probably W_2C (3·5 per cent. C, m. pt. 2580° C.)
—W. H. P.

Tungsten-thorium, a ductile alloy. L. v. Grotthuss. Metall u. Erz, 1913, **10**, 844.

One hundred grms. of purified tungstic oxide were mixed with a solution in absolute alcohol of 1·05 grm. of thorium chloride, and the alcohol evaporated with constant stirring. The mixture was dried at 100° C., heated in a rapid stream of hydrogen for $1\frac{1}{2}$ hours over a luminous gas flame, and then for half an hour over the blow-pipe (about 900° C.). The black amorphous powder thus obtained was formed into small U-shaped rods with an organic binding material, and heated in a stream of hydrogen at about 1100° C., the rods changing to gray-black, but still remaining non-metallic. They were then placed in an exhausted vessel, and heated to incandescence by a current of 5 to 7 amps. at 250 volts, ammonia being admitted at the same time. The resulting thin threads had a metallic lustre and were ductile. On increasing the thorium content to more than 1 per cent., the ductility disappeared.—T. St.

Uranium, radium, and vanadium ; A preliminary report on ——. R. B. Moore and K. L. Kithil. U.S. Dept. of the Interior, Bureau of Mines. Bull. 70, 1913. 97 pages.

A summary of available information regarding the sources of these metals, the methods used in treating the ores, and the uses of the finished products.

Carnotite deposits. These are the most important radium-bearing deposits known, and occur in the arid regions of Colorado west of the Rocky Mountains and E. Utah. The yellow carnotite (uranyl potassium vanadate, probably $K_2O,2UO_3,V_2O_5,3H_2O$; sp. gr. 4·136) is found mostly in massive white sandstone underlying the red Dakota conglomerate (lower Cretaceous) as an incrustation on the faces of joints and fractures and is deposited around and between the individual grains of the sandstone ; small cylindrical pockets of richer ore are found in places, while red calcium vanadate is occasionally met with as well as black radio-active material. The ore mined must be hand-sorted in order to yield a shipping grade, *i.e.*, 2 per cent. U_3O_8. None of the deposits are extensive, and all are more or less difficult of access. The present method of mining and sorting is wasteful, and much low-grade ore is left in the mine or thrown on the dump. The ore can be concentrated either wet or dry. In the wet process the ore is reduced to 40- or 80-mesh, the crushing being accompanied by rubbing so as to loosen the carnotite from the sand grains. On subsequent washing in a revolving tank the particles of carnotite in suspension can be drawn off after the sand grains have settled. Where water is scarce the rock is crushed to about 40-mesh and passed over an oscillating 150-mesh screen, the undersize forming the concentrate. The screen must be encased, and all the dust carefully collected. *Uraninite (pitchblende) deposits.* Near Central City, Colorado, are five mines that have produced pitchblende as very high-grade ore. About 1905—6 the Kirk mine produced 20 tons of ore averaging 35 per cent. U_3O_8 and 100 tons of 3—4 per cent. ore. Low-grade material has been mostly neglected, but it can be concentrated with fair results, and it is hoped that 0·5 per cent. ore will be utilised. The important European deposits of pitchblende are found at Joachimsthal (Bohemia) and Johanngeorgenstadt and Annaberg (Saxony). *Autunite* (uranium calcium phosphate) is mined in Northern Portugal by a French company. Several finds of uraniferous ores, such as autunite, carnotite, and torbernite (uranium copper phosphate) have been reported from South Australia. *Vanadium ores other than carnotite.* Roscoelite (vanadium mica) occurs in S.W. Colorado ; the deposit is low-grade (1—2 per cent. V_2O_5) but is being mined at a profit because it is large and easily worked. In the same State, roscoelite has been found associated with silver ore, while the ash from grahamite (a solid native bitumen) found in West Virginia and Oklahoma gave 6·77—34·5 per cent. V_2O_5. Peru possesses an important vanadium ore deposit composed chiefly of patronite (a sulphide of vanadium) besides red calcium vanadate and other minerals. The mines are worked by an American company. *Production.* In 1912, 28·8 tons of uranium oxide was produced in the United States. Assuming that the radium is in equilibrium with the uranium (the normal ratio of Ra to U being 1 : 2,940,000) this is equivalent to 9·77 grms. of radium chloride. The Austrian output for 1911 was 2·647 grms., and that from all other sources probably less than 1·5 grms. America supplied in 1912 approximately 285 tons of vanadium metal, chiefly in the form of ferro-vanadium.—W. R. S.

Gold and silver ; Zinc-dust precipitation of ——. A. M. Merton. Min. and Eng. World, 1913, 429. J. Chem. Met. and Min. Soc., S. Africa, 1913, **14**, 317—319.

Zinc-dust, or fume, has largely displaced zinc shavings as a precipitant of gold and silver from cyanide liquors. A small stream of an emulsion of zinc-dust is incorporated with the cyanide solution, which is forced through filter-presses by means of triplex pumps. The reaction between the zinc and the cyanides is complete in less than a minute provided there is thorough diffusion of the dust through the solution. The efficiency of precipitation by dust is very high (98—99 per cent.), and is unimpaired even if the precipitate carries 40 per cent. Cu. The consumption of dust will usually be 25—50 per cent. less than of shavings, while the latter cost about 30 per cent. more than dust. The essential thing is to add the right amount of dust to the liquor ; it is also important to test the dust before use, as it varies greatly in composition. It should be stored in a dry place, as it oxidises rapidly and is liable to spontaneous combustion.—W. R. S.

Sodium ; Studies on the preparation of ——. *I.* B. Neumann and S. Giertsen. Z. angew. Chem., 1914, **27**, 65—70.

The authors carried out experiments in an apparatus of about 16 kilos. capacity, constructed on the lines of Castner's apparatus. When the proper conditions were mantained, chief among which is the adoption of a device for separating the anode from the cathode and thus facilitating the evolution of water, current yields of upwards of 50 per cent. could be obtained, as compared with 30—40 per cent. in practice. An important point was the correct adjustment of the temperature of the bath which should be about 320° C., being slightly lower for high currents. If the temperature were too high the sodium globules did not unite readily, were not easily separated from the melt, and adhered to the ladle in which they were removed. In installations of suitable size, using correspondingly higher currents, it is probable that the authors' modifications would greatly improve not only the current yield but also the energy yield in the manufacture of sodium.—W. H. P.

Metals ; Densities of some —— *in the liquid state.* P. Pascal and A. Jouniaux. Comptes rend., 1914, **158**, 414—416.

The densities were determined at various temperatures by a method involving the use of a quartz float. Formulæ are given for the variations in density of tin, lead, zinc, antimony, aluminium and copper, with temperature. The curve of specific volume of tin shows a marked inflexion at 620° C., suggestive of dynamic allotropy such as is exhibited by sulphur. A metal with a high coefficient of expansion as a solid has also a high one as a liquid. The change in volume on fusion is not usually more than 1 or 2 per cent.—W. H. P.

Determination of sulphur in pyrites. Martin. *See* VII.

Fine-meshed brass gauze as a substitutes for platinum in electro-analysis. Calhane and Wheaton. *See* XXIII.

Patents.

Steel. A. J. Rossi, Niagara Falls, N.Y., Assignor to The Titanium Alloy Manufacturing Co., New York. U.S. Pat. 1,085,488, Jan. 27, 1914.

The steel contains Ti less than 0·50, C more than 0·60 per cent., and manganese, and is unalloyed with other metals.—T. St.

Steel ; Manufacture of ——. W. R. Walker, New York. U.S. Pat. 1,086,003, Feb. 3, 1914.

Steel is manufactured from iron having a phosphorus content below that of basic Bessemer iron, by partially blowing the iron in an acid converter to remove silicon and a portion of the carbon ; transferring the metal first to an intermediate basic open-hearth mixer, where the metal is treated with a basic slag of iron ore and lime, to remove phosphorus, then in portions from time to time to acid electric furnaces in which a non-oxidising atmosphere is maintained, and next to an acid mixer in which a substantial quantity of molten metal is maintained, in order to obtain uniformity as regards carbon and other ingredients.—T. St.

Ores or concentrates; Decomposition of complex ——. W. A. Hall, New York. Eng. Pat. 21,826, Sept. 25, 1912.

Complex sulphide ores or concentrates of zinc, lead and iron are subjected to the action of a reducing flame and a limited quantity of steam insufficient in itself to decompose the ore or concentrate, whereby some of the sulphur is removed in the elementary form (see Fr. Pat. 458,028 of 1912; this J., 1913, 1156), together with the volatile metallic sulphides, the latter being recovered separately by fractional condensation. The ore is kept agitated during the process, which may be carried out in a mechanical furnace of the Wedge or Herreshoff type, steam being introduced between the shelves.—A. S.

Metallurgical-furnace part. W. W. Case, jun., Denver, Colo. U.S. Pat. 1,085,540, Jan. 27, 1914.

The crucible of a tilting furnace has a short pouring spout semi-circular in cross-section and disposed at right angles to the vertical axis of the crucible. A curved lining forming a pouring trough is mounted on the furnace below the spout, both spout and trough being provided with flanges to make a suitable connection. The lid of the crucible has a lip which covers the pouring spout. The furnace cover has a central aperture, and a recess on its lower face, forming a passage way above the crucible lid for the escape of the products of combustion.—T. St.

Metals; Process of preventing oxidation of —— during annealing. J. F. Thompson, Brooklyn, and E. E. Seelye, Tomkinsville, N.Y. Assignors to The International Nickel Co., N.J. U.S. Pat. 1,085,768, Feb. 3, 1914.

Metallic articles are protected from oxidation during annealing, by first coating their surfaces with an emulsion with water of CaF_2 2 parts and $CaCl_2$ 1 part.—T. St.

Metals; Electric fusion of ——. A. P. Strohmenger, Assignor to Ester and Co., Ltd., London. U.S. Pat. 1,085,951, Feb. 3, 1914.

Two rods of metal are placed parallel to each other, with a layer between them of fusible insulating material adapted to form a slag, and containing alloying ingredients. The rods are then connected with the poles of a source of electricity so that an arc passes between their ends. The fused metal drops into a crucible, where it is heated.—T. St.

Brass-pickling solutions; Method of maintaining the efficiency of ——. R. R. Parish, Assignor to Chase Rolling Mill Co., Waterbury, Conn. U.S. Pat. 1,086,079, Feb. 3, 1914.

The solution, composed of copper sulphate, zinc sulphate, sulphuric acid and water, is circulated continuously through an electrolysing tank containing insoluble anodes and metallic cathodes, so that a predetermined amount of acidity is maintained by the removal of a portion of the copper and the restoration of an equivalent amount of sulphuric acid.—T. St.

Iron; Process for the industrial manufacture of electrolytic ——. A. Boucher, Prilly-Chasseur, Switzerland, Assignor to Soc. "Le Fer," Grenoble, France. U.S. Pat. 1,086,132, Feb. 3, 1914.

See Fr. Pat. 458,294 of 1912; this J., 1913, 1115.—T. F. B.

Iron and other metals; Manufacture of ——. *Means or apparatus in or relating to the manufacture of iron and other metals.* A. E. Bourcoud, London. U.S. Pats. 1,086,133 and 1,086,134, Feb. 3, 1914.

See Eng. Pat. 676 of 1910; this J., 1911, 629.—T. F. B.

Iron and steel; Manufacture of ——. Billings Process Co. Fr. Pat. 462,851, Sept. 22, 1913.

XI.—ELECTRO-CHEMISTRY.

Refractories; High-temperature [electrical] resistivity of —— A new method of measuring, with results for alundum. E. F. Northrup. Met. and Chem. Eng., 1914, 12, 125—128.

The refractory material was mixed with a small quantity of water and moulded under pressure into thin rectangular slabs (3·4 cm. wide, 4·8 cm. long and 0·25 cm. thick) three

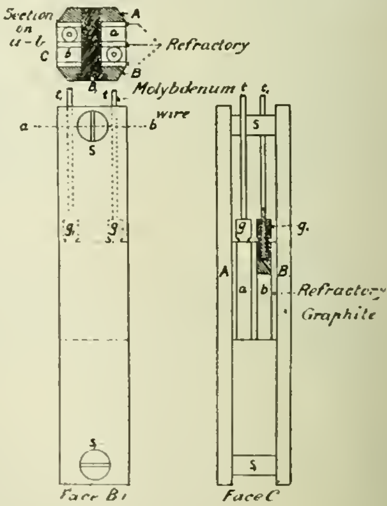

Fig. 1.

of which, after being dried, were clamped between the graphite plates A, a, B, b, (Fig. 1) by means of the graphite screws S and S_1, the external plates A, B, being sufficiently long to ensure, by their natural spring, the maintenance of a uniform pressure upon the refractory pieces during the subsequent changes of temperature. The electrical connections were made as shown in Fig. 1. and diagrammatically in Fig 2, the terminals t, t_1, of molybdenum wire, being fastened to the plates a, b, by means of the graphite screws g, g_1. If R is the measured resistance between the terminals t, t_1, l the thickness of one refractory slab, S its cross section (width × length) and ρ its specific resistance in ohms per cm.³, then $\rho = \frac{3S}{2l}R$. With the dimensions chosen, $\frac{3S}{2l} = 100$, so that $\rho_t = 100R_t$, the subscript t indicating that ρ and R are determined at the measured temperature t° C. The arrangement shown in Fig. 1 was placed in the bottom of the tubular chamber of an electrically heated furnace (Met. and Chem. Eng., 1914, **12**, 31) and the two molybdenum wires passed through a cylindrical cover-piece which tightly closed the top of the furnace, and through which a thermo-couple of platinum and platinum + 10 per cent. rhodium (enclosed in a porcelain tube) was also passed to a point close to the refractory pieces. An electrodynamometer method was used for measuring the electrical resistance, the two molybdenum terminals being joined to the + posts of the bridge arrangement shown in Fig. 3, and the thermo-couple readings made with a potentiometer. Before beginning the final measurements, the material was heated twice to about 1500° C. since it was found that the chemical composition of any refractory material is not in an equilibrium position at a high temperature unless it has been previously heated to that temperature. The measurements of temperature and resistance were taken with rising temperature in the furnace, tight clamping of the refractory pieces between the graphite plates being thus assured by expansion. It is stated that relative values obtainable by this means are accurate to within 2 or 3 per cent. and absolute values probably to within 10 or 15 per cent. The resistivity of alundum (finely ground) between 750° and 1600° C. is shown by means of a curve, the values obtained at these two temperatures being respectively 50,000 and 190 ohms per cm.³
—W. E. F. P.

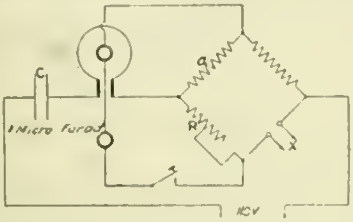

FIG. 3.

Water power resources in Alaska for electro-chemical industries. Board of Trade J., Feb. 19, 1914. [T.R.]

THE Report for the year ended 30th June, 1913, of the overnor of Alaska to the United States Secretary of the nterior states that there is a great deal of water power n Alaska that could be utilised, in conjunction with the ther natural resources of the country, for the development of electro-chemical industries. Water power is lready being developed at Speel River, about 35 miles outh-east of Juneau, the purpose being the establishment of a large electro-chemical and industrial plant to nanufacture carbides, sulphuric acid and other chemicals, ig iron from clinker iron, wood pulp, and sulphur, etc. here is a practically unlimited supply of raw materials, ncluding timber, lime, sulphur, etc., near at hand, and itable fuel will be obtainable from the Alaska coal mines hen opened, or from British Columbia.

Fine-meshed brass gauze as a substitute for platinum in electro-analysis. Calhane and Wheaton. *See* XXIII.

PATENTS.

Ozone-generator. S. Held, Assignor to The Held Co., Chicago, Ill. U.S. Pat. 1,085,579, Jan. 27, 1914.

THE space between concentric outer and inner dielectric tubes forms the ozone chamber. The outer tube is open at one end and is provided with a restricted outlet at the opposite end. In contact with the greater part of its outer surface is an electrode. The inner tube consists of a closed vacuum tube and contains a hollow electrode extending nearly its whole length. The tubes are connected at the closed end of the outer tube, and this is provided with projections on its inner surface at its open end to maintain the correct spacing between the two tubes.—T. ST.

Ozone-generator. W. O. Freet, Hackensack, N.J., Assignor to Steynis Ozone Co., New York. U.S. Pat. 1,085,598, Feb. 3, 1914.

THE generator consists of a base of insulating material, a flat electrode supported by the base, a flat dielectric supported over the electrode, and flat strips, constituting electrodes, supported in racks having vertical slots, and situated above the dielectric.—T. ST.

Furnace; Electric ——. B. Guthrie, Pittsburgh, and J. P. Karch, Sewickley, Pa., Assignors to C. P. Carpenter, trustee, Pittsburgh, Pa. U.S. Pat. 1,086,164, Feb. 3, 1914.

A CRUCIBLE is heated by the current passing between two electrodes which are movable towards and away from the crucible, in a horizontal direction. Each electrode encloses substantially one-half of the crucible, and is shaped so that it is in contact with the latter at the bottom, and diverges from it towards the top. The space between the electrodes and the crucible is filled with a broken carbon resistance.—T. ST.

Battery compounds. J. W. Mackenzie, London. From Cook Railway Signal Co., Denver, U.S.A. Eng. Pat. 7298, March 27, 1913.

SEE U.S.Pat.1,060,832 of 1913; this J., 1913, 611.—T. F. B.

Absorbent for use in the cells of electric dry batteries; Process for preparing an ——. P. Rabbidge. Fr. Pat. 462,664, Sept. 2, 1913. Under Int. Conv., Sept. 27, 1912.

Apparatus for the electrolytic production and collection of hydrogen and oxygen. Fr. Pat. 461,981. *See* VII.

XII.—FATS; OILS; WAXES.

Palm-kernel oil: Composition of ——. G. D. Elsdon. Analyst, 1914, **39**, 78—80.

FRACTIONATION of palm-kernel oil by the process of alcoholysis, as used for cocoanut oil (this J., 1913, 149), gave the following approximately quantitative proportions of fatty acids:—Caproic acid, 2; caprylic acid, 5; capric acid, 6; lauric acid, 55; myristic acid, 12; palmitic acid, 9; stearic acid, 7; and oleic acid, 4 per cent. These results indicate that it might not be possible to distinguish between certain samples of cocoanut oil and palm-kernel oil, even in the pure condition. Haller's process of alcoholysis (this J., 1907, 328; 1908, 324) does not give reliable qualitative results and is unsuitable for preliminary tests.—C. A. M.

Argemone Mexicana; The oil of ——. K. Bhaduri. Amer. J. Pharm., 1914, **86**, 49—54.

The crushed seeds of *Argemone Mexicana*, which now grows wild in India, yielded 22·3 per cent. of a thin brown oil on extraction with light petroleum. The expressed oil gradually thickened on keeping and deposited a very small amount of a red crystalline substance, m.pt. 172° C. The oil solidified at 16°—17° C. The following characters were observed: sp. gr. 0·9117 at 28° C., and 0·9007 at 100° C., refractive index, 1·46552 at 32° C.; saponification value, 185·5; acetyl value, 27·9; acid value, 146; bromine value, 102·2; Reichert-Meisel value, 0·61; Hehner value, 94·02; glycerol, 15·48 per cent.; Maumené test, 65° C.; The fatty acids contained 77 per cent. of liquid acids having the iodine value 147·4. Evidence was obtained of the presence of acetic, valeric and lauric acids.—F. Shdn.

Hydrogenated oils; Analytical constants of ——. C. Ellis. J. Ind. Eng. Chem., 1914, **6**, 117—122.

A review of the published data on the analytical characters of hydrogenated oils (see this J., 1912, 996; 1913, 201, 370, 665, 797; 1914, 206), together with some of the author's own observations. The saponification value and content of free fatty acids and of unsaponifiable matter are not appreciably affected by hydrogenation; the refractive index is diminished as is shown by the following values for hydrogenated oils, the melting points of which are given in brackets: corn or maize (55·7° C.), 1·4514; whale (41·5° C.), 1·4550; soya bean (50·3° C.), 1·4538; cocoanut ("olein") (24·7° C.), 1·4425; linseed (42·3° C.), 1·4610; palm (38·7° C.), 1·4517; palm (44·8° C.), 1·4494; peanut or arachis (34·7° C.), 1·4547. Hydrogenated arachis (peanut) and sesamé oils cannot in some cases be distinguished from lard nor hydrogenated whale oil from mutton or beef tallow by means of the usual analytical constants. —A. S.

Oil; Utilisation of used —— for lubrication. M. Pellet. Intern. Sugar J., 1914, **16**, 63—64.

According to the experience of the author, used oil preserves its lubricating properties almost intact, its density, viscosity, flash point, and acidity not being notably altered. The oil may be purified by passing it through medium-mesh wire gauze to remove solid impurities, and then treating it with steam in a tank containing a coil pierced with holes on the lower side. The steaming is continued for 15—30 minutes from the time when the mass becomes hot, and the separated oil is centrifuged or filtered through flannel, the filter being disposed in a warm place, or provided with a hot-water jacket.—J. P. O.

Sulphonated oils; Analysis of ——. *Provisional method of the Amer. Leather Chem. Assoc.* J. Amer. Leather Chem. Assoc., 1914, **9**, 68—70. (See also this J., 1914, 32.)

Moisture.—30 to 40 grms. of the oil, mixed with 75 c.c. of xylene saturated with water, are distilled from an oil bath into a graduated tube until the distillate is clear. The water in the distillate is measured. *Unsaponifiable.*—10 grms. of oil are boiled for 1 hour under a reflux condenser with 5 c.c. of aqueous potassium hydroxide (50 grms. per 100 c.c.), 45 c.c. of alcohol, and a few glass beads. After adding 100 c.c. of water and cooling, the mixture is shaken at least three times with petroleum ether (b.pt. 40°—75° C.), using 50 c.c. each time. The petroleum ether solution is washed at least three times in succession with 50 c.c. of water containing 10 c.c. of alcohol, using alcohol to break emulsions, and is then evaporated, and the residue weighed. *Combined SO_3.*—(See this J, 1914, 32.) *Total fatty oil* is taken as the difference between 100 and the sum of moisture, ash, and unsaponifiable matter.—J. R. B.

Fish-scrap fertiliser industry of the Atlantic Coast (U.S.A.). Turrentine. *See* XVI.

Patents.

Soap; Manufacture of milled ——. F. A. V. Klopfer, Dresden-Leubnitz, Germany. U.S. Pat. 1,085,437, Jan. 27, 1914.

See Eng. Pat. 2191 of 1912; this J., 1912, 546.—T. F. B.

XIII.—PAINTS; PIGMENTS; VARNISHES; RESINS.

Zinc white; Preventing the injurious effect of —— on the fastness to light of water colours. E. Täuber. Farbenzeit., 1913, **19**, 475—485. Chem. Zentr., 1914, **1**, 503.

The injurious effect of zinc white (this J., 1911, 1170) may be due to an impurity. By treating commercial zinc white with hydrogen peroxide and using glycerin in addition to gum as a vehicle, a permanent Chinese white can be obtained which apparently does not affect the fastness to light of other water colours. Zinc white has an injurious action on Prussian blue even in the dark. Calcium tungstate is recommended as a valuable though expensive white pigment, which approaches zinc white in covering power and has no injurious effect on the fastness to light of other colours.—A. S.

Paint vapours; Composition of ——. H. A. Gardner. J. Ind. Eng. Chem., 1914, **6**, 91—95.

A current of purified air was drawn through vessels which had been coated inside with a drying oil (raw linseed, soya bean, tung, and menhaden oils), or with mixtures of various pigments with raw linseed oil. Armstrong and Klein's statement (this J., 1913, 320) that no volatile metallic compounds are evolved from oil paints containing lead or zinc pigments was confirmed. The absorption of oxygen by thin films of drying oils was accompanied by the evolution of considerable quantities of carbon dioxide and organic compounds and a small quantity of carbon monoxide (detected by the liberation of iodine from heated iodine pentoxide). In the vapours from drying paints the presence of aldehydes, acids (formic acid, etc.), carbon dioxide and monoxide was detected; the production of volatile substances appeared to be stimulated by the presence of basic pigments and oil of turpentine.—A. S.

Wood turpentine industry; The present status of the —— E. H. French and J. R. Withrow. Met. and Chem. Eng., 1914, **12**, 95—99.

In a resumé of the general methods of manufacture, th economics of the steam, solvent, alkali, bath, and destructive distillation processes are considered, particulars bein given of the approximate yield and operating cost in eac case, and suggestions made as to possible improvement and future developments. The authors are of opinio that for the successful operation of the steam proce a minimum price of 50 cents. per gal. for wood turpentin is necessary; that the solvent process may prove commercial value if operated on a scale sufficientl extensive to permit of the utilisation of the treated chi for the economic manufacture of paper pulp: and that t alkali process (essentially the manufacture of paper pu from resinous woods, with recovery of turpentine a rosin) will eventually be of commercial importan although at present requiring capital expenditure develop the mechanical details. Since the destructive distillation process has alone withstood the recent price depression, it is concluded that this method possesses inherent advantages; in processes of this type, however, considerable improvement is required in refining and in the utilisation of waste products. It is stated that although the industry practically owes its existence to abnormal market conditions, the manufacture of wood turpentine will necessarily become of far-reaching importance in the future, as a means of utilising an absolutely waste product and at the same time clearing cut-over lands for occupation.—W. E. F. P.

Turpentine; Action of aluminium chloride on oil of ——. W. Steinkopf and M. Freund. Ber., 1914, 47, 411—420.

By the action of aluminium chloride on French oil of turpentine cooled by ice and kept agitated, the chief product was a resinous polymeride of pinene melting at 77°—78° C. When, after the treatment, the reaction product, without separation of the aluminium chloride, was decomposed by heating, a mixture of substances was obtained of the same qualitative composition as the mixture obtained under similar conditions from amylene, hexylene, etc. (compare this J., 1910, 10, 338), *i.e.*, the most volatile portion consisted mainly of saturated paraffin hydrocarbons, then as the boiling point rose the fractions contained increasing quantities of naphthenes and, later, of polynaphthenes, whilst the least volatile portions consisted of oils of the same composition and properties as lubricating oils from natural petroleum.—A. S.

Abietic acid and some of its salts. E. O. Ellingson. J. Amer. Chem. Soc., 1914, 36, 325—335.

Pure abietic acid, prepared from colophony by extraction with 70 per cent. alcohol and recrystallisation from 95 per cent. alcohol, melted at 150°—152° C. and appeared to be oxidised at temperatures near the melting point, the heat of combustion of the melted acid being somewhat lower than that of the unmelted acid. The salts of the acid with sodium, potassium, and some of the heavy metals were prepared, but nearly all of them contained more than the theoretical quantity of abietic acid. Sodium abietate was soluble in water and in methyl, ethyl, and amyl alcohols. The abietates of the heavy metals, on he other hand, were insoluble in water, slightly soluble n methyl alcohol, but readily soluble in most organic olvents.—A. S.

Patents.

mpregnating or coating surfaces, binding colours, and addition to colours principally for the purpose of rust prevention; Manufacture of compositions for ——. R. Eberhard, Munich, Germany. Eng. Pat. 20,954 of 1913, dated of Appl., Dec. 3, 1912.

ILs or fats, or their distillation or oxidation products, are eated with permanganic acid, in conjunction with erchlorides of the heavy metals; stannic anhydride ay also be added. For example: manganese perloride, 3 parts, dissolved in ether, 10 parts, and peranganic acid, 3 parts, are mixed with linseed oil, 100 arts, to which stannic anhydride, 1·5 part, has been lded; or antimony pentachloride, 2 parts; dissolved in chloroform, 15 parts, and permanganic acid, 5 parts, are mixed with linseed oil, 100 parts, in which tin tetrachloride, 5 parts, and stannic anhydride, 1·5 part, have been dissolved.—E. W. L.

Colour-lake and process of making same. A. Strupler, Assignor to Farbwerke vorm. Meister, Lucius, und Brüning, Höchst on Maine, Germany. U.S. Pat. 1,085,178, Jan. 27, 1914.

XIV.—INDIA-RUBBER; GUTTA-PERCHA.

Rubber exports from the Amazon Basin in 1913. Board of Trade J., Feb. 28, 1914. [T.R.]

H.M. Consul at Pará reports that the quantity of rubber exported from Pará, Manaos, Iquitos, and Itacoatiara, *via* Pará, during the years 1912 and 1913, was as follows:—

——	Fine.	Medium.	Coarse.	Caucho.	Total.
Year 1913.	Kilos.	Kilos.	Kilos.	Kilos.	Kilos.
To the United States	7,296,134	1,387,132	5,511,869	3,272,716	17,467,851
To Europe	11,618,956	1,604,731	2,344,861	6,676,778	22,245,326
Total, 1913	18,915,090	2,991,863	7,856,730	9,949,494	39,713,177
Total, 1912	21,585,629	3,488,771	9,311,559	8,473,344	42,859,303

Rubber; Yield of —— from Manihot Glaziovii. E. Fickendey. Gummi-Zeit., 1914, 28, 747—748.

It has been proposed to increase the flow of latex from *Hevea Brasiliensis* by removing the dead parts of the bark before tapping, down to the green cork-cambium, and repeating this periodically during the tapping period (Ger. Pat. 265,937). This process fails in *Kickxia* trees in which there is no wound response. The author gives experiments showing that the method causes a better yield in the case of *Manihot* trees also; details of the treatment of the trees are given. (See also this J., 1911, 374).—H. E. P.

Synthetic caoutchouc from isoprene. G. Steimmig. Ber., 1914, 47, 350—354.

Harries (this J., 1913, 203, 983) concluded that synthetic caoutchouc, prepared by polymerisation of isoprene by heat in presence of glacial acetic acid, was identical with natural caoutchouc, from the similarity of the diozonides of these two substances, and the fact that both yielded lævulinic acid and lævulinic aldehyde on hydrolysis, which occurred with the same reaction-velocity. Harries also suggested that another caoutchouc might be produced by the asymmetric condensation of two molecules of isoprene. The author applied Harries' methods to the caoutchouc prepared according to the patents of the Badische Anilin und Soda Fabrik (see this J., 1913, 152, 372, 667), by heating isoprene in presence of ozonides or peroxides or by the action of sodium on isoprene in presence of carbon dioxide; these products differ from that obtained by heating isoprene. It was found that, in addition to lævulinic acid and aldehyde, the products of hydrolysis of the diozonide contained succinic acid and acetonylacetone. The latter was separated from lævulinic aldehyde by converting both substances into their diphenylhydrazones and decomposing these with steam, when 1 mol. of phenylhydrazine was split off in each case, the lævulinic acid derivative giving phenylmethyldihydropyridazine and the acetonylacetone derivative 1-phenylamino-2.5-dimethylpyrrole, the latter of which is volatile in steam. The caoutchouc obtained by heat polymerisation of isoprene gave similar results, but no succinic acid or acetonylacetone could be detected in the products of hydrolysis of the diozonide from natural caoutchouc. It is deduced that natural caoutchouc is composed only of 1.5-dimethylcyclo-octadiene-1.5 rings, whereas the above artificial caoutchoucs contain an estimated quantity of 20 per cent. of 1.6-dimethylcyclo-octadiene-1.5 which may be considered to result from the asymmetric condensation of isoprene.—H. E. P.

Reclaimed rubber and plantation rubber. W. F. de B. Maclaren. India Rubber J., 1914, **47**, 269—272.

The author estimates that in recent years the amount of waste rubber goods annually collected has been about 400,000 tons; the scrap therefrom capable of treatment, 280,000 tons; rubber compounds recovered, 140,000 tons (United States and Canada, 65,000 tons; Great Britain, 25,000 tons; the Continent, 50,000 tons); actual rubber contents, 56,000 tons. Allowing for the rubber worn away from tyres and for articles sent to out-of-the-way regions, and not recoverable, it seems clear that this quantity of reclaimed rubber can only have been collected by drawing on the world's accumulated stocks of old rubber. It is considered that reclaimed rubber does not displace plantation rubber so much as inferior raw rubber and fillers, and that as plantation rubber becomes cheaper it will be difficult for reclaimed rubber to compete in price to the same extent as hitherto.—H. E. P.

Vulcanisation of rubber; Influence of nitrogenous and resinous constituents on the ——. H. P. Stevens. Kolloid-Zeits., 1914, **14**, 91—96. India-Rubber J., 1914, **47**, 403—406.

Following previous work (this J., 1912, 999, 1099; 1913, 203) on the nitrogenous and insoluble constituents of rubber, the author has tried the effect of incorporating various substances with rubber which has been freed from insoluble constituents by treatment with benzene as described previously. Peptone in a slightly damp condition was incorporated directly by means of a mixing machine and also by emulsifying an aqueous solution with a solution of the rubber in benzene. Starch was incorporated directly. The results of experiments with a number of samples subjected to different preliminary treatments are shown in the following table: the samples were mixed on the hot rolls with 7 per cent. S, then rolled into a sheet, vulcanised in the usual way, and tested after 1 week.

		Resistance to stretching.	Sub-permanent extension.	Vulcanisatica coefficient.
No.	Sample.	Load in grms. per sq. mm. of cross-section of sample required to stretch the rubber to five times its original length.	Extensioa per cent., immediately after removing load after five stretchings with a maximum load of 200 grms. per sq. mm.	Calculated to rubber free from protein and resia.
1	Untreated rubber (Unsmoked plantation sheet from Malaya)	178	25·6	2·86
2	Rubber swollen in benzene	182	24·4	2·83

Sulphur in rubber; Determination of ——. H. P. Stevens. Analyst, 1914, **39**, 74—78.

On oxidising rubber with nitric acid a variable loss o sulphur takes place owing to the volatilisation of product containing sulphur. Such volatile products may b absorbed by passing the gases into a solution of potassiu hydroxide, nitric acid, or even water, and the absorbe sulphur may be subsequently determined as bariu sulphate. Or the oxidation of the rubber product may b carried out in a vessel provided with a suitable con densing apparatus, such as a Young's fractionati column with ground-glass connection. A sample unvulcanised rubber containing 7·3 per cent. S yielded onl 7·02 per cent. when oxidised in a beaker. When oxidis in a flask connected with a U-tube containing nitric aci the contents of the flask contained 7·10 and those of the U-tube 0·19 per cent. S.—C. A. M.

Patents.

Caoutchouc ; Vulcanisation of products resembling or related to ——. J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen-on-Rhine, Germany. Eng. Pat. 8781, April 14, 1913.

The products obtained as described in Eng. Pat. 975 of 1913 (this J., 1914, 93) may be vulcanised. For example the product obtained according to the fifth example may be vulcanised by heating with 10 per cent. of sulphur. The vulcanised product is light gray in colour. The product obtained according to Eng. Pat. 26,550 of 1912 (this J., 1913, 1164) and treated according to Eng. Pat. 975 of 1913 (*loc. cit.*) with 8 per cent. of sulphur may be vulcanised, forming a light gray product, by heating in a press for two hours at two atmospheres steam pressure. If heated for three hours at three atmospheres pressure an almost black soft product is obtained. With higher proportions of sulphur and prolonged heating products resembling ebonite may be obtained.—E. W. L.

Vulcanised rubber ; Process for preparing a product analogous to ——. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 268,387, Dec. 25, 1912. Addition to Ger. Pat. 266,618.

The product of the polymerisation of βγ-dimethylbutadiene described by Kondakow (J. prakt. Chem., **64**, 109), is vulcanised in presence of a derivative of piperidine or its homologues, *e.g.*, N-thiopiperidine, benzal-dipiperyl, etc.—T. F. B.

Rubber ; Process for regenerating ——. C. Harries. Ger. Pats. 267,993 and 267,994, Dec. 29, 1912, and Jan. 21, 1913. Additions to Ger. Pat. 267,277 (see this J., 1914, 94).

(1.) The decomposition of the hydrohalogenides of caoutchouc is effected by heating with bases at a high temperature and under pressure. (2) The hydrohalogenides are decomposed by heating with carbonates or other salts of weak acids, at normal or increased pressure.—T. F. B.

Caoutchouc-like products ; Process of manufacturing ——. A. Caroselli, Assignor to Chem. Fabr. Flörsheim Dr. H. Noerdlinger, Flörsheim on Maine, Germany. U.S. Pat. 1,086,139, Feb. 3, 1914.

See Ger. Pat. 253,517 of 1910 ; this J., 1913, 36.—T. F. B.

Caoutchouc ; Process for producing substances resembling ——. Farbenfabr. vorm. F. Bayer und Co. Second Addition, dated July 1, 1913, to Fr. Pat. 434,989, Oct. 7, 1911. Under Int. Conv., July 22, 1912.

See U.S. Pat. 1,073,845 of 1913 ; this J., 1913, 1164.—T. F. B.

Rubber ; Cementing of ——. A. Pidoux, Geneva, and P. de Carsalade du Pont, Brussels. Eng. Pat. 11,175, May 13, 1913. Under Int. Conv., May 11, 1912.

Process for preparing isoprene. Ger. Pat. 268,101. *See* XX.

XV.—LEATHER ; BONE ; HORN ; GLUE.

Sulphides in lime liquors ; Determination of ——. J. R. Blockey and P. V. Mehd. Collegium, 1914, 73—75.

The failure of McCandlish and Wilson (this J., 1913, 153) to obtain correct results by the method of Blockey and Mehd (this J., 1912, 369) is due to the fact that they omitted to add ammonium chloride in preparing the reagent which should consist of a *N*/10 solution of zinc sulphate to which has been added ammonia until the precipitate has just redissolved and also 50 grms. of ammonium chloride per litre. McCandlish and Wilson also used liquor of much lower concentration than are met with in practice. The mechanism, from the point of view of the ionic hypothesis, of the reactions involved in the estimation of sulphides in lime liquors with zinc sulphate is discussed.—J. R. B.

Analysis of sulphonated oils. See XII.

Condensation products of formaldehyde [and naphthalenesulphonic acids] : Manufacture of soluble ——. J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. Eng. Pat. 7137, March 25, 1913.

Readily soluble condensation products, stated to possess valuable tanning properties, are obtained by treating naphthalenesulphonic acids or their homologues with formaldehyde or its equivalent, with or without the use of condensing agents, under suitable conditions. In particular, a large excess of sulphuric acid and too prolonged an action thereof, should be avoided. Similar products are obtained by sulphonating the insoluble condensation products of formaldehyde or its equivalent and naphthalene or its homologues. *Example.* Ten parts of naphthalene are heated with 12·5 parts of 98 per cent. sulphuric acid at 130°—140° C. When sulphonation is complete, the mass is cooled to 80°—90° C., and 4 parts of 30 per cent. formaldehyde are added, with constant agitation, keeping the temperature between 60° and 100° C After a time the mass becomes thick, whereupon sufficient water is added to enable it to be stirred, and stirring is continued, at the same temperature, until the odour of formaldehyde has disappeared. The cooled product is a solid, resinous, slightly coloured mass soluble in cold water. The solution is itself capable of tanning and also has the property of rendering soluble the less easily soluble portion of quebracho.—T. F. B.

Tanning hides and skins ; Process and apparatus for ——. A. Bracher. Ger. Pat. 268,126. Oct. 6, 1911.

The hides or skins are suspended on long shafts, and are moved forward from time to time, in the direction of their length, towards the end of the vat, at which fresh tanning liquor is introduced, the spent liquor being withdrawn from the other end of the vat. By this means the hides are progressively treated by stronger liquors. —T. F. B.

Leather ; Process for preparing multi-coloured, figured ——. A. Wolff. Ger. Pat. 268,449, Oct. 24, 1912.

Leather which has been mordanted with a chromium, aluminium, or iron compound is printed with a mordant dyestuff together with a thickening material such as is used in textile printing ; the dyestuffs are fixed by steaming at temperatures below 100° C., preferably between 60 and 70° C.—T. F. B.

Tannic extract and process of manufacturing the same. X. F. Debédat, Bordeaux, France. Eng. Pat. 5369, March 3, 1913, Under Int. Conv., March 7, 1912.

See Fr. Pat. 441,217 of 1912 ; this J., 1912, 830.—T. F. B.

Drying varnished leather or the like ; Process for ——. C Heyl. Fr. Pat. 462,501, Sept. 12, 1913 Under Int Conv., Sept. 12, 1912.

See Eng. Pat. 20,795 of 1913 ; this J., 1914, 95.—T.F.B.

Leather ; Process for treating —— to waterproof it and to render it non-slipping. A. McLennan. Fr. Pat. 462,932. Aug. 28, 1913. Under Int. Conv., Sept. 16, 1912.

See Eng. Pat. 21,081 of 1912 ; this J., 1914, 95.—T.F.B.

XVI.—SOILS ; FERTILISERS.

Organic nitrogen of Hawaiian soils. W. P. Kelley and A. R. Thompson. J. Amer. Chem. Soc., 1914, **36**, 429—444.

Products of acid hydrolysis. The soils examined were of the laterite class and comprised silty loams, a loam containing considerable gravel, a highly organic sandy soil, silty soils, and a highly humic soil. The content of total nitrogen ranged from 0·122 to 1·241 per cent., nitrate nitrogen 0 to 70 parts per million, and ammonia nitrogen 10 to 220 parts per million, all calculated to the water-free soil. Samples of the air-dried soils (50 grms.) were heated with 750 c.c. of strong hydrochloric acid for 10 hours under a reflux condenser, and in the filtered solution the proportions of the different classes of nitrogenous compounds were determined. From 67·51 to 91·80 per cent. of the total nitrogen in the different soils was brought into solution during the hydrolysis. The amide nitrogen (determined by distillation with magnesia) ranged from 18·99 to 30·96 (average 23·91) per cent. of the soluble nitrogen, the basic nitrogen (precipitated by phosphotungstic acid) from 5·01 to 13·81 (average 9·98), and the non-basic nitrogen (by diff.) from 54·82 to 70·42 (average 64·57) per cent.

Effects of heat on soil nitrogen. The effect of heating in an air-bath and in presence of steam under pressure was studied. The nitrates were decomposed, disappearing almost completely at 200° C. The ammonia-nitrogen increased considerably between 150° and 200° C., usually decreasing again at 250° C. The effect of steam at 2 atmospheres pressure was similar to that of heating in air at 150° C. The effect of heating to 200° C. on the organic nitrogen compounds varied with the different soils, but in general there was a loss of nitrogen and formation of considerable quantities of ammonia, largely at the expense of the compounds which yield non-basic nitrogen on acid hydrolysis.

The nitrogen of humus. The soils examined, the same as those used in the experiments described above, contained from 0·004 to 0·041 per cent. N soluble in 1 per cent. hydrochloric acid. After treatment with the acid, humic substances were extracted from the soils by means of a 3 per cent. solution of sodium hydroxide ; except in two cases the solution contained more than one-half of the total nitrogen. A portion of the alkaline solution was acidified with dilute hydrochloric acid and the precipitates subjected to acid hydrolysis. The detailed results show that whilst the absolute amounts of amide, basic, and non-basic nitrogen in the humus are less than the quantities produced by hydrolysis of the entire soil, the total humus nitrogen contained relatively more amide and basic nitrogen and less non-basic nitrogen than the total nitrogen of the soil. This indicates that the formation of humus is accompanied by a considerable simplification of the protein complex and hence may be regarded as a step towards the production of available nitrogen.—A. S.

Fish-scrap fertiliser industry of the Atlantic coast (*U.S.A.*). J. W. Turrentine. Bull. U.S. Dept. Agric. No. 2, Bureau of Soils, Dec. 27, 1913. (See also this J., 1914, 96).

The fish-scrap industry is centred round Chesapeake Bay and comprises about 40 factories employed in converting the "menhaden" fish into manure and collecting the oil. The actual fishing takes place from April to November or December. A specimen of this fish on analysis was found to contain: water, 77·150, and oil, 3·914 per cent. 12,000 to 15,000 fish give 1 ton of dried scrap and the 900,000,000 caught annually produce 70,000 tons of dried scrap. The yield of oil varies mainly with the season of the year: in the spring no oil may be obtained, whereas in the autumn 1000 fish may give 12 to 15 gallons. In 1900 the average yield at the Rhode Island factories was 5·76 gals. per 1000 fish. The moisture and oil are expressed from the fish (previously cooked by the aid of steam) by means of a continuous action-press. The scrap is finally dried by hot air in a revolving drum 30 to 40 ft. long by 6 ft. diameter, through which the material passes continuously, emerging with a moisture content of about 7 per cent. Before marketing the fish scrap is usually mixed with other fertiliser ingredients. The average analysis of ten samples of dried fish scrap give :—Nitrogen, 9·13 per cent., phosphoric acid (P_2O_5) 7·25 per cent., moisture about 7 to 9 per cent. oils 6·99 per cent., the remainder being mostly organic matter. The oil and water pressed out are pumped into tanks heated by steam pipes to facilitate separation, the oil being run off over consecutive weirs into barrels or tanks. About 35,000 barrels or about 2 to 2½ million gallons of oil are produced annually, and in 1911 the price was 23 to 28 cents per gallon. The following values of the specific gravity and iodine value of menhaden oil are given :—

	Sp. gr. at 20° C.	Iodine value (Hübl).
Extra bleached winter	0·9237	150·4
Bleached refined	0·9273	161·2
Regular	0·9249	165·7
Dark brown	0·9250	154·5

The oil varies from light amber to dark brown in colour, and was formerly used for currying leather and as an illuminant. Of all the fish oils "menhaden" is said to be the best for use in paint manufacture, and when mixed with 25 per cent. of linseed oil and a "drier" gives excellent results. It is also used as a lubricant and for tempering steel. Menhaden oil can replace linseed oil in the production of printing ink and in the manufacture of patent leather.—N. C. A.

Obtaining products [*oils and a fertiliser*] *from sewage sludge.* Eng. Pat. 1564. *See* XIXb.

XVII.—SUGARS ; STARCHES ; GUMS.

Sugars ; Differences in the analysis of raw ——. F. Sachs. Z. Ver. deut. Zuckerind., 1914, 144—157.

The author has collated the results of analyses, made in each case by about 30 British and Continental chemists, of 22 first or second product beet sugars. The ratio of ash to organic non-sugar in the different samples ranged from 1·5 to 2·2, save in one, probably abnormal sample. Of the polarisation values (663 in number), 81·2 per cent differed from the mean for the sample by less than 0· per cent., and the results were practically as accurate with the second as with the first products. The values fo invert sugar (in most cases trace or nil) generally agree very well. Of the ash-contents, 84 per cent. did no differ from the mean for the sample by more than 0·0 per cent. ; the results were rather more accurate wit the first than with the second products. Small quantities of raffinose were found in some cases, but the results were often very discordant.—L. E.

Magnesia ; Rôle of —— in the carbonatation process [*of sugar manufacture*]. H. Pellet. Intern. Sugar. J., 1914, **16**, 77.

Magnesia introduced into sugar juice by the use of impure limestone causes various difficulties, chiefly in increasing the amount of incrustation in the effect evaporators (this J., 1914, 154). When in the cane or the beet factory it is impossible to obtain a material free from magnesia, carbonatation should be stopped at an alkalinity of 0·5—0·6 grm. CaO per litre, and the juice filtered. At this point practically all the magnesia is insoluble, whereas if the operation be continued, a greater or less amount passes into solution.—J. P. O.

Sugar manufacture ; Use of bagasse carbon for decolourisation in white ——. W. Clacher. Intern. Sugar J., 1914, **16**, 64—66.

Bagasse carbon is stated to possess considerable decolourising power. It is preferably used at two different stages of sugar manufacture, viz., as soon as feasible after the juice leaves the mill, using as fine a powder as can be worked (the carbon separates in the scums); or after concentration to syrup before entering the vacuum pans, the syrup being run through a cistern, similar to the type used in refineries. After use the carbon may be revivified by heating as in the case of animal charcoal, and when finally spent may be utilised as fuel.—J. P. O.

Carbohydrates ; Picrate colourimetric method for the determination of ——. W. M. Dehn and F. A. Hartman. J. Amer. Chem. Soc., 1914, **36**, 403—409.

The authors recommend, for the rapid determination of sugars, measuring the depth of colour produced by heating under standardised conditions with a solution of picric acid rendered alkaline with sodium carbonate: the use of sodium hydroxide is inadmissible owing to the decomposing action on the sugars. The colour produced is compared with that of standards prepared by treating a pure sugar under the same conditions. The method may be applied to the determination of lactose in milk after coagulation and separation of the casein. (See also Chapman, this J., 1910, 1413.)—A. S.

Sugar and the like ; Centrifugal apparatus for separating liquids from ——. A. Mazzacani, Bologna, Italy. Eng. Pat. 14,096, June 18, 1913.

For moulding masses of sugar a centrifugal machine is provided with triangular vertical wedges attached to the inside surface of the drum, and between the wedges are open moulds or frames held in position by overhanging rims at the tops of the wedges. The upper walls of the frames and the rims on the wedges which project over them, are curved to a circle having its centre in the plane of the bottom on or beyond a line connecting the lower corners of he frame situated towards the centre of the drum. Thus he masses of sugar formed in the frames are easily removed by pulling the tops forward towards the centre of the drum. When the wedges are removed the machine operates as an rdinary centrifugal drainer.—J. F. B.

Purifying and decolourising liquids, especially sugar solutions ; Process for ——. F. Tiemann. Fr. Pat. 461,485, Aug. 19, 1913.

XVIII.—FERMENTATION INDUSTRIES.

Malt ; Formation of colour and aroma in curing ——. T. Langer. Z. ges. Brauw., 1914, **37**, 90—93.

For the production of dark aromatic malt it is essential that the grain should not be dried to a high degree on the top floor. The curves representing variations in the moisture-content of the grain on the top floor and the relative humidity of the superincumbent stratum of air are parallel, being similarly affected by any irregularity of the air current. The author gives a short account of recent work on the action of amino-acids on sugars and the significance of this action in respect of the formation of colour and aroma during the curing of malt (cp. Matthews and Lott, this J., 1908, 869; Ling, *ibid.* 1034; Maillard, *ibid.* 1912, 144; Lintner, Z. ges. Brauw., 1912, 554).—L. E.

Malt extracts ; Determination of the diastatic power of ——. A. Monnier. Ann. Chim. analyt., 1914, **19**, 51—54.

Commercial malt extracts contain large quantities of reducing sugars, hence in determining the diastatic power by Lintner's method it is necessary, in addition to the usual quantity of 5 c.c. of Fehling's solution introduced into each test-tube, to add quantities of Fehling's solution corresponding exactly to the reducing sugars present in the different amounts of the malt extract solution placed in the tubes. The author prefers to express the results in terms of maltose: 10 grms. of a malt extract having a diastatic power of 100 (Lintner) will produce 77·8 grms. of maltose from starch in 1 hour at 18° C. Commercial malt extracts, of which 10 grms. produce from 10 to 16 grms. of maltose may be considered very rich in diastase; extracts yielding from 5 to 10 grms. of maltose are fairly active, whilst those giving less than 3 grms. are unsatisfactory.—W. P. S.

Yeast ; Nitrogenous nutrition of pressed ——. H. I. Waterman. Folia microbiol., Holländ. Beiträge zur ges. Mikrobiol. 2, Heft 2. Chem. Zentr., 1914, **1**, 484—485.

The nutrient solution used consisted of a solution in tap-water of: glucose (anhydrous) 2, KH_2PO_4 0·2, and $MgSO_4$ 0·1 per cent., and in most cases 0·1 per cent. of the nitrogenous compound. After sterilising for 10 mins. at 120° C., the solution was inoculated with a pure culture of pressed yeast and kept at 30° C. No growth took place in the absence of a nitrogenous compound. Growth took place in presence of nitrogenous compounds of many different types, but especially with aliphatic amines, aromatic amines with amino-groups in the side-chain, ammonium chloride, and ammonium nitrate. Potassium nitrate, sodium nitrite, nitro-methane, and the compound, $C(CH_2OH)_3NO_2$, proved unsuitable as sources of nitrogen for the yeast. No growth occurred in the presence of amides of non-nitrogenous acids except in cases (*e.g.* urea, formamide, etc.) where these reacted with water to yield ammonia. Amides of amino-acids, such as asparagin, aspartic acid, hippuric acid, α-aminocinnamic acid amide, gave favourable results.—A. S.

Invertase ; Chemical constitution of ——. I. J. M. Nelson and S. Born. J. Amer. Chem. Soc., 1914, **36**, 393—403.

Invertase was prepared from 200 lb. of pressed yeast, which was allowed to autolyse in presence of toluene, the resulting liquid being filtered and the enzyme precipitated by alcohol and purified by re-precipitation from aqueous solution with alcohol, treatment with lead acetate and kaolin, dialysis, and precipitation with alcohol in presence of a small quantity of an added electrolyte (sodium chloride, potassium acetate, or acetic acid). The final product (about 200 grms.), after drying in a vacuum over sulphuric acid, gave the biuret, Millon, and xanthoproteic reactions for proteins when sufficient material was used: the most active preparation had an activity of ± 0°=37 mins. at 37° C. (see this J., 1890, 816, 1049), contained: ash 0·9, N 1·3 and P 0·3 per cent. The aqueous solution did not coagulate on heating, gave no precipitate with phosphotungstic acid, mercuric acetate or lead acetate, and the enzyme could not be salted out by ammonium sulphate, magnesium sulphate, or zinc sulphate. Yeast gum was prepared from the invertase by Salkowski's method (this J., 1894, 411; 1901, 489): it contained phosphorus, one sample showing 0·32 per cent. and another, not quite so pure, 0·23 per cent. An acetyl derivative (acetyl value 42·5—44·4 per cent.) of the gum, prepared by the action of acetyl bromide or of a mixture of acetic anhydride and sulphuric acid, contained 0·25—0·31 per cent. P; among the products of hydrolysis of the acetyl derivative were mannose and dextrose. After hydrolysis of the invertase with 10 per cent. sulphuric acid for 4 hours, the solution gave precipitates with phosphotungstic acid and mercuric acetate. The protein isolated from these precipitates represented only a small proportion of the nitrogen content of the invertase; it was free from phosphorus, soluble in water, did not reduce Fehling's solution, and gave a strong biuret reaction. Invertase is not destroyed by the action of trypsin (Wroblewski, J. prakt. Chem., 1901, **64**, 1; this J., 1901, 1009), diastase (Mathews and Glenn, J. Biol. Chem., 1911, **9**, 29; this J., 1911 439), ptyalin, pancreatic amylase, or castor bean lipase.—A. S.

Enzymes; Chemical composition and formation of ——. X. Influence of temperature and aeration on the formation of invertase. H. Euler and H. Cramér. Z. physiol. Chem., 1914, **89**, 272—278. (See this J., 1914, 97.)

The formation of invertase in living yeast when the latter is kept in nutrient sugar solutions proceeds more rapidly at 16° than at 39° C. and is not accelerated but rather retarded by vigorous aeration.—J. H. L.

Maltase of beer yeast; Conditions of activity of the ——. III. The nature of the different kinds of inhibition of enzymic action. L. Michaelis and P. Rona. Biochem. Zeits., 1914, **60**, 62—78. (See also this J., 1913, 442, 1123; 1914, 37.)

The inhibitive influence which some compounds exert on the activity of enzymes may be due either to a diminution of the velocity-constant of the enzymic hydrolysis, or to affinity, and consequent combination, between the inhibiting substance and the enzyme. From a study of the influence of various substances on the kinetics of the decomposition of α-methylglucoside by yeast extract, the author concludes that sodium chloride, sodium nitrate and glycerol inhibit the process by lowering the velocity-constant of hydrolysis, whereas dextrose and lithium chloride act simply by combining with the enzyme and thus reducing the active concentration of the latter. No inhibition is produced by lævulose or β-methylglucoside. The affinity of dextrose for the enzyme is about 5 times greater than that of α-methylglucoside itself.—J. H. L.

Invertase action; Different causes of inhibition of ——. L. Michaelis and H. Pechstein. Biochem. Zeits., 1914, **60**, 79—90. (See preceding abstract.)

Lævulose inhibits the action of invertase by combining with the enzyme and thus rendering it inactive. Glycerol and α-methylglucoside have no affinity for invertase but they lower the velocity-constant of its hydrolytic action. Maltose, lactose and β-methylglucoside neither possess any affinity for invertase, nor do they affect its activity in any way. It appears therefore that a hydrolysable sugar (disaccharide, glucoside) which is not decomposed by invertase has no affinity for this enzyme. The combination of invertase with a hydrolysable sugar is accordingly the necessary and sufficient condition for the hydrolysis of the latter.—J. H. L.

Fermentation; Alteration of the concentration of hydrogen ions during ——. H. Lüers. Z. ges. Brauw., 1914, **37**, 79—82. (See also Emslander, this J., 1914, 212.)

Ten per cent. solutions of sugar containing small quantities of nutrient salts, and possessing a concentration of hydrogen ions ($p_H=5·47$) approximately the same as that of brewery worts before fermentation, were fermented with yeast (5 grms. per litre) at 8° and at 25° C. A 10 per cent. sugar solution containing no salts was similarly fermented at 25° C. In all cases a considerable amount of acid was formed, and practically the same final concentration of hydrogen ions was attained ($p_H=2·66$—$2·73$). Another sugar solution, of which the concentration of hydrogen ions had been raised to this value by addition of lactic acid prior to fermentation, underwent only a slight increase of acidity during fermentation (final value of $p_H=2·51$); the degree of attenuation attained in this case was however only 39·6, compared with 67·3 and 60·7 in the other cases. It appears therefore that in the fermentation of sugar solutions, with or without salts, and at widely different temperatures, the yeast always tends to produce the same final concentration of hydrogen ions, independent of the initial value of this factor. An experiment with brewery wort ($p_H=5·11$) gave somewhat different results; the concentration of hydrogen ions increased to $p_H=3·67$ and finally diminished again to $p_H=4·00$.—J. H. L.

Fermentative equilibria; Resumption of hydrolysis or synthesis in consequence of alterations made in the composition of the mixture. E. Bourquelot and M. Bridel. Comptes rend., 1914, **158**, 206—209.

After equilibrium has been attained in solutions containing dextrose, alcohol and glucoside in presence of the corresponding enzyme (emulsin or α-glucosidase, see this J., 1913, 251, 378, 456, 762) further synthesis can be induced by addition of more sugar, or on the other hand further hydrolysis may be provoked by the removal of sugar, for example, by addition of yeast, and in fact continued fermentation of the sugar will lead finally to the hydrolysis of the whole of the glucoside originally present. It is very probable that in germinating plants, the living cell, acting as the yeast in the authors' experiments, consumes the products of hydrolysis of the reserve food-stuffs, and thus renders possible the continued and complete hydrolysis of the latter by the same enzymes which previously effected their synthesis.—J. H. L.

α-Methylgalactoside; Biochemical synthesis of ——. H. Hérissey and A. Aubry. Comptes rend., 1914, **158**, 204—206. (See also Bourquelot and others, this J., 1913, 251, 378, 456, 762.)

The authors, finding that α-methylgalactoside is ver slowly hydrolysed by maceration juice prepared fron bottom fermentation yeast, attempted to synthesise i by means of the same agent. A solution containin 95—100 grms. of galactose, 2 litres of yeast maccratio juice, 1·5 litres of pure commercial methyl alcohol (99· per cent.) and sufficient water to make up the liquid t 10 litres, was left for 4 months in presence of toluen From 5 litres of the product about 1 grm. of α-methy galactoside was isolated.—J. H. L.

Cane sugar syrup; Influence of small amounts of eth alcohol on fermentation in ——. C. B. Cochran an J. H. Perkins. J. Ind. Eng. Chem., 1914, **6**, 141.

Syrups of sp. gr. from 1·2112 to 1·26 at 20° C. were ma by dissolving granulated cane sugar in warm wat varying quantities of alcohol (up to 5 per cent. by vo were added, and fermentation tests with yeast (Fleisc mann's yeast cake) were made at 31°—32° C. In presen of quantities of alcohol up to 1 per cent., fermentati was markedly accelerated; 1·25 per cent. had litt influence and higher percentages retarded fermentatio —A. S.

Wines and fermented beverages; Determination of to solids in ——. P. Malvezin. Ann. Chim. analy 1914, **19**, 62—65.

To obtain the total solids free from glycerol, 50 c.c. the wine are evaporated at 80° C. to a pasty consiste in a flat bottomed flask connected with an exhaust pump. The temperature is then raised to 100° C., a current of steam passed through the flask for 1 hour and the residue dried at 100° C. for 10 minutes, the low pressure being maintained throughout.—W. P. S.

Betaine; Action of micro-organisms on ——. F. Ehrlich and F. Lange. Z. Ver. deut. Zuckerind., 1914, 158—171.

The ammonia formed in the biochemical decomposition of betaine cannot be detected in most cases (see this J., 1913, 986). It is now found, however, that if the decomposition is effected with *Penicillium glaucum*, *Aspergillus niger*, or certain allied organisms, an appreciable quantity of ammonia can be detected in the culture liquid. It is suggested that this discovery may find technical application in the treatment of the betaine in molasses and vinasse. —L. E.

Patents.

Brewers' worts; Caramelising of ——. W. T. Ramsden, London. Eng. Pat. 3064, Feb. 6, 1913.

In apparatus where the wort is heated to temperatures above 220° F. (104° C.) in a closed vessel, the lower part of which is steam-jacketed, a rouser, having flexible blades working close to the walls of the vessel, is provided with the object of maintaining the wort in circulation and preventing the formation of a scale of caramelised wort on the hot parts of the vessel.—W. P. S.

Producing lactic acid from waste doughs of cracker or biscuit bakeries. Eng. Pat. 14,479. *See* XIXa.

XIXa.—FOODS.

Casein in milk; Rapid method for determining ——. W. O. Walker. J. Ind. Eng. Chem., 1914, **6**, 131—133.

The method of titrating with alkali after addition of formaldehyde, recommended by Richmond (this J., 1911, 148) for the determination of total protein in milk, can also be used for the rapid determination of casein: using 10 c.c. of milk, 1 c.c. of $N/9$ alkali = 1·63 per cent. of casein.—A. S.

Peptone. I. A. Bernardi. Biochem. Zeits., 1914, **60**, 56—61.

By heating a solution of Witte's peptone for several hours with freshly prepared cupric hydroxide, a blue solution was obtained which after filtration, concentration, addition of alcohol and purification of the precipitate thus formed, yielded a compound corresponding to the formula $C_{51}H_{92}N_{14}O_{24}CuS$. By dissolving this in water and treating it with hydrogen sulphide the copper was removed, and the substance, $C_{51}H_{94}N_{14}O_{24}S$, obtained which appeared to possess fairly definite chemical characters different in some respects from those of the original peptone. —J. H. L.

Boric acid normally present in, or added to, foodstuffs; Rapid determination of ——. G. Bertrand and H. Agulhon. Comptes rend., 1914, **158**, 201—204. (See also this J., 1910, 375; 1914, 105).

The colourimetric method previously described (*loc. cit.*) has been applied to a number of foodstuffs and the results are tabulated. The quantities of boric acid found, ranged downwards from 0·12 grm. per kilo. of dried material. In carrying out the colourimetric method the distillation of the methyl borate should be included, as otherwise the method is scarcely of more than qualitative value.—J. H. L.

Boric acid in foods and other substances; Determination of ——. Jay. Comptes rend., 1914, **158**, 357—358.

Employing a method described previously by Dupasquier nd himself (this J., 1895, 889), the author has found the ollowing quantities of boric acid per kilo. of various egetable substances:—dry figs, 0·045 grm.; dry carrots, ·052 grm.; fresh onions, 0·129 grm; grapes, 0·080 to ·220 grm.; tobacco, 0·124 grm.; the ash of sweet chestnuts, 6·0 grms. Boric acid is, therefore, widely distributed and is absorbed from the soil by vegetables. The author is of opinion that boric acid is not assimilated by animals when taken in small doses.—W. P. S.

Linseed; Rate of liberation of hydrocyanic acid from ——. S. H. Collins and H. Blair. Analyst, 1914, **39**, 70—74.

The samples were digested with water, with and without acids, etc., and the volatile products were expelled by a current of hydrogen at 45° C. at the rate of 10 litres per hour. The hydrocyanic acid was received in dilute sodium hydroxide solution, and cyanides were colourimetrically determined therein by the Prussian blue test. A sample of Calcutta linseed yielded 0·38 mgrm. of hydrocyanic acid per grm. when treated with water, half of the amount being emitted in 46 mins., whilst an aqueous solution of hydrocyanic acid yielded half the total amount in 26 mins., and from 98 to 99 per cent. in 3 hours. On acidifying the linseed with hydrochloric acid ($N/100$) the action of the enzyme was inhibited, and the same effect was produced by the addition of pepsin and rennet in acid solution. Even $N/1000$ acid checked the rate of liberation of the hydrocyanic acid. From these results it appears that linseed cannot under ordinary conditions produce hydrocyanic acid when given to non-ruminant animals, owing to the action of the acid in the stomach. In the case of ruminants any small quantities of hydrocyanic acid formed during rumination would probably escape into the air, so that there is little chance of full-grown cattle being poisoned by dry linseed or linseed cake. As regards the use of linseed mash for calves the mode of preparing the mash is an important factor. Linseed that has been heated with a large volume of water at 100° C. for 30 mins. is no longer capable of yielding hydrocyanic acid, but heating the mash at 60° C. only slightly checks the action of the enzyme, whilst at 90° C. the cyanogenetic action is nearly inhibited. On the other hand if dry linseed be heated for 30 mins. at 100° C., the subsequent evolution of hydrocyanic acid is increased. Fine grinding of the seed in a mortar also results in increased liberation of hydrocyanic acid. Where calves have died from prussic acid poisoning the explanation appears to be that lumps were formed in heating the linseed with water at 100° C., that only a little hydrocyanic acid was then liberated in the presence of a small quantity of water, and that when subsequently the lumps were broked up in the stomach of the calf, the hydrocyanic acid mechanically enclosed in them was quickly liberated. Removal of oil concentrates both enzyme and glucoside, and, hence, linseed cake is liable to be more poisonous than the original linseed. —C. A. M.

Beetroot leaves [*as cattle food*]. H. Hitier. Bull. Soc. d'Encour., 1914, **121**, 67—78.

The storing of beet leaves and tops in silos for use as cattle food is recommended. According to Saillard (Conférences à la Société industrielle de St.-Quentin et de l'Aisne, March 5, 1911) the total cost would be 2·3 francs per metric ton (1s. 10d. per ton), and the composition of the fodder (calculated on the dry matter) would be: proteins, 18·81; non-nitrogenous substances, other than cellulose, 62·38; and cellulose, 18·81 per cent. Beet leaves contain about 3 per cent. of oxalic acid (referred to the dry matter), partly in the free state, hence the ration should be previously mixed with a suitable amount of calcium carbonate. Bachelier (La Sucrerie Indigène, 1913, 488) claims to have obtained good results in feeding cattle and sheep with a mixture of equal parts of beet leaves and tops and distillery pulp to which some grain was added, the ration having the following composition: water, 72·15; nitrogenous substances, 3·73; fat, 0·98; carbohydrates, 10·20; cellulose, 2·27; and ash, 10·67 per cent. Mixed rations such as this may be preserved by means of the ferment "lacto-pulpe," the results being similar to those previously observed with beet slices (this J., 1910, 1027) and the product being readily taken without any injurious effects. —J. P. O.

Picrate colourimetric method for the determination of carbohydrates. Dehn and Hartman. *See* XVII.

PATENTS.

Lactic acid from waste doughs of cracker or biscuit bakeries ; Process for producing ——. E. Saxe, New York. Eng. Pat. 14,479, June 23, 1913.

THE refuse dough from biscuit making, both raw and scorched, consisting of flour, sugar and milk is boiled with water until the starchy matters are dissolved ; the starch is then converted by boiling the solution with dilute sulphuric acid, a lactic ferment is added and the liquid fermented at a temperature of 36° C., with the addition of lime to neutralise excessive acidity. The fermented solution is concentrated and the lactic acid liberated by adding sulphuric acid, filtering and concentrating.
—J. F. B.

Preservatives for raw, fresh, or green foods. S. Rosenbaum, Ujvidék, Hungary. Eng. Pat. 16,359, July 16, 1913.

A MIXTURE of alum, 45 to 50, ground mustard seed, 30 to 35, and salicylic acid, 15 to 25 parts by weight, is sprinkled into vessels used for storing such substances as cucumbers, peas, beans, etc., before the vessels are closed.
—W. P. S.

Grain ; Milling of ——. E. Zappert, London. From F. A. V. Klopfer, Dresden-Leubnitz, Germany. Eng. Pat. 20,115, Sept. 5, 1913.

THE grain is passed through a series of disintegrators surrounded by sieves of gradually increasing degrees of fineness ; the grist from the first three disintegrators is conducted, separately, to sieves, the portion which does not pass through each sieve being transferred to the next disintegrator in the series.—W. P. S.

Grain ; Method of treating washed or damped ——. C Jaquet, Strasburg, Alsace. Eng. Pat. 20,787, Sept. 15, 1913.

To attain uniformity in the degree of humidity of washed or damped grain, the latter is subjected to a current of air or other gas, whilst passing from the supply bin to the milling apparatus.—W. P. S.

Agar ; Purification of ——. F. Steinitzer. Ger. Pat. 269,088, July 26, 1912.

SOLUTIONS containing alimentary substances and agar, *e.g.*, meat broth-agar, become turbid on long standing, or when repeatedly heated, owing to the presence of calcium and aluminium salts in the agar. These compounds may be precipitated by treatment with alkali or alkaline salts, especially sodium phosphate, but if an agar solution be so treated the insoluble aluminium or calcium compounds remain to a considerable extent in colloidal solution and cannot be separated by filtration. According to the present patent the agar is moistened with a quantity of a solution of sodium phosphate or carbonate insufficient to cause notable swelling, and is then dried first in the air and later at 100°—110° C. On subsequently dissolving in hot water (with addition of some hydrogen peroxide to bleach the agar), the calcium and aluminium compounds do not go into colloidal solution, and may be removed by filtering, centrifuging, or the like.—A. S.

Milk ; Process for making desiccated ——. C. H. Campbell. Fr. Pat. 462,973, Sept. 25, 1913. Under Int. Conv., Oct. 7, 1912.

SEE U.S. Pat. 1,070,781 of 1913 ; this J., 1913, 921.—T. F. B.

Soup ; Process for making a solution of substances with the odour and taste of ——. Andernache Dörrgemüse und Conserven-Fabrik Luithlen und Neumann. Fr. Pat. 463,105, Sept. 30, 1913.

SEE Eng. Pat. 22,052 of 1912 ; this J., 1913, 621.—T. F. B.

XIXB.—WATER PURIFICATION ; SANITATION.

Carbon monoxide ; Laws of absorption of —— *by blood in vivo.* M. Nicloux. Comptes rend 1914, **158**, 363—365.

RESULTS of experiments on the absorption of carbon monoxide by blood *in vivo* show that practically the same results are obtained as when the experiments are carried out *in vitro* (see this J., 1914, 99). In the case of dog's blood the reaction constant, K, was found to have a value of 0·00316. When an animal breathes air or oxygen containing a quantity of carbon monoxide insufficient to cause death, the carbon monoxide is absorbed by the blood up to a certain limit which cannot be exceeded. Oxygen is capable of displacing carbon monoxide from blood, and the administration of oxygen is, therefore, essential in cases of carbon monoxide poisoning.—W. P. S.

PATENTS.

Water ; Method and means for purifying [removing free chlorine from] ——. T. Goldschmidt Akt.-Ges., Essen-on-the-Ruhr, Germany. Eng. Pat. 23,569, Oct. 17, 1913. Under Int. Conv., Nov. 8, 1912.

THE water is passed through a layer of filtering material consisting of a mixture of 1 part by weight of powdered iron, aluminium, or tin and 10 parts of sand. This mixture may be regenerated or revivified, when necessary, by treating it with dilute hydrochloric acid to remove the thin films, probably of oxides or hydroxides, which are formed.
—W. P. S.

Water-sterilising tank. S. Held, Assignor to The Held Co., Chicago, Ill. U.S. Pat. 1,085,578, Jan. 27, 1914.

THE tank contains superimposed annular channels whose radii become greater in the downward direction. Water admitted at the top of the tank runs from channel to channel, and is discharged from an outlet at the bottom. In the channels are perforated tubular members communicating with a supply of compressed ozonised air.
—T. ST.

Sewage sludge ; Process for obtaining products [oils and a fertiliser] from ——. J. Noad and Oil Shale Products, Ltd., London. Eng. Pat. 1564, Jan. 20, 1913.

PRESSED sewage sludge is distilled at a temperature of from 400° to 500° F. (204° to 260° C.) in a retort such as that described in Eng. Pat. 18,433 of 1909 (this J., 1910, 1448). Water or steam may be admitted to the retort during the distillation. The fatty and oily matters distilling over are separated from the condensed water and the aqueous portion of the distillate is added to the residue discharged from the lower part of the retort, the mixture thus obtained forming a fertiliser. Dilute sulphuric acid may be added to the distillate in order to convert the ammonia into ammonium sulphate, or the acid may be added to the raw sludge.—W. P. S.

Liquids [sewage effluents] ; Apparatus for the aeration and gasification of ——. T. K. Irwin, London. Eng. Pat. 1925, Jan. 23, 1913.

THE effluent is conducted into a centrifugal drum having a porous outer wall through which the liquid is forced. This outer wall may consist of a series of layers of perforated plates or gauze with a layer of sand on the inside or a porous medium like cement or unglazed porcelai may be used ; an inner layer of sand is also employe in the latter case. Means are provided for the introduction of air or suitable reagents into the liquid in th drum and for removing and renewing the inner layer o sand.—W. P. S.

Liquids ; Apparatus for the aeration and gasification of —— T. K. Irwin, London. Eng. Pat. 3526, Feb. 11, 191 Addition to Eng. Pat. 1925, Jan. 23, 1913 (preceding

MEANS for supplying solid or liquid material to the centr fugal drum, and for removing solid material from th walls of the latter, are carried or supported by the central shaft of the drum. Devices are described for maintaining a difference in speed between the drum and the cleaning apparatus.—W. P. S.

Disinfectants; Preparation of ——. J. J. Balthasart, Brussels. Eng. Pat. 1911, Jan. 23, 1913.

One part of a 20 per cent. solution of hard or soft soap is emulsified with 3 parts of a mixture of tar oils containing phenol, cresol, and the like, both preferably heated to 50° C. Formaldehyde or analogous substances may also be added.—W. P. S.

Refuse-destructor. H. N. Leask, Egremont. U.S. Pat. 1,085,445, Jan. 27, 1914.

See Eng. Pats. 22,137 of 1909 and 7458 of 1910; this J., 1910, 1267.—T. F. B

XX.—ORGANIC PRODUCTS; MEDICINAL SUBSTANCES; ESSENTIAL OILS.

Strychnine; Determination of —— in the presence of quinine. C. Simmonds. Analyst, 1914, **39**, 81—83.

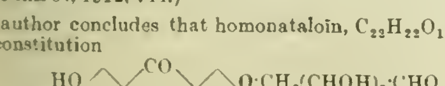
The method is based upon the fact that a 4 per cent. acid solution of potassium ferrocyanide precipitates strychnine much more readily than quinine. Slight simultaneous precipitation of quinine invariably occurs, but the quantity is small in the absence of excess of ferrocyanide. The mixed alkaloids from *e.g.* 50 c.c. of "syrup of iron phosphate with quinine and strychnine" are weighed and dissolved in 50 c.c. of 20 per cent. sulphuric acid, and the solution treated with 5 c.c. of 4 per cent. ferrocyanide solution, added drop by drop, with continual stirring. After a few hours, the precipitate is collected and lightly washed with 3 successive portions of about 3 c.c. of 5 per cent. sulphuric acid, then transferred to a funnel by means of about 10 c.c. of 10 per cent. ammonia solution and water, and extracted successively with 15, 10, and 5 c.c. of chloroform. The united extracts are shaken with 30, 10, and 10 c.c. of 20 per cent. sulphuric acid, and the precipitation and extractions repeated until the chloroform extracts are again obtained. The chloroform is then evaporated (with the addition of a little alcohol at the end to prevent spurting), and the residue of strychnine dried at 100° C. and weighed. If desired the quinine may be determined in an aliquot portion of the filtrate by precipitation with ammonia and extraction with chloroform. It is essential that not much more than 0·1 grm. of strychnine should be present in 50 c.c. of the acid; otherwise separation of strychnine sulphate may occur.—C. A. M.

Purines. XIV. 2.8-Dihydroxy-1.7.9-trimethylpurine, an isomeride of caffeine and 2.8-dihydroxy-1.7-dimethylpurine, an isomeride of theobromine. C. O. Johns. J. Biol. Chem., 1914, **17**, 1—7.

2.8-Dihydroxy-1.7.9-trimethylpurine, m. pt. 240° C., was prepared by alkylating 2.8-dihydroxy-1.9-dimethylpurine with dimethyl sulphate. It is more soluble in water than caffeine and, unlike the latter, does not give a ourple colouration when evaporated with chlorine water and he residue moistened with ammonia. 2.8-Dihydroxy-1.7-limethylpurine, prepared in the same way from 2.8-lihydroxy-1-methylpurine, crystallises in acicular prisms rom water and chars below 320° C. On further methylation t is converted into 2.8-dihydroxy-1.7.9-trimethylpurine. F. Shdn.

lomonataloïn and nataloïn; Constitution of ——. E. Léger. Comptes rend., 1914, **158**, 185—188. (See also this J., 1912, 744.)

HE author concludes that homonataloïn, $C_{22}H_{22}O_{10}$, has he constitution



and that nataloïn, $C_{23}H_{24}O_{10}$, which is present with it in Natal aloes, has a similar constitution except that the group ·CH₂OH is replaced by C_2H_4OH. Both compounds appear to contain a pentose molecule with a free aldehyde group, and both give rise to penta-acetyl derivatives.—J. H. L.

Lemon oils; Determination of the hydrocarbon content of concentrated ——. E. Böcker. J. prakt. Chem., 1914, **89**, 199—207.

Ten c.c. of the oil are measured into a cassia flask and the citral determined by shaking with freshly prepared sodium sulphite solution according to Burgess' method (this J., 1901, 1178). If the amount of undissolved oil is small, the citral is removed in the same way from another 5 or 10 c.c. of the oil. 5 c.c. of the oil freed from citral are transferred to a stoppered funnel of 600—700 c.c. capacity containing 500 c.c. of 51 per cent. alcohol (by volume) cooled to —2° to 0° C. The whole is thoroughly shaken, when the aromatic portions of the oil pass into solution leaving the hydrocarbons practically undissolved. The funnel is inverted, kept for 8—10 hours in ice-water at 0° C., carefully returned to the upright position and allowed to stand till the alcoholic portion has become clear, which may take from 12 to 48 hours. The alcoholic portion is drawn off and the oil (hydrocarbons) transferred to a small measuring cylinder, any drops adhering to the funnel being washed down with a little 51 per cent. alcohol. Larger quantities of the original oil can be fractionated at reduced pressure to separate terpenes and sesquiterpenes. The citral in the separate fractions is determined as above and the undissolved oil from each treated with a corresponding volume of 51 per cent. alcohol so as to ascertain the relative proportions of terpenes and sesquiterpenes.—F. Shdn.

Essential oils; Constituents of ——. *Nopinane, β-dihydrolimonene and carane.* F. W. Semmler and J. Feldstein. Ber., 1914, **47**, 384—389.

When the hydrazones of certain ketones are heated with sodium ethoxide, hydrocarbons are produced. Nopinane, C_9H_{16}, obtained in this way from nopinone boiled at 149° C. at 747 mm., had the sp. gr. 0·8611 at 22°/22° C., $n_D = 1·46141$, and was optically inactive. β-Dihydrolimonene, $C_{10}H_{18}$ (prepared from dihydrocarvone) boiled at 168°—169° C. at 750 mm., had the sp. gr. 0·8217 at 21°/16° C., $n_D = 1·45673$, and was optically inactive. Carone similarly yielded carane, $C_{10}H_{18}$, b. pt. 49°—50° C. at 9 mm., sp. gr. 0·8381 at 20°/20° C., $n_D = 1·45823$ and $\alpha_D = -34°$. The characters of dihydroterpinolene prepared from pulegone were: b. pt. 169°—170° C. at 748 mm., sp. gr. 0·8189 at 22°/21° C., $n_D = 1·45823$. Tanacetane, $C_{10}H_{18}$, obtained from tanacetone boiled at 156°—157° C. at 747 mm., had the sp. gr. 0·8158 at 22°/21° C., and $n_D = 1·44121$.—F. Shdn.

Dihydroxydiaminoarsenobenzene [Salvarsan] and silver Compounds of chlorine, bromine and iodine with ——. J. Danysz. Comptes rend., 1914, **158**, 199—201. (See Ehrlich and Bertheim, this J., 1912, 407.)

Silver chloride, bromide and iodide, when freshly prepared, dissolve in solutions of Ehrlich's arsenobenzene hydrochloride (606), but the bromide and iodide only dissolve slowly and it is best to dissolve them first in solutions of potassium cyanide. The preparation of the new products presents no difficulty and is typified in the following particular case:—A solution of silver bromide in potassium cyanide solution is added drop by drop to a solution of the arsenic compound. As each drop falls a precipitate is formed which redissolves, and the liquid becomes darker in colour and disengages hydrogen cyanide. As soon as a permanent precipitate is produced, it is redissolved by addition of hydrochloric acid drop by drop, and in this way it is possible to introduce 1 mol. of silver bromide for each mol. of arsenobenzene hydrochloride. From the solution thus obtained sulphuric acid precipitates the arsenobenzene-silver bromide compound in the form of an insoluble sulphate, which after being washed free from the last traces of potassium chloride and cyanide forms a powder varying in colour from orange yellow to deep brown according to the quantity of silver in it. It dissolves readily in water rendered slightly alkaline with sodium carbonate. The chlorine compounds possess the least, and the bromine compounds the most pronounced antiseptic and therapeutic properties. Dihydroxydiaminoarsenobenzene may combine with various proportions of silver salts, but certain limits cannot be passed without lessening the therapeutic activity of the products. The toxicity of the bromine compound is nearly the same as that of dihydroxydiaminoarsenobenzene, whilst its sterilising power *in vitro* and *in vivo* is considerably greater. The compounds of dihydroxydiaminoarsenobenzene with mercury, gold, and platinum, though rather more active than the silver compounds, are less stable and relatively much more toxic.—J. H. L.

Cholesterol ; Colourimetric determination of ——. A. Grigaut. J. Pharm. Chim., 1914, **9**, 146—149.

Liebermann's reaction (development of a purple colouration passing rapidly through blue into green, when acetic anhydride and sulphuric acid are added to a solution of cholesterol in chloroform) can be used for the estimation of cholesterol. The time required to develop the maximum colour, and the length of time this colour remains constant, depend on the amount of sulphuric acid used. The colouration is compared with that given by a standard solution of cholesterol, using the same amount of sulphuric acid must be used in each case. The estimation is correct to within 5 per cent.—T. C.

Benzoic acid ; Simple test for halogens in ——. E. Wende. Apoth.-Zeit., 1914, **29**, 157.

A mixture of 0·1 grm. of benzoic acid and 0·5 grm. of yellow mercuric oxide is heated in a dry test-tube with constant turning over a small flame about 1 cm. high. When the reaction is over, about 10 c.c. of dilute nitric acid are added, the whole heated nearly to boiling and filtered. The filtrate should not give more than a slight opalescence with silver nitrate solution.—F. Shdn.

Spirit of nitrous ether ; Determination of ——. D. B. Dott. Pharm. J., 1914, **92**, 164.

The method for the determination of spirit of nitrous ether based on the reaction :

$$2C_2H_5NO_2+2KI+H_2SO_4=2C_2H_6O+2NO+K_2SO_4+I_2,$$

with titration of the liberated iodine by thiosulphate, gives high results, owing to oxidation of nitric oxide by atmospheric oxygen to nitrogen peroxide, which liberates a further quantity of iodine. A simple form of apparatus to overcome this defect consists of a bottle fitted with a cork through which passes a short length of glass tubing reaching to just below the cork ; the stem of a thistle funnel slides freely in this tube and reaches to the bottom of the bottle. Four c.c. of potassium iodide solution and 2 c.c. of dilute sulphuric acid are placed in the bottle, which is then filled to within 6 c.c. with magnesium sulphate solution. Five c.c. of the spirit are introduced gradually through the thistle funnel, the bottle is shaken, emptied into a dish after 5 mins., and the solution titrated with thiosulphate.—A. S.

Spirit of nitrous ether ; Note on an old sample of ——. D. B. Dott. Pharm. J., 1914, **92**, 164.

Spirit of nitrous ether prepared by the rapid method described by the author in 1909 (Pharm. J. (4), **28**, 429)—addition of a strong solution of sodium nitrite to a mixture of alcohol and sulphuric acid and filtering from the precipitated sodium sulphate—maintains its strength well on keeping. A sample which in 1909 was rather over the B.P. standard showed 2·35 per cent. $C_2H_5NO_2$ when recently tested.—A. S.

Esters of chromic acid. H. Wienhaus. Ber., 1914, **47**, 322—331.

The chromic esters of tertiary alcohols are obtained on treating a solution of the alcohol in carbon tetrachloride or light petroleum with an excess of dry chromic anhydride, pouring off the liquid through a filter, and concentrating in a vacuum. Primary and secondary alcohols are oxidised by this treatment. The neutral esters of chromic acid, A_2CrO_4 (where A represents the alcohol residue) are formed ; they are liquid or crystalline, range in colour from yellow to wine-red, and are soluble in ether, benzene, acetone, and glacial acetic acid, but insoluble in water. They resist hydrolysis by aqueous alkalis and baryta, but readily yield the tertiary alcohol when warmed with alcoholic alkalis. The reaction, which also takes place with aqueous chromic acid, may be used for the detection of the acid, and in many cases for distinguishing tertiary alcohols ; it also serves for the isolation of the alcohols. The preparation of the chromic esters of a number of hydroaromatic alcohols is described. The esters of α- and β-terpineol and the *p*-menthanols resulting from their catalytic hydrogenation were somewhat unstable, and could not be obtained crystalline. Methylfenchyl chromate, m.pt. 130° C. (with decomposition), $[\alpha]_{\text{Li red}}=-30\cdot0°$ in carbon tetrachloride or light petroleum, formed red crystals, stable in absence of light; ethylfenchyl chromate, $[\alpha]_{\text{Li red}}=+22\cdot5$, decomposed on heating ; methylbornyl chromate formed light orange crystals which decomposed on heating : it was lævorotatory in carbon tetrachloride solution ; cedryl chromate, m. pt. 115° C., formed yellowish-red prisms ; ledyl chromate (from ledum camphor), m. pt. 92° C., $[\alpha]_{\text{Li red}}=+30\cdot0°$, formed wine-red monoclinic prisms. Methylborneol produced a red colouration in carbon tetrachloride containing chromic anhydride, while camphor did not.—O. E. M.

Catalytic hydrogenations ; The reaction velocities of —— in presence of platinum black. G. Vavon. Comptes rend., 1914, **158**, 409—412.

The velocity curves for the absorption of hydrogen in the case of substances which can fix several molecules of this gas (*e.g.* limonene), have a gradient which varies considerably with the quantity of catalyst present. Apparently the metal can become fatigued so that its activity is sufficient to bring about the easier stages quite readily, but is not enough for the more difficult stages. This is more marked on heating the catalyst to temperatures of between 300° and 500° C., when its activity can be varied and suited to the different stages in a quite regular manner. After heating to temperatures above 500° C. it becomes quite inactive.—W. H. P.

Determination of the diastatic power of malt extracts. Monnier. See XVIII.

Patents.

Medicinal preparations containing menthol and formaldehyde. C. Buchwald, Düsseldorf-Gerresheim, Germany. Eng. Pat. 15,915, July 10, 1913.

Menthol (10 parts), formaldehyde, preferably in the polymerised form (2 parts), and "anæsthesine" (2 parts) are added to melted ceresin or similar fusible carrier. Boric acid (2 parts) may also be added if desired.—T. F. B.

Methylphenylglycine-arsinic acid and its reduction product, arsenomethylphenylglycine ; Process for preparing ——. Poulenc frères, and K. Oechslin. Fr. Pat. 462,276, Nov. 18, 1912.

The esters of methylphenylglycine-arsinic acid, obtained by the action of arsenious chloride on phenylglycine esters are very easily saponified by means of excess of sod at a temperature about 60° C. ; when the solutions ar acidified by acetic or hydrochloric acid, methylphenyl glycine-arsinic acid, $H_2O_3As.C_6H_4.N(CH_3)CH_2.COOH$, i precipitated in the form of white crystals, sparingly solubl in water, which do not melt on heating but evolve carbo dioxide, with formation of dimethylaminophenylarsini acid. Reduction of methylphenylglycine-arsinic acid b means of sodium hydrosulphite at a high temperatu results in the production of arsenomethylphenylglycin which is stable towards air and oxidising agents, and solubl in solutions of sodium hydroxide or carbonate, formin neutral salts.—T. F. B.

p-Aminophenylarsinic acid ; Process for preparing ac derivatives of ——. Chem. Fabr. auf Actien, vorm E. Schering. Ger. Pat. 268,983, Nov. 9, 1912.

p-Aminophenylarsinic acid is converted into iod acyl derivatives by the usual methods. The produc are stated to have a low toxicity compared with the aminophenylarsinic acid.—T. F. B.

Aromatic stibinic acids; Process for preparing ——. Chem. Fabr. von Heyden A. G. Ger. Pat. 269,205, Aug. 6, 1912. Addition to Ger. Pat. 254,421 (see Eng. Pat. 16,350 of 1912; this J., 1913, 109).

Secondary and tertiary aromatic stibinic acids are obtained by decomposing aromatic diazo compounds with antimonious oxide substituted with one or two aromatic groups. (See also this J., 1913, 711, 841, 925.)—T. F. B.

Aromatic stibinoxides or their derivatives; Process for preparing secondary ——. Chem. Fabr. von Heyden A. G. Ger. Pat. 269,206, March 8, 1913. Addition to Ger. Pat. 268,451 (see this J., 1914, 219).

Diarylstibinic acids or their derivatives are converted into secondary aromatic stibinoxides by treatment with reducing agents.—T. F. B.

Benzyl alcohol; Process for obtaining ——. F. W. Klever. Fr. Pat. 462,438, Sept. 10, 1913. Under Int. Conv., Sept. 11, 1912.

Benzyl chloride can be converted quantitatively into benzyl alcohol by heating it, in presence of excess of water, with magnesium hydroxide, an alkaline-earth hydroxide, zinc hydroxide, or other basic hydroxide other than that of lead, the mixture being thoroughly agitated during the process. When one mol. of benzyl chloride is treated with 0·6 mol. of magnesium hydroxide at 100° C. in presence of 8 to 10 times the theoretical quantity of water, a yield of about 96 per cent. of benzyl alcohol is produced. When calcium hydroxide is used, the yield is somewhat lower. —T. F. B.

Benzyl esters of lower fatty acids and benzyl alcohol from benzyl chloride; Process for obtaining ——. F. W. Klever. Fr. Pat. 462,439, Sept. 10, 1913.

Good yields of benzyl esters of the lower fatty acids are obtained by heating a mixture of benzyl chloride and an anhydrous salt of the acid in presence of a small quantity of the free acid itself, *e.g.*, 0·1 to 1 mol., the presence of water being avoided. The following mixture is given for the preparation of benzyl acetate:—Benzyl chloride, 1 mol.; anhydrous sodium acetate, 1·1 to 1·2 mols.; glacial acetic acid, 0·1 to 1 mol. For preparing benzyl formate the following mixture may be used:—Benzyl chloride, 1 mol.; anhydrous sodium formate, 1·1 to 1·2 mols.; anhydrous formic acid, 1·25 to 1·5 mols. The mixture obtained after the preparation of benzyl acetate by this method may be heated with water until the odour of the acetate has disappeared, the liquid neutralised and the benzyl alcohol separated.—T. F. B.

Hydrohalogen addition products of acetylene; Process for making ——. Chem. Fabr. Griesheim-Elektron. Fr. Pat. 462,711, Sept. 17, 1913.

Acetylene and a hydrogen halide are caused to combine by passing them over heated catalytic substances at the ordinary pressure or under increased pressure. Mercury salts are especially suitable for use as catalysts, but other substances, such as metals, oxides, etc., can be used. The catalyst can also be used in solution or in suspension. The reacting gases may be passed over the catalyst simultaneously or alternately; for example, a solution of a mercury salt may be saturated with hydrogen chloride, and acetylene then passed into it. When the gases are applied simultaneously, it is advisable to bring them to the reaction vessel from different points. In the case where the catalyst is used in the form of a liquid, the reaction can be carried out under pressure and at a temperature above he normal boiling point of the liquid.—T. F. B.

soprene; Process for preparing ——. Badische Anilin und Soda Fabrik. Ger. Pat. 268,101, Feb. 11, 1913. Addition to Ger. Pats. 255,519 and 268,100 (see Eng. Pats. 21,616 of 1912 and 13,327 of 1913; this J., 1913, 924).

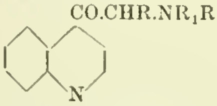
Methylbutenol ethers are converted into isoprene by eating with catalytic substances at high temperatures, and preferably under diminished pressures. The methylbutenol ethers may be obtained by the action of alcoholic potash on compounds such as 2.4-dibromo-2-methylbutane or 3-bromo-2-methylbutene-(2), $(CH_3)_2C:CBr.CH_3$. —T. F. B.

Quinolylketones; Process for preparing ——. Verein. Chininfabr. Zimmer und Co. Ger. Pat. 268,830, March 30, 1913.

Quinolinecarboxylic esters and esters of the general formulæ, $R'.CH_2COOR''$ (where R' = hydrogen or alkyl; R''=alkyl) are treated with sodium ethoxide or other alkaline condensing agent, and the β-ketone ester is converted into the quinolylketone by the usual method. —T. F. B.

Aminoketones of the quinoline series; Process for preparing ——. A. Kaufmann. Ger. Pat. 268,931, March 26, 1913.

Quinolyl-4-ketones, in which the carbonyl group is adjacent to a methyl or methylene group, are treated with halogens or substances which evolve halogens and then with primary or secondary aliphatic amines. The products have the general formula,



(where R and R_1 represent hydrogen or alkyl and R_2 alkyl), and possess antipyretic properties.—T. F. B.

Bismuth gallocarboxylate; Process for preparing basic ——. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 268,932, Aug. 23, 1912.

Basic bismuth salts of gallocarboxylic acid are obtained by the action of the acid on acid solutions of bismuth salts or on bismuth hydroxide. They are suitable for use as antiseptics for internal or external application.—T. F. B.

C-Propenylphenolcarboxylic acids and their nucleus substitution products; Process for preparing ——. L. Claisen. Ger. Pat. 268,982, Nov. 3, 1912.

C-Allylphenolcarboxylic acids, obtained from O-allylphenolcarboxylic acids and their nucleus substitution products (see Ger. Pat. 268,099; this J., 1914, 220), are converted into the corresponding C-propenylphenolcarboxylic acids by heating with alkali hydroxides.—T. F. B.

o-Dihydroxyphenyl-α-propanolamine; Process for preparing optically active ——. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 269,327. Nov. 26, 1911.

Synthetic, racemic *o*-dihydroxyphenyl-α-propanolamine is separated into its optically active components by the aid of *d*- or *l*-tartaric acid. A sparingly soluble *d*-tartrate of the lævorotatory base is obtained, the therapeutic (hæmostatic) properties of which are more marked than in the racemic base.—T. F. B.

Hydroxybenzoyl-o-benzoic acids, their homologues and substitution products; Preparation of esters of ——. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 269,336, Jan. 19, 1913.

Therapeutically active compounds are obtained by esterifying hydroxybenzoyl-*o*-benzoic acids, or their homologues or substitution products, by the usual methods, with alcohols other than methyl alcohol.—T. F. B.

o-Aminophenylsulpho-acetic acid; Process for preparing ——. Farbwerke vorm. Meister, Lucius, und Brüning. Ger. Pat. 269,337, Jan. 23, 1913.

o-Nitrophenylsulpho-acetic acid is reduced by means of iron or zinc dust in neutral or feebly (organic) acid solution, the mixture is made alkaline, and the free aminophenylsulpho-acetic acid is separated from the filtered solution of its alkali salt by adding the equivalent quantity of an acid in the cold. The product can be readily converted into sulphazone.—T. F. B.

Sulphazone; Process for preparing ——. Farbwerke vorm. Meister, Lucius, und Brüning. Ger. Pat. 269,428, Nov. 16, 1912.

o-NITROPHENYLSULPHO-ACETIC acid is treated with metallic iron in neutral solution or suspension, preferably in presence of a neutral salt, and excess of mineral acid is then added. The yield is stated to be about 95 per cent. of theory, whilst that obtained by the process of Claass (Ger. Pat. 256,342; see this J., 1913, 417) is only about 77 per cent.—T. F. B.

aa′-Diphenyl-N-methyl-γ-piperidone; Process for preparing ——. J. D. Riedel A.-G. Ger. Pat. 269,429, July 18, 1913.

DIBENZAL-ACETONE is condensed with methylamine to form *aa′*-diphenyl-N-methyl-γ-piperidone, which is applicable in medicine or for the preparation of medicinal products.—T. F. B.

Monochlorhydrin from glycerin and hydrochloric acid; Process for preparing ——. Sprengstoffwerke Dr. R. Nahnsen und Co. A.-G. Ger. Pat. 269,657, Dec. 19, 1912.

GLYCEROL vapour is treated with gaseous hydrogen chloride *in vacuo*, and the product is passed for a considerable time through a series of tubes heated to 170°—180° C., to complete the reaction. The liquid thus obtained is passed into a retort heated to about 150° C., and the monochlorhydrin is separated from the lower-boiling products by cooling.—T. F. B.

Acetaldehyde; Preparation of ——. Consortium f. Elektrochemische Industrie G. m. b. H., Nuremberg, Germany. Eng. Pat. 6000, March 11, 1913. Under Int. Conv., May 22, 1912.

XXII.—EXPLOSIVES; MATCHES.

Cap-compositions which do not cause rusting in rifle barrels. O. Mertens. Z. ges. Schiess- u. Sprengstoffw., 1914, **9** 70—71.

THE rusting of rifle-barrels by chlorate cap-compositions was found to be caused by chlorine. By substituting barium nitrate for the chlorate, adding basic substances such as certain carbonates, diphenylamine, etc., to suppress the deteriorating action of the nitrate on the fulminate, and covering the composition with tinfoil and a varnish free from moisture, a stable cap which did not cause rusting was produced. It was deficient in power, however; to improve this, the proportion of fulminate, or the total quantity in the cap, was increased, or some of the antimony sulphide was replaced by a more easily ignited substance, such as antimony phosphide.—O. E. M.

PATENT.

Explosive mixtures which can be detonated directly; Process for preparing ——. Ver. Köln-Rottweiler Pulverfabriken. Ger. Pat. 267,542, April 28, 1912.

A SALT of a nitrated naphthalenesulphonic acid is mixed with a nitrate, and also, if desired, with other explosive components. The salts of mononitronaphthalenesulphonic acid when mixed with nitrates can be detonated directly.
—T. F. B.

XXIII.—ANALYTICAL PROCESSES.

Electro-analysis; Fine-meshed brass gauze as a substitute for platinum in ——. D. F. Calhane and T. C. Wheaton. Met. and Chem. Eng., 1914, **12**, 87—89.

BRASS wire gauze (100 meshes per linear inch) has been successfully used (over a period of two years) in the electrolytic determination of copper, zinc and nickel The cathode employed was made from a piece of gauze 5¼ in. by 3¼ in., the longer edges of which were lapped ove and hammered down, and the shorter ones bent over 12 in. loop of copper wire (22-gauge) the ends of whic were afterwards twisted together. The cylinder thu formed was thinly plated with copper, then washed dipped in alcohol, dried and weighed for use. The anod consisted of a spiral made from 10—12 in. of platinu wire weighing about 1 grm. In the case of ammoniac solutions, the copper wire stem of the cathode had a insert of platinum wire, two pieces of which, each 3 i long, were attached to the gauze, twisted together and s joined to the stem. Brass gauze could not be used in th separation of silver from copper in cyanide solution, the zinc dissolved and silver was deposited; but in a successful cases the efficiency of the brass was equal that of platinum gauze, the time factor for the form with still electrolyte being nearly as good as that for th latter with magnetic stirring. Details are given of the procedure followed in the electro-analysis of copper scale and various alloys of nickel, copper and zinc.—W. E. F. P.

Silica; Solubility of —— in hydrochloric, nitric, and sulphuric acids. M. Wunder and A. Suleimann. Ann. Chim. analyt., 1914, **19**, 45—49.

When hydrated silica is evaporated to dryness with hydrochloric acid, the residue heated to 110° C., and the silica separated in the usual way, about 0·75 per cent. remains in solution, but may be recovered by evaporating the filtrate to dryness and collecting the insoluble residue thus obtained. Similar results are found when nitric acid is used, but, owing to the difficulty of removing all the nitric acid by washing, there is a tendency for the results to be too high. About 3·5 per cent. of the weight of the silica remains in solution when sulphuric acid is used (in this case, the mixture cannot be evaporated to complete dryness), but the loss is recovered by a second evaporation. Hydrated silica was found to dissolve in dilute hydrochloric acid of various strengths (1 : 2; 1 : 1; 2 : 1) to the extent of from 0·03 to 0·33 grm. per litre, the largest quantity being dissolved at 100° C. by the 2 : 1 acid. Nitric and sulphuric acids dissolved smaller quantities, namely, from 0·02 to 0·1 grm. per litre.—W. P. S.

Ferric salts; New method of titration of —— by reduction. C. Russo. Gaz. chim. ital., 1914, **44**, I., 1—8.

The direct titration of ferric salts with stannous chloride solution gives accurate results only in daylight and when the iron solution is concentrated. The author has found that accurate results can be obtained even with dilute solutions and in artificial light if 2 drops of a 10 per cent. solution of methylene blue be added as indicator and the solution contains free hydrochloric acid in the proportion of about 10 c.c. of the concentrated acid per 100 c.c. The acid ferric solution is heated to boiling, 2 drops of the methylene blue solution are added, the boiling is continued until practically all dissolved air is expelled from the solution, and the latter is then titrated with a standardised solution of stannous chloride (about $N/5$): towards the end of the titration the solution is heated to boiling and the stannous chloride added drop by drop until the blue colour begins to fade; after again boiling for a few minutes a drop of stannous chloride is usually sufficient to complete the decolourisation. In a mixture of ferrous and ferric salts, the ferrous salt may be titrated with permanganate, the slight excess of the latter decomposed with oxalic acid, and then the total ferric salt determined as above after addition of hydrochloric acid.—A. S.

Nitrates, chlorates, and peroxides; New method of analysis by reduction of ——. C. Russo and G. Sensi. Gaz. chim. ital., 1914, **44**, I., 9—15.

The method of titrating ferric salts with stannous chloride in presence of methylene blue as indicator (see preceding abstract) has been applied to the analysis of nitrates, chlorates, and manganese dioxide. For the analysis of nitrates a flask of about 500 c.c. capacity is used, provided with inlet and outlet tubes for a current of carbon dioxide; the outlet tube passes to the bottom of a second flask of 300 c.c. capacity containing 120 c.c. of water to which a solution of decolourised methylene blue (2—3 c.c. of water, 2 drops of a 10 per cent. solution of methylene blue, and 1 drop of $N/5$ stannous chloride, heated to boiling) has been added. After all the air in the large flask has been expelled by carbon dioxide, 3 grms. of ferrous ammonium sulphate and about 0·2 grm. of the nitrate are introduced, followed by 10 c.c. of concentrated hydrochloric acid. The mixture is heated gently at first and finally to boiling and the water in the smaller flask is also heated to boiling. When the reaction is completed, the flames are removed and the current of carbon dioxide is cut off: on cooling, the boiled water is sucked over from the smaller into the larger flask, and the solution in the latter is then titrated with stannous chloride as described in the preceding abstract. In the case of chlorates access of air has practically no effect on the results. The ferrous salt is added to the boiling solution of the chlorate, followed by 10 c.c. of concentrated hydrochloric acid, added gradually. When the reaction is completed, the solution is titrated with stannous chloride. For the analysis of manganese dioxide a weighed quantity is suspended in 100 c.c. of boiled water, then the ferrous salt and hydrochloric acid are added, the whole is boiled until a clear solution is obtained, and this is titrated with stannous chloride.—A. S.

Titanium; Use of the ammonium salt of nitrosophenylhydroxylamine ("cupferron") in the quantitative separation of —— from iron. W. M. Thornton, jun. Amer. J. Sci., 1914, **37**, 173—178.

Titanium is quantitatively precipitated by "cupferron" (see this J., 1910, 115, and 1911, 1090) in presence of tartaric acid and oxidation of the tartaric acid after separating iron as sulphide is therefore unnecessary. To the solution containing iron and titanium, tartaric acid equal to three times the combined weight of the oxides of iron and titanium present (about 0·4 grm.), is added, the solution neutralised by ammonia, 2 c.c. of sulphuric acid (1 : 1) added, and the volume made up to about 100 c.c. Hydrogen sulphide is then introduced until the iron is reduced, the solution made ammoniacal, and more hydrogen sulphide introduced until the iron is completely precipitated. The filtrate is acidified with 25 c.c. of sulphuric acid (1 : 1), the hydrogen sulphide expelled, the acid partially neutralised with ammonia so as to leave about 2·5 c.c. of sulphuric acid (1 : 1) for every 100 c.c. of solution, and a slight excess of a 6 per cent. solution of "cupferron" in cold water added in the cold. The precipitate is allowed to settle, filtered, and washed with cold water. The filter and precipitate are transferred wet to a weighed platinum crucible, dried at 110° C., and heated very carefully at first, and then strongly until the weight is constant.—T. St.

Hydroxyl groups; Use of pyridine as a solvent in the determination of —— by means of alkyl-magnesium halides. A. P. Tanberg. J. Amer. Chem. Soc., 1914, **36**, 335—337.

Pyridine has been recommended by Zerewitinoff (this J., 1908, 839; 1911, 107; 1912, 1057; 1913, 1162) as a solvent in the determination of hydroxyl groups by means of methyl-magnesium iodide. The author has been unable to obtain satisfactory results with either commercial or specially purified pyridine, and blank determinations with different samples showed that considerable quantities of gas are evolved on treatment with a solution of methyl-magnesium iodide in anhydrous amyl ether. —A. XXIV.—MISCELLANEOUS ABSTRACTS.

Palladium ; Sorption [adsorption and absorption] o hydrogen by ——. F. Halla. Z. physik. Chem., 1914, **86**, 496—505.

THE work of Andrew and Holt (Proc. Roy. Soc. 1913, A. **89**, 170—186) which leads to the conclusion that palladium is dimorphic, is discussed and the author shows that palladium black prepared by Graham's method is not inactive. He also shows that occlusion by active palladium is not hindered at ordinary temperatures by contact with the inactive metal. The velocity curve of adsorption by active metal is in agreement with the view that the first process is a mechanical adsorption on the surface of the metal followed by diffusion towards the interior, which proceeds more rapidly at first on account of the heat produced by the initial adsorption.—W. H. P.

Fluorine in the animal economy. A. Gautier. Comptes rend., 1914, **158**, 159—166. (See also this J., 1912, 663, 703.)

THE author has observed a certain uniformity in the relative amounts of fluorine and phosphorus present in animal tissues. In the more vital tissues (muscles, glands, nerves, and secretions such as milk, blood, etc.) the ratio by weight of fluorine to phosphorus is 1 : 350—750 or more. In bone, cartilage, tendons, etc., it is 1 : 130—180, whilst in structures which may almost be regarded as non-living (hair, feathers, nails and skin) it is 1 : 3—8, corresponding approximately with the relative amounts of fluorine and phosphorus present in fluophosphates such as apatite.—J. H. L.

Books Received.

UEBER DIE KONSTITUTION UND KONFIGURATION VON VERBINDUNGEN HÖHERER ORDNUNG. (Vortrag, gehalten in Stockholm an 11 Dezember 1913, in Anschluss an die Entgegennahme des Nobelpreieses.) Von Professor Dr. ALFRED WERNER. Julius Springer's Verlag. 1914. Berlin, W 9. Linkstr. 23—24. Price M. 1.20. Pamphlet of 21 pages.

FORTSCHRITTE DER EDELMETALLAUGEREI WÄHREND DER LETZTEN JAHRZEHNTE. Von R. BORCHERS. Verlag von W. Knapp. Halle (Saale), 1913. Price M. 7.80.

THIS volume ($9\frac{3}{4}$ by $6\frac{3}{4}$ ins.), contains 151 pages of subject-matter, with 136 illustrations, and alphabetical indexes of names and subjects. The classification of the subject matter is as follows:—I. GOLD. (*a*) Chlorinating processes. (*b*) Cyanide treatment, etc. II. SILVER. (*a*) The Patera-Hofmann process. (*b*) The Ziervogel process.

* New Books.

PROF. J. WATSON BAIN IN THE CHAIR.

THE USE OF DRY AIR IN THE BLAST FURNACE.

BY H. G. GIRVIN.

The average amount of moisture in the air at our Hamilton Works, where the dry blast plant is located, was 3·152 grains per cubic foot for the year 1912, and slightly higher for 1913, about 3·25 grains per cu. ft. These data are obtained by averaging hourly determinations during the whole year. Assuming a daily average content of 3·152 grains of moisture per cu. ft. and 50,000 cu. ft. of air per minute we find that we are blowing into our furnaces a little more than 16 tons of water vapour in 24 hrs. Of course in the summer months the moisture contained in the air is much higher than in the winter time, and we frequently extract as much as 33 to 35 tons of water in one day. Our best record has been the extraction of 39·9 tons in 24 hrs.

Briefly, our system is to reduce the temperature of the air to 32° F. by means of cooled brine, and then to cool the air further to from 0° to 5° F. In the summer about two-thirds of the moisture is extracted in the first stage of the process, and in the second stage the percentage of moisture can be reduced to any desired limit.

The following is a description of the units in the dry blast system, as installed at the Hamilton Works of the Steel Co., Canada, Ltd. :—

The Steam End. The compression side of this plant consists of three horizontal machines, twin cross-compound type (De La Vergne pattern) Each machine has one high pressure horizontal steam cylinder 24 in. in diameter and 33 in. stroke, and one low-pressure horizontal steam cylinder 48 in. in diameter and 33 in. stroke, with long-range Corliss automatic cut-off and governor.

The high pressure side is designed to withstand a pressure of 150 lb. and the low side a pressure of 50 lb. per sq. in. above the atmosphere with safety and without undue heating.

The engines will work the compressors with maximum economy at normal speed of 65 r.p.m. under the following conditions :—

Discharge pressure, 150 lb. per sq. in. above atmos. ; suction, 17 lb. per sq. in. above atmos. ; steam, 125 lb. per sq. in. above atmos. ; vacuum, 24 in. mercury in exhaust pipe.

When running non-condensing the engines will make 65 r.p.m. under the following conditions :—

Discharge pressure, 190 lb. per sq. in above atmos. ; suction, 17 lb. per sq. in. above atmos. ; steam, 90 lb. per sq. in above atmos.

The Ammonia End. The ammonia compressors have a refrigerating capacity of 300 tons each under the above conditions, and consist of two water-jacketed horizontal double-acting compressors 18¼ in. diameter and 33 in. stroke ; they have been tested to a hydrostatic pressure of 500 lb. per sq. in. and are absolutely gas tight.

The ammonia condensers (De La Vergne type) are of the double-pipe surface condensing variety, consisting of 78 stands containing 12 double pipes each, and are arranged and connected in three units, each having 26 stands, the pipes being 2 in. and 1¼ in. respectively. The total weight of these condensers is 125,400 lb., and the total effective cooling surface is 6270 sq. ft. This, of course, represents the outer surface of the 1¼ in. pipe, as the 2 in. pipe carries the ammonia.

The ammonia condensers are of sufficient size to condense enough ammonia to cool 1908 U.S. galls. of brine per minute from 17° F. to 7° F., when working in connection with the other units and with condensing water at a temperature of 80° F. and a condensing pressure of 190 lb. per sq. in. This is equivalent to 678 refrigerative tons per 24 hours.

The ammonia receivers, of which there are six, are made of wrought iron, each being 12 ft. long and 15 in. diameter, tested to 1000 lb. pressure. They are horizontal, and receive the ammonia from the condensers. There it is carried into the bottom of the brine coolers, which are large insulated tanks containing the brine coils. The liquid ammonia is passed in through an expansion valve and the tank is filled to within about a foot of the top. The compressor pumps the gasified ammonia from the top of these tanks at a pressure of 17 lb. (gauge pressure) and delivers it to the condensers again, still in the form of gas, at a pressure from 100 to 190 lb., thereby making a complete cycle.

The brine coolers are of the Isbell-Porter Shell type and are four in number, each with a riveted steel shell 59 in. in diameter and 12 ft. long, closed with cast iron dished heads and supported on cast iron columns. Each cooler has sufficient 1¼, 1½, and 2-inch double-wound pipe coils of extra heavy wrought iron pipe, to aggregate a cooling surface of about 10,000 sq. ft. for the four coolers. Each coil projects through stuffing boxes well secured at each end, and assembled in junction-boxes at the top and bottom. All coolers are thoroughly insulated. They have sufficient capacity to cool 1908 U.S. galls. of brine per minute from 17° F. to 7° F. when operating with the other parts of the refrigerating apparatus with ammonia suction pressure of 17 lb. per sq. in. The total weight of the four coolers is 145,000 lb., and the brine referred to is calcium chloride brine with a sp.gr. of 1·21 and a specific heat of 0·70.

To circulate the brine we have four steam pumps. Three of these are of the cross-compound crank and fly-wheel type, with a capacity of 700 galls. per minute each, and the fourth one is of the duplex compound type, with a capacity of 1000 galls. per minute.

We also have two fans, one at each end of the building, to draw the outside air into the building and over the brine coils at a slight increase in pressure. These are driven by vertical steam engines, and each fan has a capacity of 40,000 cb. ft. per minute.

The brine pumps force the brine through the coils in the brine coolers, where it is cooled by the evaporating ammonia to the temperature required, and then to the brine coils in the refrigerating room proper where these are located. The pipes in this part of the building are made of 2-inch lap-welded iron pipe, each length of pipe 20 ft. long *plus* the return bends, and if placed in one line would stretch 40 miles. These pipes have a cooling surface of 132,000 sq. ft.

The oiling system in connection with these machines is of the gravity feed type, with water, separators and Burt filters. This plant has run on 40 galls. of engine oil for over 13 months, and will easily exceed this record.

The air, which has now passed completely through the system, is delivered to the blowing-engines at a moisture content of about 0·85 grain per cb. ft. and a temperature of about 20° F. Both temperature and water vapour can be controlled to a nicety, thereby eliminating the one great variable in the running of blast furnaces.

We find in practice that the actual saving in fuel is far greater than can be shown by calculation. This may be accounted for in several ways. The temperature of the top gases is greatly reduced, the loss of stock in the form of flue dust is materially lessened, and figuring per unit of production, the amount of coke, stone, and air charged is much less, therefore the capacity of the stoves, blowing-engines etc., is correspondingly increased, and the working capacity of the furnace is also increased, giving a greater production.

According to our records, we are producing more iron with less coke consumption than we did when running under the conditions of natural air. I have taken averages for a whole year in each case, and for the sake of comparison have used the records showing the best results during the last six years, for a single year under both dry and natural blast.

On basic iron our furnace A produced in 1913 about 16 per cent. more iron with 12 per cent. less coke than it did in 1907, which was the best year under natural blast. and our furnace B, making foundry iron, produced 22·3 per cent. more iron in 1913 with 2·7 per cent. less coke than in 1908 which was the best year under natural blast.

One peculiar factor in the dry blast plant is that occasionally in winter, when the temperature falls to say 10° or 15° below zero, the moisture in the outside air is lower than we require, and therefore, as we prefer to have a constant rather than an extremely low moisture content, we sometimes run the dry blast plant backwards, and add to the original percentage of moisture. Ordinarily we keep the moisture content in the dried air uniformly between 0·80 and 0·90 grain per cb. ft. For instance, on February 12, 1914, the temperature of the outside air was 5° F. below zero and the moisture content was 0·2 grain per cb. ft. This air was delivered to the furnace at a temperature at 11·2° F. with moisture at 0·76 grain. To do this it was necessary to add to the blast 5557 lb. of moisture in the 24 hours. This was accomplished by passing 10 per cent. of the first stage brine circulation through a closed coil steam heater and keeping the first stage brine at a temperature of 20° F. Cold dry air from the outside was warmed in passing the first stage coils and rapidly absorbed moisture by sublimation of the snow on the second stage coils. Regulation of the moisture can be effected in this manner as long as any snow remains on the second stage coils.

Thus, as the records show, there has been a general improvement in amount of product, also from cast to cast the chemical composition of the metal produced is more uniform, and lastly this has been accomplished with less fuel per ton of product under the conditions of dry blast as compared with that of natural air.

In concluding, I wish to express my thanks to Mr. Jas. Campbell, Chief Engineer of the dry blast, to Mr. John Scott, our Consulting Engineer, and to Mr. Corbett Whitton, all of whom kindly gave me every facility to obtain any data required.

London Section.

Meeting held at Burlington House on Monday, March 2nd, 1914.

PROF. W. R. HODGKINSON IN THE CHAIR.

THE BLEACHING OF CHEMICAL PULP AND SUGGESTIONS FOR A STANDARD METHOD.

BY ARTHUR BAKER AND JAMES JENNISON.

In view of the publication in Nos. 95 and 96 of the Papier-Zeitung of a paper under the title of " Die Bleichende Wirkung von Chlorkalklösungen auf Zellstoff," by E. Simonsen, the authors have been induced to publish the results of experiments carried out in 1906, on the same subject.

The question was then studied more particularly from the industrial, or manufacturing point of view, rather than the chemical standpoint, and we have determined :—

1. The rate of bleaching at constant temperature.
2. The rate of bleaching at varying temperatures.
3. The influence of residual bleach liquor on the economy of the process.
4. The influence of preliminary acid or alkaline treatment, and the effect of adding the bleach in two portions.
5. The influence of the concentration of the pulp.

The method adopted in carrying out the experiments to be described below was as follows :—

Several sheets of the pulp chosen, which was a typical easy bleaching sulphate pulp, were allowed to become thoroughly air dry, representative samples were taken for the moisture determination, and the remainder was cut up and carefully weighed out into 50 grm. lots. In conducting an experiment one of these lots was carefully torn up by hand into very small pieces, thrown into a known bulk of water, and the pulp obtained thoroughly churned with a strongly made egg-beater fitted with teeth, until a finely divided and uniform pulp was obtained. This was filtered through a large porcelain funnel of about 8 in. diameter, the filtrate being poured through again until all the fine fibres were retained. The pulp was finally transferred to a 4-lb. stoppered bottle and sufficient water added to make it possible to mix effectively the contents by vigorous shaking after the addition of the bleach solution required by the condition of the experiment. The bleach was then added, and the observations taken as demanded by the nature of the trial.

This procedure was adopted in all cases, and was found to be all that was necessary when using an easy bleaching pulp. But in some later experiments, when using a strong non-bleaching sulphite, we found it impossible to obtain a uniform pulp in this manner. The half-stuff in such cases was obtained by breaking up the sheets in an experimental beater, making up to a known bulk and taking an aliquot portion.

After bleaching, the pulp was filtered through filter paper by throwing on to the filter funnel, and the residual liquor exhausted by a water pump. The pulp was then washed with fresh water until the filtrate was free from chlorine by the starch iodide test. The first liquor and washings were made up to bulk, and the available chlorine estimated in an aliquot portion. The pulp left on the filter was washed with dilute acetic acid, and finally with water, until free from chlorine by the silver nitrate test, exhausted by the pump, air dried, and if the yield was required, finally oven dried. In such cases a weighed filter paper was used above.

This method reduced the inevitable browning on drying to a minimum, and the pulp was available for making into sheets for reference.

In all our experiments tap water was used. It had a temporary hardness of 0 parts per 100,000.

The bleach is expressed in all cases as bleaching powder containing 35 per cent. available chlorine.

Series I. Rate of bleaching at constant temperature.
Weight of pulp, 50 grms. air-dry ; 46·03 oven dry.
Concentration of pulp 1 : 16, when bleach is added.

TABLE I.

Bleach taken on oven-dry pulp, 18·15 *per cent.*
Temp. 65° F.

Time bleaching hours.	Bleach used on oven-dry pulp.	Colour.
	per cent.	
2	9·74	Poor
4	10·80	Not good
8	12·65	Good
12	14·31	Excellent
16	15·14	Excellent

The following curve plotted out with the time in hours as ordinates, and the percentage of bleach consumed on the oven-dry pulp as abscissa, illustrates in a more graphic manner the above results.

In this series of trials it will be noticed that a larger amount of bleach was added than necessary to bring the pulp to a good colour, which would tend to exaggerate any action taking place and thus show what was going on more clearly. The bottles were placed in the dark during the period of bleaching.

Series II. Rates of bleaching at variable temperstures

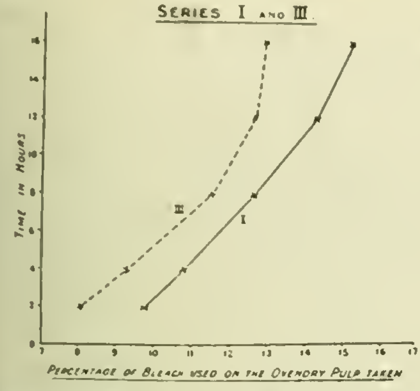
TABLE II.

Bleach taken on oven-dry pulp, 18·15 *per cent.*

Temp. °F.	Per cent. of bleach used on oven dry pulp.	Time bleaching.	Colour.
65	9·74	2 hrs.	Poor
100	15·05	2 hrs.	Excellent
120	17·45	2 hrs.	Excellent
140	18·15	80 mins.	Not good
160	18·15	50 mins.	Not good

The above series is strictly comparable with Series A curve plotted out below serves for comparison with th for Series I.

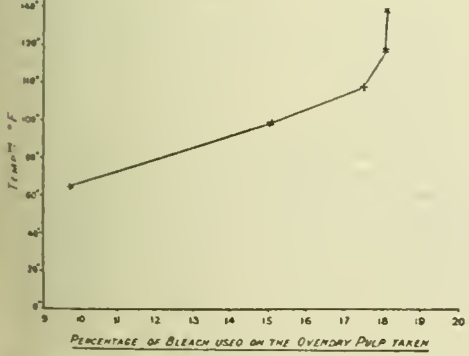
These figures show in a very clear manner how harmful is the action of high temperature upon the economy of the operation, and how deleterious with reference to the colour of the bleached half-stuff. Yet one is sorry to say that in many mills this point seems to be entirely lost sight of.



We estimated the yield of bleached pulp in the above series of experiments, and found the losses to be :—

At 100° F. the loss was 1·684% on the oven dry pulp taken.
120° F. ,, 1·860% ,, ,,
140° F. ,, 2·191% ,, ,,
160° F. ,, 2·782% ,, ,,

In Hofman's "Praktisches Handbuch der Papier-Fabrikation," second edition, there is mention on page 148 of some experiments conducted by Dr. Charles Cresson, who had repeatedly weighed pure wood cellulose before and after bleaching, and failed to find any discrepancy worth mentioning.



Our results on this head from Series 2 confirm what resson says, provided that the operation is carried out a reasonable temperature

On the large scale the loss between the half-stuff un-cached stage and the finished paper is anywhere about —5 per cent., the bulk of which is due to loss of small res in handling.

On comparing the curve plotted out from the results tained in Series No. I. with those published by Sindall and ckford in the World's Paper Trade Review for cember 2. 1904. on the rate of bleach consumption, we nd that the rate of bleach consumption in our trials s about 20 per cent. higher than they obtained in their periments. Thinking that possibly the large excess of ach present in our case might have caused the rate to be elerated in the earlier stages of the operation, we re-ted the whole of that series, using an amount of bleach der equal to the amount consumed during 2 hours at emperature of 100° F. in Series No. II., viz., 15·05 per t. of bleach powder on the oven dry pulp taken.

eries III. Rate of bleaching at constant temperature h less bleach present than in Series No. I.

TABLE III.

Temp. 65 F. *Bleach added*, 15·05 *per cent.*

Time bleaching hours.	Bleach used on oven dry pulp.	Colour.
	Per cent.	
2	8·07	Very poor.
4	9·33	Poor
8	11·56	Good
12	12·65	Excellent
16	12·82	Excellent

The results are plotted out below, against those obtained in Series 1.

It will be observed that the curves are almost parallel until the later stages when the bleach consumption falls off slightly in Series No. III., showing that the relative rate of bleach consumption is the same until about 12 hours have elapsed.

The results seem to indicate that at this concentration of pulp there will always be about 10—20 per cent. of the bleach added, left unconsumed in the residual liquors, if the bleaching is only carried on a reasonable length of time, *i.e.*, not exceeding 12 hours at a temperature of 65° F. or for 2 hours at a temperature of 100° F.

Griffin and Little say in their book—"We have frequently tested the liquor in the chest, in order to determine the proportion of chlorine present after the pulp had come to colour, and have found in many cases it amounted to ¼ or more of that originally introduced."

This is possibly quite common in many mills where it is the custom to use a fair excess of bleach to hasten the process.

We shall see later that the concentration of the pulp is a most important factor in hastening the time occupied for the bleaching operation, as well as reducing the waste of unconsumed bleach in the back liquor to a minimum.

On examining the colours of the bleached pulps obtained in Series I. and II., we observed that the colour of the pulp bleached for 2 hours at 100° F. and that of the pulp bleached for 12 hours at 65° F. were practically identical. Further, the amount of bleach consumed under the conditions of these two trials were approximately the same. We therefore decided that the other trials should be carried out at a temperature of 100° F. for a period of 2 hours, as this time and temperature were very convenient for conducting a number of experiments side by side.

It was explained above why an excess of bleach was taken in Series I. and II. From the comparison of colour and bleach consumption, it appeared that as far as economy went there was little to choose between bleaching for 12 hours at 65° F. or for 2 hours at 100° F., at any rate under the conditions of those experiments.

We therefore repeated the tests under the same respective conditions, but using the same amount of bleach as in Series III., viz., 15·05 per cent.

The results given below were confirmatory of the previous trials with a greater amount of bleach present. The slightly higher bleach consumption at 100° F. is probably explained by the figures obtained in Series IV.

The conditions of experiment were exactly the same as in Series III., the temperature and time varying.

TABLE IIIA.

Bleach added 15·05 *per cent.*

Time bleaching.	Temp.	Per cent. of bleach used on oven dry pulp.	Colour.
2 hrs.	100° F.	13·34	Excellent
12 hrs.	65° F.	12·65	Excellent

Series IV. The influence of residual liquors.

TABLE IV.

Bleach added 15·05 *per cent.*

Per cent of bleach used on oven dry pulp.	Colour.	
13·34	Excellent	Fresh bleach
14·47	Not so good	Fresh bleach + residue

In this series the amount of bleach added was made up in one instance of part bleach contained in some back liquor obtained from a previous trial, and of part fresh bleach solution, the total amount being equal to 15·05 per cent. on the pulp taken. The result of the test being compared with the standard obtained with the same amount of fresh bleach under the same conditions, *i.e.*, 2 hours at 100° F.

The bleach in the second experiment in Table IV. was made by mixing 0·4519 grm. bleach in the back liquor with 6·4776 grms. in the fresh bleach solution.

From the above results it is quite evident that some of the bleach in this experiment was used up by further action on the organic matter present in the back liquor, which action is no doubt accelerated by increased temperature.

Very possibly the slight increase of bleach consumption mentioned in Series III. is accounted for on this ground, also taking into consideration the slight decomposition of the bleach itself which very likely takes place.

In order to further study the influence of back liquors, we made up solutions of fresh bleach, and a solution composed of part fresh bleach and part bleach contained in some mill back liquors.

The solutions were kept in the dark, contained in stoppered glass bottles, and tested periodically, with the following results :—

Table V.

Time standing.	Solution containing	
	100 per cent. fresh bleach.	19 per cent. bleach in the back liquor. 81 per cent. fresh bleach.
	Loss per cent.	Loss per cent.
0 hours	—	—
48 hours	Nil	10·2
1 week	Nil	27·0
2 weeks	2·8	47·0

Fresh solutions made up on similar lines to the above were now tested for 2 hours at 100° F. and for 2 hours at 65° F. The available chlorine contents of the solutions used are given :—

Solution 1 contained 0·7346 grms. of available chlorine from fresh bleach and 0·0098 grm. ditto from back liquor, made up to 300 c.cs.

Solution 2 contained 0·7346 grm. available chlorine from fresh bleach, made up to 300 c.cs.

Table VI.

Solution.	Time.	Temp.	Loss per cent.
1.	2 hrs.	65° F.	11·80
2.	2 hrs.	65° F.	Nil.
1.	2 hrs.	100° F.	23·13
2.	2 hrs.	100° F.	0·47

These figures illustrate very clearly how uneconomical it is to use back liquors over again, and confirm some similar results published by Temperly (Paper and Pulp, January 1901). Since no details are given of the strength of the solutions he employed, it is impossible to compare them in a satisfactory manner. Our results appear, however, to confirm his in a general way.

Series V. The influence of preliminary alkaline and acid treatment, and of adding the bleach in two portions.

Seeing that we were dealing with the question from the standpoint of an easy bleaching pulp, we did not think it worth while trying the effect of a preliminary washing with water, as a pulp requiring such treatment on the large scale could not be classified as an easy bleaching one.

Afterwards, however, we examined the water extract from the unbleached pulp on which the trials had been made with reference to the amount of bleach which the faintly coloured water extract would account for.

Fifty grms. of the air dry pulp was extracted with 1½ litres of cold water. Two separate 500 c.cs. were taken to which was added 50 c.c. of bleach solution of a known strength. During the time the solutions were under observation, one was kept at 100° F. and the other at 65° F.; 50 c.c. of bleach solution contained 2·3399 grms. 35 per cent. bleaching powder.

Table VII.

Solution.	Temp.	Loss per cent. on the bleach added.		
		2 hrs.	4 hrs.	5 hrs.
1.	100° F.	5·58	5·58	5·58
2.	65° F.	4·29	4·29	4·29

These are the losses caused by the extract contained in 500 c.c., therefore if the whole extract had been taken the losses would have been trebled.

The figures show that a certain amount of bleach is consumed in oxidising organic matters which could be extracted by washing with water, but as the economy thus effected would in the case of a pulp requiring say 12 per cent. bleach only amount to 15 per cent. of 12 per cent., *i.e.*, 1·8 per cent. bleach on the pulp taken, it is hardly worth the time and trouble that would have to be spent on it during the washing process.

The amount of bleach consumed by the wash waters of the pulp we had under consideration are very closely in agreement with the 1·5 per cent. obtained by Sindall and Heckford in experiments conducted on somewhat similar lines (see Paper Trade Review, October 7, 1904).

Our results show that the extract is rapidly oxidised, after which little action goes on in the way of decomposing the remaining bleach.

We thought, however, that it might be worth while trying if any economy could be effected by a preliminary acid or alkaline treatment. With an easy bleaching pulp like the one under consideration the results were disappointing, for although the colour was much improved by the acid treatment in the case of soda pulp and by alkali treatment in the case of sulphite pulps, the economy effected in the bleach consumption was insignificant. The acid treatment consisted in saturating the pulp with a solution of hydrochloric acid in amount equal to 1 per cent. on the weight of air dry pulp, which was allowed to stand 2 hours, the pulp was then washed on the filter until the filtrate was free from chlorides, when the pulp was ready for bleaching in the usual way. The alkali treatment was effected in exactly the same manner, 1 pe cent. caustic soda being used on the air dry pulp taken

In the trial where the bleach was added in two portions the second lot of bleach was added immediately the firs was consumed. This latter trial was undertaken becaus it is still the practice in some mills to add the bleach i this manner, without first washing out the product extracted by the first lot of bleach. The results ar instructive, and only what one would expect from a consideration of the earlier trials with back liquor.

Table VIII.

Alkali and acid treatment. Bleach added, 15·05 *per cen*

Per cent. of bleach used on oven dry pulp.	Colour.	Treatment.
13·34	Excellent	None.
12·80	Excellent	Alkaline
12·95	Brilliant	Acid
12·47	Not so good	Bleached in tw portions

The colour of the bleached pulp that had had a previo acid treatment was brilliant in comparison with others, the pulp having had a previous alkaline treatm being a good second. In the trial in which the bleach added in two portions the colour was poor. In the lat case the bleach was added in two equal portions, the lot being exhausted in 40 mins.

Series VI. The influence of the concentration of pulp.

We were well aware from numerous experiments this factor is perhaps the most important one in bleaching of material in the pulp state. Indeed, one might say that it is impossible to obtain the highest economy without careful attention to this most vital point.

Sindall and Heckford emphasise this in their remarks on the subject, as also do Cross and Bevan in their text book on papermaking, but do not give any data bearing on the question.

The former investigators say in an article published in the Paper Trade Review, September 16, 1904 :—

"This question of the proportion of water in relation to the bleach consumption is really an important one. The influence of the quantity of water used per cwt. pulp in the beater is not so fully appreciated by papermakers as it should be, and a few definite trials under carefully regulated conditions would soon convince them that the operation of bleaching wood pulp is not such a simple matter of routine after all. 'More water more bleach' is a common expression, and a common experience, but it is a fact that has not been properly studied. We are ready to accept the idea that the extra bleach is simply consumed by the extra water itself. But the amount used is always considerably in excess of that actually required to neutralise the water, and we are forced to seek some better explanation. Probably the active bleach in solution attacks the chlorinated organic compounds formed during the process, and the actual bleaching of the pulp is retarded, so that not only is the consumption of bleach greater, but the period occupied is longer."

We conducted 3 trials at different concentrations of the pulp, the intermediate one being the same concentration used throughout all the experiments detailed above.

TABLE IX.

Temperature, 100° *F. Time,* 2 *hours. Bleach added,* 15·05 *per cent.*

Per cent. of Bleach used on oven-dry pulp.	Concentration.	Colour.
11·86	1·24	Very poor
13·34	1·16	Excellent
14·04	1·12	Brilliant

The results are not only of interest, but we think of value, showing that the idea that the bleach is consumed by the water, or that it is used up in attacking chlorinated organic compounds is erroneous, as the above trials show conclusively that the bulk of the bleach is simply left unchanged in the back liquor.

The old mill maxim "more water more bleach" is thus ounded on fact. The explanation appears to be, that n weak solution the action is not sufficiently energetic o cause a reasonable exhaustion of the available chlorine. n other words, it is a case of mass action.

All the above described experiments were conducted on n easy bleaching so called soda pulp, which was really sulphate pulp. We found however, that the results btained applied equally well with reference to easy bleaching sulphite pulps, with the exception, already mentioned, hat with a preliminary alkaline treatment the colour btained after bleaching was much better than that given y a preliminary acid treatment.

The net result of the work we have carried out is as ollows :—

1. That the use of back liquors is attended with an ncrease in the bleach consumption, and accompanied by lowering of the colour of the resultant bleached pulp.

Its only legitimate use is in the early washing of boiled gs, or similar operations, prior to bleaching, when it n be thoroughly removed before the bleach is added to e clean half-stuff.

2. That preliminary washing either by water, dilute id, or dilute alkali, is not worth while in the case of easy leaching pulps.

3. That the concentration of the pulp is the most portant factor to be taken into consideration, and due gard to this point is absolutely essential in order to obtain the highest economy in the bleaching process as carried out in the paper mill.

4. That when bleaching with the aid of heat, a temperature of 120° F. should not be exceeded, our results tending to show that temperature of 100° F. is all that is necessary. Wherever possible the pulp should be heated before the bleach is added, as if heated when the bleaching is going on there must always be excessive local heating of the pulp, even if a fairly rapid circulation of the stuff is maintained, of course detracting from the economy of the operation.

Due regard having been paid to the above points, it is a matter for consideration whether the operation is best carried out at 100° F., or at say the temperature of the atmosphere. It is simply a question of cost of equipment.

In bleaching at 100° F. it is tolerably certain that it will be necessary to circulate the pulp during the greater part of the time it is bleaching, whilst practice has shown that when bleaching for a considerable length of time in the cold, occasional agitation is all that is necessary, in spite of teaching to the contrary. Some manufacturers have realised this, and it is modern practice to fit bleaching potchers with fast and loose pulleys in order to economise power.

All work upon the subject of bleaching pulps leads one to the point—Why is there not a standard method of bleaching pulp, and standards of colour for reference in cases of dispute ? There can be no question that a standard method would meet with general approval. Various investigators have raised the question, and it has even been discussed by the Wood Pulp Association. As Sindall and Bacon point out in their work, "The Testing of Wood Pulp," the real difficulty is not the method of performing the operation, but rather the difficulty of fixing suitable standards of reference. They put forward in a tentative sort of way the suggestion that the use of Lovibond's Tintometer might meet the case, but it has apparently found little support. Whilst the tintometer is a useful instrument in the hands of a skilled operator for certain purposes in other industries, it is our opinion that such a method for measuring the colour of bleached wood pulp is extremely unlikely to find favour in the pulp and paper industries, not because of any inherent defects in the proposed method of judging colour value, but simply because the type of man who usually sells and buys pulp would be the last person to pay any attention to such a highly technical method of stating colour value.

Looking at the subject from a practical point of view, one must arrive at the conclusion that any standard test which will find general acceptance must be simple and easily understood by the commercial man, on the point of reference to colour value. Settle this point, and a standard method of procedure in the actual bleaching test itself will soon be agreed upon by all interested.

We therefore suggest that four standards of colour should be fixed by suitable representatives of pulp and paper manufacturers. These standards to be matched in dull porcelain as follows :—

A. Colour obtained by first quality easy bleaching sulphite.

B. Colour obtained by second quality easy bleaching sulphite.

C. Colour obtained by first quality easy bleaching sulphate.

D. Colour obtained by second quality easy bleaching sulphate.

Under the conditions of the standard test given below. Standards to be kept by the Paper Makers Association and the Wood Pulp Associations of the various countries as official standards. The buyer would then be enabled to contract for a bleaching pulp with a specific clause in his contract to the effect that the pulp mentioned would give under the conditions of the standard test a colour of A., B., C. or D. with a stated percentage consumption of bleaching powder. In a case of dispute, the arbitrators would then have available a recognised standard of bleaching quality, and would not be compelled to fall back upon what is commercially known as the "brand," whatever that may happen to mean in any particular case.

Each paper maker and pulp seller would be able to provide himself with similar standards to the official ones, and once knowing the percentage of bleach powder required to produce a colour represented by any one of the four standards could, by a glance at his colour standards, readily form an estimate of the value of any pulp as far as its bleaching qualities were concerned.

Following is the method employed in making the actual bleach test itself :—

Suggested standard bleaching test :—

Minimum quantity to be taken, 10 grms.

10 grms.—10 per cent. air dry pulp.

160 c.c. of water containing bleaching powder (35 per cent chlorine) equivalent to 12 per cent of bleaching powder on the pulp taken.

Temperature—100° F. Time of bleaching—2 hours.

We have used this test for some years, and find it can be suitably carried out by tearing the pulp into shreds by hand, throwing into a litre of water, agitating with a powerful egg beater made of brass, and fitted with teeth, until a uniform pulp is obtained. Throw the resultant pulp into a porcelain filter and exhaust with the water pump, finally squeezing by hand, leaving the pulp approx. 30 per cent. dry. Place in a suitable vessel which is standing in a water bath, and is at the temperature of the bath, *i.e.*, 100° F. Take 100 c.c. of water at 105° F., add the requisite number of c.c. of bleach solution to give the required percentage, and pour on to the pulp. Stir well, and bleach for two hours at 100° F., stirring occasionally with the thermometer.

We find that with filtered mill solution at 4½° Tw. approximately 30 c.c. of bleach solution will be required. This is checked at the time of the experiment.

After the time has expired throw the bleached pulp upon the porcelain funnel, exhaust with the pump, wash, make the filtrate and washings to 2 litres and titrate an aliquot portion. Calculate the bleach consumed as percentage on the 10 per cent. air-dry pulp taken.

We use a calcium chloride bath, fitted with a steam coil, and are able to make a dozen tests side by side, but any arrangement that will provide a constant temperature of the water bath will answer quite as well.

Make suitable sheets of the pulp for reference, and it is important to note that these should be air dried.

By bleaching at 100° F. one is able to make a large number of tests in a short time, and with suitable apparatus to make a large proportion side by side.

DISCUSSION.

Mr. R. W. **SINDALL** said that the paper-maker found that the consumption of bleach varied from say 8 per cent. up to 25 per cent. of the weight of pulp used. It was therefore important to him to have some method by which the minimum of bleach required to produce a given colour should be readily estimated. Discordant results were often due to causes such as the method of extracting the bleaching powder and antiquated methods of treating the pulp. From his own experience he had found it necessary to correlate the actual consumption of the bleach with the colour produced, in order to find the lowest consumption of bleach at which the maximum colour was reached. He used the tintometer as standard of colour because it was the handiest instrument. He quite agreed that in the hands of an untrained man deplorable mistakes and disputes might occur, but in the hands of a trained observer the tintometer could be used for the purpose. By its aid, an independent observer had been able to place in the correct order a series of pulps bleached at 100° F. and at the ordinary temperature, with amounts of bleaching powder varying from 2 to 20 per cent.

Dr. E. K. **RIDEAL** said that in the standardisation of bleach pulp the actual acidity or alkalinity, as the case might be, of the bleach used, should be stated, because the bleaching power was considerably raised in presence of free acid.

Mr **GRANT HOOPER** said that the suggested test struck him as leaving the essential point still to be decided. He took it that at the end they had still to decide what degree of colour remained in the pulp. It seemed to him to be very much better to follow the line which Mr. Sindall had suggested, namely, to rely directly on the tintometer. In the use of that instrument for deciding the colour of such a substance as flour, he had found no difficulty, and Mr. Sindall's experience seemed to have been equally satisfactory. The authors had suggested that the use of the tintometer by the practical man was a difficulty, but there were many trained persons incapable of deciding finer shades of colour. Would the amount of bleach used invariably indicate the degree of whiteness, and if not, was it not better and more direct to rely on the tintometer in the first instance ?

Mr. **BAKER**, in reply, said that the alkalinity of the bleach solution used should not be overlooked in fixing the details of the standard test. The effect of free lime was to retard the operation. He believed that Cross and Bevan had dealt with that subject very thoroughly in a paper called "Some Considerations of the Chemistry of Hypochlorite Bleaching." With regard to the question of colour, the difficulty was not one of fine differences, but of very marked differences. They had found in practice that under the conditions of the standard test all pulps sold as bleaching pulps fell within the range of the proposed standards. The trials exhibited, which represented a large number of pulps, had been roughly classified into four classes, which might form a basis for fixing four colour standards. There was a wide difference between the highest and the lowest colour. As regards the colour measurement, he was afraid if they put before the business head of a concern a series of tintometer readings, it would not be very convincing, but if they could put before him some definite colour values representing the colour obtained by stated percentages of bleach consumption, he would readily make up his mind. It was certainly their intention to state the percentage of bleaching powder as well as the colour.

A TABLE OF SPECIFIC GRAVITIES OF SPIRITS CORRESPONDING TO INDICATIONS OF GLASS HYDROMETERS FOR USE WITH BEDFORD'S CORRECTED SIKES' TABLES.

BY JITENDRA NATH RAKSHIT AND SACHINDRA NATH SINHA, M.A.

Bedford, in his "Corrected Sikes's Tables" for ascertaining the strength of spirits with glass hydrometers (see this J., 1913, 1172), reproduces the specific gravity table (see page 130) from Sikes' original tables, which was meant for use with brass hydrometers. But he has not made it quite distinct in his book how far the results obtained are affected (1) by the use of tables meant for brass instruments, with those of glass, and (2) by the application of what was meant to be true strength on the basis of Ure's experimental determinations o spirit strengths relative to those of Otto Hehner's which formed the basis of the corrected Sikes' table for glass hydrometers.

A table for this purpose is readily prepared in the following way. Taking any indication, *e.g.*, 86·2°, the corresponding spirit strength found from Bedford's table at 60° F. i 41·50 per cent. proof spirit. By Hehner's table (Analyst vol. 5.) the specific gravity for a spirit containing 41·5 pe cent. proof spirit is 0·9724. Hence 86·2° indication b glass hydrometer represents 0·9724 specific gravit whereas that from Table I. of Bedford is 0·9726. Th table thus constructed gives the specific gravities of spiri at 60° F. compared with water at 60° F. for an indicatic at 60° F., and the reverse.

Again, if a specific gravity determined at anoth temperature by glass pyknometer, which is, in fact, apparent gravity, is referred to this table, an apparent i dication is also obtained. Next by the use of Bedford corrected table for the above apparent indication tr spirit strength may be obtained. Thus the error due the different temperature in pyknometrical determinatio may be conveniently eliminated.

Meeting held at the Grand Hotel on Friday, February 6th, 1914.

MR. JULIUS HÜBNER IN THE CHAIR.

ON THE COAGULATION OF THE LATEX OF HEVEA BRAZILIENSIS, AND ITS BEARING ON THE STRENGTH OF RUBBER.

BY NEWTON W. BARRITT, B.A.,

International Institute of Agriculture, Rome, formerly Economic Botanist, Federated Malay States.

The question of strength in rubber has been exercising the minds of rubber growers and their chemists since plantation rubber first entered the market in competition with the native Brazilian product. With outputs increasing and prices steadily declining since 1910, this competition has become keener and the question of quality has assumed greater importance. Notwithstanding this, our knowledge of the strength of rubber is limited chiefly to physical determinations. The manufacturer of rubber goods has a definite standard of quality. He can make reliable determinations of the strength of different samples of rubber and upon them base his valuation. On the other hand, little or no reliable information is available as to what these qualities depend upon or with what they are directly associated. Consequently the planter is still at a loss to know why his rubber is inferior in strength to the native Fine Hard Para and what means he may adopt to improve it. At the present prices* of Fine Hard Para and plantation rubber, 3s. 2d. and 2s. 3d. respectively, the superiority of the former, considering its 15 to 20 per cent. impurity, is equivalent to an increased value in the caoutchouc of 75 per cent. as compared with the plantation product.

Though some authorities do not admit the existence of any superiority in Brazilian rubber, nevertheless many theories have been put forward to account for it. Numerous empirical methods of preparing rubber have been devised, more or less in imitation of the Amazonian smoking method, but none except direct imitations of this method have been proved equal to it, and these, unfortunately, are not adaptable to plantation conditions. Samples of rubber have been prepared at the Botanical Gardens, Singapore, by the smoking method of coagulation, and after vulcanisation gave physical tests equal to those of Fine Hard Para.† Many estates also claim to have produced superior samples of rubber, but, as Eaton has already pointed out, these results are not the outcome of scientific experiment, but of fortunate methods adopted by careful managers and factory superintendents. In 1907 Beadle and Stevens conducted experiments to show that plantation rubber was superior to Fine Hard Para and obtained results accordingly. Results so undoubtedly exceptional are of little value unless fully interpreted in relation to the methods of coagulation employed and the subsequent treatment of the rubber.

Now the Amazonian smoking method consists essentially in coagulating successive films of latex on a stick rotating in a jet of smoke produced by the slow combustion of certain palm nuts. The influences to which the latex is subjected in such a process are increase of temperature, action of smoke, action of volatile organic acids, evaporation of water and consequent concentration of serum.

The use of acetic acid as a coagulant, now generally adopted by most estates in the East, was suggested by its occurrence in the distillation products of wood and in Brazilian rubber, and the practice of smoking sheet rubber in drying sheds is believed to improve the quality of plantation rubber on the supposition that Brazilian rubber owes its superior strength to the action of smoke and other distillation products of wood.

The effect of temperature on coagulation and the quality of the rubber has not been worked out. Henri observed that the "Brownian movement" of the globules of caoutchouc increases with rise of temperature and the caoutchouc becomes less viscous. The writer found that coagulation takes place more readily as the temperature is increased up to 70° or 80° C., but that at higher temperatures it is more difficult to obtain. This result is in agreement with Whitby's suggestion as to the existence of a coagulating enzyme in latex.

The evaporation of water and the consequent increase in concentration of the serum as a factor influencing coagulation, appear to have been entirely neglected by previous workers—a negligence which is all the more surprising when we consider the recent progress in the study of colloidal proteins and their behaviour in salt solutions of various concentrations. This attitude towards such an obviously important factor is no doubt due to the prevailing ideas concerning the part played by the protein in the coagulation of the latex and the quality of the final product. The manufacturer's appreciation of the obvious merits of a clean rubber has encouraged the planter to produce rubber which is almost chemically pure caoutchouc, on the supposition that quality was dependent on purity. The inferior physical properties of synthetic rubber and of caoutchouc prepared from raw rubber do not support such a supposition. Besides, Lock and Bamber have shown that the breaking strains of a number of samples of plantation rubber vary inversely as the percentages of caoutchouc contained in the samples; while Beadle and Stevens, working on the insoluble nitrogenous constituents left after solution of the caoutchouc hydrocarbon in benzene, have shown that their removal from a sample of rubber results in a deterioration of the sample. The nitrogenous constituent would thus appear to exercise a greater influence on the quality of rubber than is generally supposed.

Biffen and Weber both held the view that the proteins play an important part in coagulation, forming a clot which entangles the caoutchouc globules, and that variations in coagulation are dependent on the qualities of the particular albuminoids present in the latex. Frank also supported this view by his experiments on the latex of *Hevea* and *Kickxia*. On the other hand, De Jong and Tromp de Haas obtained coagulation of the latex of *Castilloa elastica* after removal of the proteins by means of alcohol. Spence obtained similar results with *Kickxia*, and Crossley obtained coagulation of *Hevea* latex after considerable dilution with water. Gardner removed the protein from the latices of *Hevea*, *Castilloa*, and *Micranda* by dialysis after digestion with papain, and obtained coagulation in each case. Henri, as a result of microscopic examination, concluded that protein was not essential to coagulation, but he, along with Weber, drew a distinction between coagulation and coalescence or mere fusion of the caoutchouc globules. Zimmermann observes that coagulation can take place in the absence of protein, but believes that the protein in the latex tends to promote coagulation.

The writer examined the behaviour of *Hevea* latex microscopically and found that agglutination and coalescence of the caoutchouc globules is possible without any change taking place in the condition of the protein solution, and that small clots of caoutchouc are formed in this way. This process he considers to be quite independent of true or complete coagulation, in which the caoutchouc globules are embedded in a matrix of coagulated protein. Fusion of the globules and protein with formation of a homogeneous structure takes place when pressure is applied.

Considering these facts, it seemed to the writer that a study of the colloidal properties of latex under different conditions might afford interesting information likely to lead to a better understanding of the process of coagulation and to a clearer conception of strength in rubber. A considerable amount of work on the coagulation of *Hevea* latex by acids and salts has already been done by various workers, notably Parkin, Crossley, Eaton, Whitby, and others, but with little consistency in the results; while apparently no one, except perhaps Whitby, has attempted a quantitative comparison of the effects of different concentrations of the same and of different reagents.

Accordingly, with this object in view, the writer carried out the following experiments on the coagulation of fresh *Hevea* latex in solutions of varying concentration of acid and salt. The experiments were conducted by methods similar to those of Wood in his work on the strength of wheat gluten.

Concentration of Acid.

---

* India Rubber Journal, Nov. 15, 1913.

† L. Wray in Bulletin of Straits Settlements, Vol. X.

In the absence of facilities for dialysing the latex, the following mode of procedure was found most suitable. A number of large test-tubes were each marked at 50 c.c. and numbered from 1 to 60. Standard solutions of acid and salt were run in from a burette in sufficient quantities to make the required strengths, as shown in the above table. One half c.c. of clean fresh latex was then added to each tube, and the liquid thoroughly stirred to effect complete diffusion of the latex throughout. The tubes were placed in racks and allowed to stand for 24 hours to ensure equilibrium between the colloid and its solution. A comparative examination of the tubes was then made. The numbers of all the tubes in which coagulation was just short of completeness were indicated in the table as shown above. The points thus obtained were plotted on squared paper with concentrations of acids as abscissæ and concentrations of salt as ordinates. Such a graph shows the coagulating effect of varying concentrations of salt as measured against the disintegrating effect of varying concentrations of acid. The method of working and the appearance of the latex in varying concentrations of sodium chloride and hydrochloric acid is shown in Plate I. The curves obtained for various acids and salts are given in Plates II., III. and IV.

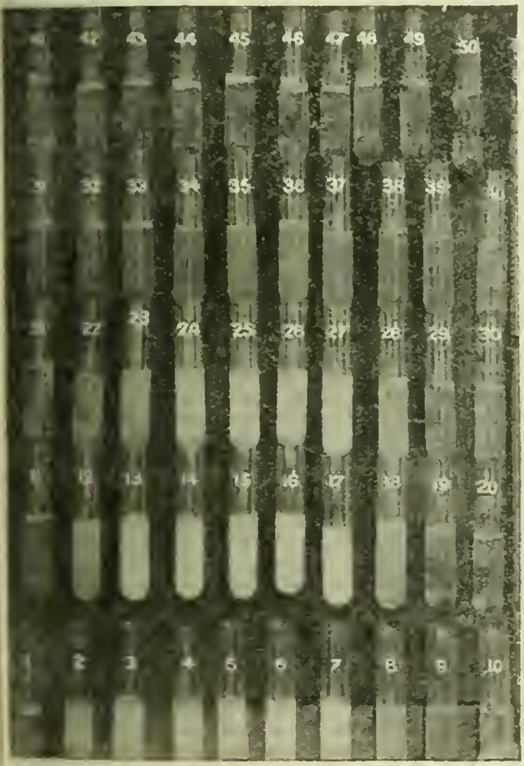

Plate I.

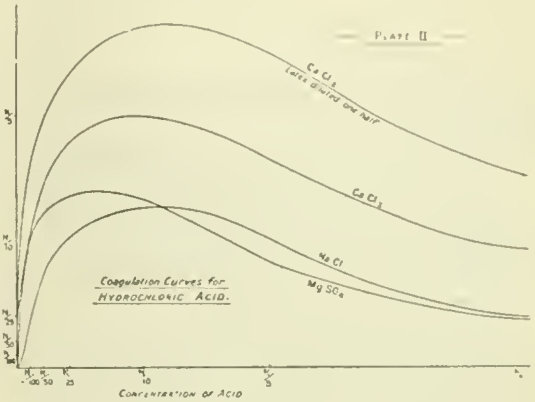
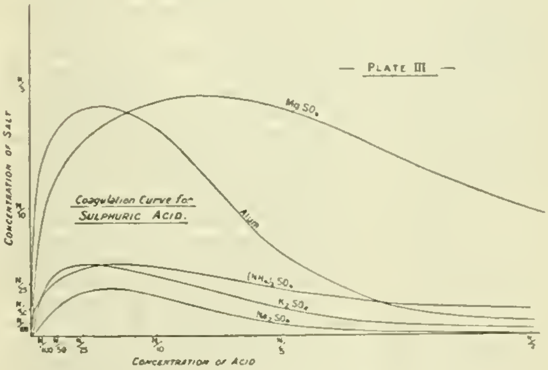
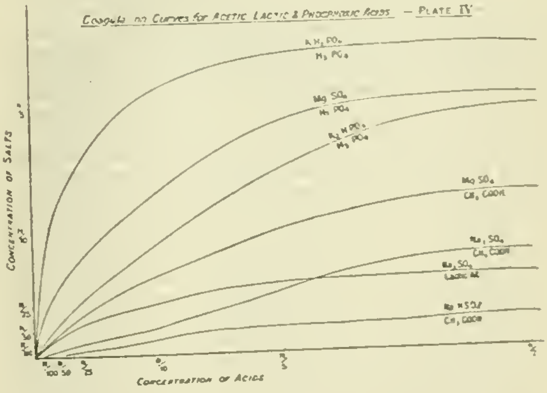
At concentrations of acid and salt corresponding to ny point within the curve coagulation does not take lace and the solution remains permanently milky, though thin skin or coagulum, due to the creaming of the rger caoutchouc globules, may form at the surface. xamination of the opaque serum after several days iows the presence of caoutchouc globules in a state of rownian movement.

At concentrations of acid and salt corresponding to ıy point outside the curve coagulation is complete, and caoutchouc globules are to be found in the serum hich is quite clear. Proceeding from any point of ncentration inside the curve in a vertical direction, as e concentration of the salt increases, the degree of agulation increases, becoming complete on reaching a int outside the curve and increasing in intensity the ther we get from it.

The difference in intensity of the coagulation between points remote from the curve and points adjacent to it was distinctly perceptible in all experiments. The coagula formed by high concentration of salt at points distant from the curve were tougher and stronger in texture, while those formed at low concentration of salt were soft and spongy. Thus one could easily arrange a number of samples of coagula according to their position with respect to the curve. On rolling the samples, however, these differences were much less obvious.







The water-absorbing capacity of the protein in the different samples was determined as follows. The clots from a vertical series of tubes were first washed thoroughly in running water, and dried between sheets of blotting paper and in the open for 24 hours. They were then weighed and afterwards dried to a constant weight in a steam oven. The results were as follows :—

Loss of water on heating rubber to 100° *C.*

Sample.	Initial weight.	Dry weight.	Difference.	Percentage loss.	Concentration of Salt.	Concentration of Acid.
1	3·55	3·16	0·39	10·9	N	N/50
2	3·10	2·76	0·34	10·9	N/2	N/50
3	3·17	2·90	0·27	8·5	N/5	N/50
4	2·70	2·54	0·16	5·9	N/10	N/50
5	2·05	1·92	0·13	6·3	—	2N

thus showing that the water-absorbing capacity of the coagulum varies inversely as the concentration of salt in the serum.

Examination of the curves shows that the inhibiting effect of acids on coagulation increases with increase of concentration of acid up to a certain maximum. Beyond that, in the case of hydrochloric and sulphuric acids, the inhibiting effect begins to diminish with increasing concentration of the acid, until at a concentration of *N*/2 coagulation takes place without the addition of salt. With acetic, lactic, and phosphoric acids, further increase in concentration has no effect, and these acids are unable to produce coagulation at any concentration in the absence of salt. Small differences in the concentration of the organic acids have very little influence on the degree of coagulation produced by salts. Particularly is this the case with acetic acid in the presence of sodium sulphate or bisulphite. This accounts for the fact that acetic acid as used on plantations allows considerable variation in the strength required for coagulation.

Sulphuric acid in the presence of sodium salts behaves similarly but in a less degree. At concentrations of sodium salts above *N*/25 coagulation is produced at all concentrations of acid. Eaton, using undiluted latex, found that coagulation was produced at all concentrations of sulphuric acid. It follows, therefore, that the concentration of salts in latex corresponds to at least *N*/25 sodium sulphate. Comparison of the coagulating effect of various salts shows that the valency of the radicles does not appear to exert much influence. Considering the curves for sodium salts, the sulphate is more powerful than the phosphates or chloride, and comparing the effects of the basic radicles, arranged in order of effectiveness they form a series thus: Na, K, NH_4, Al, Mg. These results do not agree with those of Wood, who found that with wheat gluten the coagulating effect of salts was related to the valency of the kations. They agree, however, with Hofmeister's series, and probably represent the comparative water-drawing capacities of the salts.

Chick and Martin, experimenting with egg albumen, found that the precipitation of protein was analogous to the salting out of alcohol. The first effect of concentrated salt is to withdraw water from the protein aggregates. When precipitation is about to take place, the anion or kation of the electrolyte present can complete the process by neutralising the charges of the particles. Thus in studying the total effect of the concentration of salt on coagulation, the influence of the ions of the electrolytes must be regarded as subsidiary to the dehydrating effect of the salt as a whole. It would appear that coagulation of latex is analogous to the salting-out of proteins like casein and egg-albumen. On this supposition, the addition of salts like sodium and magnesium sulphate to latex causes a separation into two phases, one protein-rich and the other protein-poor, whatever the charge upon the protein aggregates, if enough salt be added. Such phase-separation would be facilitated if the particles were positively charged, that is, in solutions more acid than the isoelectric point. With negatively charged particles in an alkaline solution, the charge cannot be neutralised by the more potent SO_4'', which, if adsorbed, would still further increase the negative charge. Thus the addition of the proper quantity of acid to latex, normally alkaline, gives the particles a positive charge, and enables the salts in the latex to effect coagulation.

The system on separating into two phases attains equilibrium, and any alteration in the amount of any one of their three components is followed by a change both in their composition and volume. Thus increase in concentration of salt or of protein is followed by a corresponding increase in the protein-rich phase (precipitate). This influence of the quantity of protein on coagulation is seen in the curves for HCl and $CaCl_2$, showing that latex diluted until it contains half the quantity of protein requires more salt to effect coagulation. Eaton also gives analytical results in support of this theory as follows:—

Sample.	Vol. of latex.	Vol. of water added.	Vol. of acetic acid, 1 per cent.	Composition of Coagulum. Protein, per cent.	Composition of Coagulum. Ash per cent.
	c.c.	c.c.	c.c.		
1	100	200	10	2·2	0·13
2	100	100	10	2·4	0·10
3	100	50	10	2·5	0·12
4	100	—	10	2·6	0·12

The influence of the increase in the concentration of salt on the physical properties of the coagulum has already been shown. It also affects the composition, but to a less degree. Increase in the salt component is divided proportionally between the two phases, so that most of it remains in the watery phase and only a small quantity enters into the protein-rich phase, which loses a certain quantity of its water. Chick and Martin found this to be the case with egg-albumen and in the above analysis of rubber there is very little difference, if any, in the salt content of the coagulum formed at different concentrations of the latex. In Eaton's analysis this increase was so small as to be imperceptible. His results show little or no difference in the salt content on diluting the latex.

The foregoing results support the theory of Biffen-Weber and others that the protein constituents play a most important part in coagulation and determine to a considerable degree the physical properties of the resulting rubber coagulum.

According to the analysis of Seeligmann, *Hevea* latex from Brazil contains 55 per cent. of water and 9 per cent. of mineral salts, chiefly sodium and calcium, in combination with complex organic acids. It follows therefore that in the Amazonian smoking method, coagulation of the latex takes place at a concentration of salt higher than 18 per cent. It seems very probable that the high concentration of salt and protein in this process is a factor determining the superior qualities of Brazilian rubber, and that the dilution of latex on Eastern plantations by the direct addition of water and acid solution is largely responsible for the inferiority of plantation rubber. If this be the case, then those substances (the protein and ash), hitherto regarded as undesirable impurities in the rubber, are just the factors upon which the quality of the product depends.

This theory would account for the variability which exists among plantation rubbers even from the same estate. Tapping experiments in several countries have shown that the yield and composition of the latex vary considerably with respect to the percentages of caoutchouc, protein and ash, according to the length of tapping, age of trees and rainfall. This variation in composition, in addition to that directly due to artificial dilution of th latex in the factory, will result in considerable variatio in the quality of the rubber produced from day to day The standardisation of plantation rubber therefor involves testing the daily output of the factories, since, i the method of preparation were standardised, the natura variation in the composition of latex itself would caus daily variation in the quantity of rubber produced. I then, dilution of the latex lowers the quality of the rubbe it should be possible to improve it by increasing th concentration of salts or protein in the latex. The writ has prepared samples of rubber by coagulation in th presence of varying concentrations of salt, but befo expressing an opinion on the value of this method, man facturers' tests of these samples are being obtained. such tests, however, require a considerable time, t results so far obtained were considered sufficiently suggestive to warrant publication by themselves. The results of these vulcanising tests will be published as soon as available.

Spence, as a result of microscopic examination of Para rubber, attributes the superior qualities of Fine Hard Para to the presence of tough protein fibres. He does not account for the differences in the degree of toughness of the fibres of different rubbers, nor does he attempt to correlate the existence of such fibrous material running through the caoutchouc with the physical properties of rubber. The writer has not been able to detect the presence of fibres in raw rubber. Observation of the process of coagulation under the microscope showed that the caoutchouc globules are embedded in the protein rather than *vice versa*, and that on pressing the coagulum beneath the coverslip coalescence of the caoutchouc and protein takes place with formation of what appears to be a solid solution of the two constituents.

The part played by caoutchouc globules during coagulation also requires consideration. Since they exist in the latex in a state of Brownian movement which is considerably affected by changes in concentration of salt and acid, it is very probable that their physical properties in the final product are also affected by these changes. Schidrowitz has shown that the viscosities of rubber solutions in benzene vary according to the quality of the rubber. In preparing such solutions, the clear liquid is decanted off from the insoluble nitrogenous constituent. It follows therefore that the properties of the protein in the rubber have no influence on the viscosity determination and that the condition of the caoutchouc itself varies according to the method of preparation of the sample. Further, if the quality of a sample of rubber is dependent on the properties both of the caoutchouc and of the protein, and these properties may vary in different directions at the same time, it is possible that a given sample of rubber may be inferior in general physical properties to another sample after vulcanisation, but superior to it in the viscosity test. This is found to be the case in actual practice, and as a result much doubt has been thrown on the value of viscosity tests.

The problem that remains to be solved, therefore, is what conditions determine the physical properties of the caoutchouc in rubber. The writer leaves further discussion of this question until the above-mentioned vulcanisation tests are available.

Before concluding I wish to express my indebtedness to Mr. Sharples, A.R.C.Sc., of the Mycological Department, Fed. Malay States, who conducted experiments in conjunction with these on the effect of varying salt concentrations on the growth of organisms causing the spotting of plantation rubber, results of which will appear elsewhere; also to Mr. Lambourne, F.R.H.S., Superintendent of Government Plantations, for assistance in many other ways.

Summary.

It is shown that the physical properties of the coagula of *Hevea* latex depend on the concentration of acid and salts in the serum at the time of coagulation, and it is suggested that these have an important bearing on the difference in quality between rubber produced by different methods, notably Fine Hard Para and plantation rubber.

Suggestions are made for improving the plantation methods of coagulation and the difficulties of standardisation are shown.

POWER AND HEAT COSTS IN CHEMICAL WORKS.

BY T. ROLAND WOLLASTON, M.I.M.E.

At the Annual Dinner of the Manchester Section, a speaker expressed the view that the future of British chemical industries was assured if the horse-power could be obtained at a cost of 30s. per annum. This suggested to the author that it might be of value to set forth the true position in regard to power costs in chemical works.

There is hardly an industry in the country in which chemistry is not associated with engineering in the production of saleable commodities, therefore one must perforce deal with the above subject on broad and general lines. In chemical works economy "power" and "heat" costs seem to be inseparable, but to vary in relation to one another in a marked degree. For example, in two different works, of each 100 tons of coal consumed, one will require 20 tons for motive power and 80 tons for heating, whilst the other will have these conditions reversed. The substitution of more economical engines for power purposes in the two works will have very different significance. This may perhaps be best illustrated by a recent case in my own experience. A firm consulted me upon a proposal to pull out several small and wasteful steam engines and to substitute two gas engines with suction gas plants. They had good boiler plant, but in bad condition and inefficiently worked. Though the engines were wasteful, the bulk of the steam generated seemed to be utilised for heating and boiling, and the boiler efficiency seemed to be low.

Simple tests confirmed these suspicions. The boiler efficiency was only about 50 per cent. and only 20 per cent. of the steam generated went for motive power. Upon the basis of burning 100 tons of coal, 20 tons of this would go for power. The installation of the gas plant would reduce this amount say to 5 tons, or the whole consumption to 85 tons. The alternative suggested was to spend half the money the gas plants would have cost on boiler house improvements so as to bring its efficiency up to 70 per cent. Thus without any alteration within the works the 100 tons of coal would be reduced to about 72 tons. The first proposal, taking capital charges into account, showed 15 per cent. on its outlay involved, the second 50 per cent. on its outlay, obviously the better proposition from every point of view.

The chemist is by his training eminently qualified to analyse such cases. He generally knows more of the theory of combustion and evaporation than the engineer, but often fails apparently to turn his knowledge to practical account. He may for example install an automatic carbon dioxide recorder, spend much time in keeping it in order, and treasure the records like bank notes, and all the time be letting his well-burnt gases go to the chimney at 700° temperature while he feeds his boilers with cold water.

I have seen some of the very best engineering in chemical works, and some of the very worst. To particularise :—

Boilers. with brickwork settings tumbling to pieces, once perhaps well covered but with the covering flaking off, grate surface too large or too small for normal output, and induced or forced draught apparatus absorbing an unknown but abnormal amount of the steam generated.

Steam and hot-water pipes. in long and straggling ranges improperly proportioned, and with lagging, if any, in condition worse than useless.

Small steam engines and steam pumps.—In the late Sir Frederick Bramwell's Presidential Address to the Institution of Civil Engineers (Vol. 80 trans.), Jan., 1885, will be found the following passage :—" You would be astonished to hear that, in an investigation instituted last year by the Corporation of Birmingham, when considering whether they should approve of a proposal to lay down power distributing mains throughout their Streets, it was found, on indicating some six non-condensing Steam Engines taken indiscriminately from among users of power and ranging from 5 N.H.P. up to 30 N.H.P., that the consumption in one instance was so high as 27·5 lbs., while it never fell below 9·6 lbs. and the average of the whole was as much as 18·1 lbs." (these figures represent coal per indicated horse-power).

One sees such engines to-day in chemical, bleach, and steel works ; 10 lb. of coal per 1 H.P. means £18 per horse power per year for fuel alone when coal is 12s. per ton. The generation of steam in nearly every chemical works represents a substantial portion of the works costs. Manufacturers will haggle with the coal merchant over 3d. per ton when making contracts but, having burnt the coal, can often only account for a small fraction of its potential heat.

The following is a simple method of carrying out continuous tests, already adopted by many, and valuable out of all proportion to their cost. They involve no new principles nor ideas but are, on the contrary, the ordinary boiler efficiency tests in simplified form. The only costly apparatus required is some form of water meter, which should be considered an essential part of every steam plant equipment. Procedure is fully indicated by the test sheet shown, which can be conveniently duplicated in book form.

BOILER TEST SHEET.

Test made at........................ Date........................ Test made by......................

Type of Boiler.................. Boiler No......... Maker's Name.................. Size of Boiler........

Time.	Gauge Press. in lb. per sq. in.	Temperature of		Chimney Draught. Inches.	Coal delivered.			British Thermal Units.	Moisture Loss per 10 lb. of Coal.	Ash.			Unconsumed Coal in Ash.	Water Meter Reading.	% CO_2 in Gases.	Remarks
		Feed Water.	Chimney.		Tons.	Cwt.	Qr.			Cwt.	Qr.	Lb.				
1	2	3	4	5		6		7	8		9		10	11	12	13

Columns 1, 2, 3, 4, 5, 11, may be filled in three times a day, to obtain fair averages, and are not beyond the abilities of a youth. Chimney temperatures and draught are advantageously read from thermometer and manometer attached permanently at the chimney base. Coal weights may be conveniently obtained from the check office. Ash should be weighed by the fireman and the moisture in coal tested at intervals by placing 10 lb. on a sack in a warm place over the boiler and re-weighing after four or six hours. Flue gases may be tested for carbon dioxide in the works laboratory, say, twice a week from a continuously working aspirator extemporised from old bottles or carboys. B.T.U. in coal may be obtained by occasional laboratory tests.

The important figure required is boiler efficiency. Assuming a normal and reasonably constant boiler pressure the B.T.U. per lb. of steam will be so nearly constant as to be permanently adopted. For example, steam at 100 lb. pressure from feed at 60 requires 1157 B.T.U. per lb. Thus if in one week 20 tons of coal be burned under the boilers, the coal having 12,000 B.T.U. value per lb., and if 30,000 gallons of water be evaporated the efficiency will be :—

$$\frac{300,000\times 1157\times 100}{20\times 2240\times 12,000}=64\cdot 5 \text{ per cent.}$$

This is not very good. First-class boiler plants have shown on test upwards of 80 per cent. efficiency, but one cannot expect to maintain this, and an average of 70 per cent. would be considered satisfactory.

Only columns 2, 3, 7, and 11 of the test sheet are utilised in this efficiency calculation, and so long as it leads to a reasonably good figure the other columns may be ignored. If and when a falling-off occurs it is obvious that the remaining columns offer excellent circumstantial evidence to locate the cause, for example careless stoking, dirty boilers or flues, faulty brickwork settings or the like.

Let me add two notes here. Be sure you are justified in crediting the boilers with dry steam and not mist. Scum, grease, or high alkalinity of the boiler water or hard firing with spasmodic steam withdrawals may lead to priming and to crediting the fuel with latent heat not actually transmitted. Also, so far as is possible, ascertain the amount of steam used in any forced draught arrangement that may be used. Some of these auxiliaries swallow a substantial amount of steam which is hard to gauge.

The points which constitute good practice in conducting steam from boilers to point of utilisation are well understood but too often ignored. Briefly they are : (1) Let the pipes take the shortest and most direct course possible. (2) Keep down the sizes so as to avoid condensing surface so far as is consistent with low friction and maintenance of pressure. (3) Lag the pipes well with good non-conducting composition and maintain the lagging in good, dry, and proofed condition. The watchful manager will have his hot pipes examined and the lagging repaired, and tarred or painted at frequent intervals. (4) Fit draining arrangements to steam pipes wherever water can accumulate.

I lean strongly to the belief that the ordinary boiler furnace does not provide a satisfactory means of burning coal to advantage and I am hoping for a general expression of opinion from those present upon the subject. The same chemical reactions are supposed to take place whether coal is burnt in a bed 9 inches deep on a boiler grate or 6 feet deep in a gas producer. The volatile constituents are distilled off by the heat and are consumed mixed with secondary air admitted above the grate. The incandescent and coked fuel is penetrated by the air from below the grate, the oxygen of which is converted first to carbon dioxide then in a higher zone to monoxide, and this is or should be burned also with secondary air. With the gas producer the gas is generated and burnt under conditions closely approximating theoretical accuracy. In the boiler furnace even in the best practice a very large amount of excess air is used which vitiates the results, while the maintenance of the correct conditions for combustion in a thin bed over an area of say 20 square feet is a matter of impossibility even with the most perfect mechanical stoking devices. In the boiler furnace, however, the radiant heat of combustion is usefully employed while in the producer it is generally dissipated. Numerous attempts have been made to adapt the principle of the gas producer to boiler firing, with greater or less success. Mr. E. C. Mills, of this city, is just now experimenting, with I believe considerable success, with a producer type of furnace attachable to boilers of the Lancashire and other types, in which the air for combustion is highly pre-heated through the agency of the radiant-heat of combustion.

Hitherto the firing of boilers by producer gas has only proved to be a paying proposition when by-products could be extracted from the gas previous to its combustion, and even then only on a large scale. The all-round efficiency of the apparatus is necessarily low, while the ordinary recovery producer requires a large amount of steam to be associated with the air blast, and this is only generated at considerable expense. Professor Bone has, however, demonstrated that very high gas efficiencies can be obtained from boilers specially designed for gas firing. His firm will, guarantee 90 per cent. and his system is probably not the only one by which such efficiencies will be attained. In the near future we shall probably have recovery gas producers capable of generating all the steam they need for blast from the heat in their outgoing gas. Then the use of the recovery gas producer in conjunction with special boilers will enable the plant as a whole to work at approximately the same efficiency as the normal hand fired boiler, and the resultant by-products, sulphate of ammonia and tar, will be a handsome set-off against fuel costs, or may in certain cases even exceed them and show a profit. The recovery of by-products from fuel used will become common practice in chemical works of any size. Several large chemical works in Lancashire and the Midlands already work on these lines, and the few figures in my possession indicating some actual results are confidential.

In modern producer recovery plant about 70 lb. of ammonium sulphate is obtained per ton of coal gasified for each 1 per cent. nitrogen in the coal, and about the same weight of tar, and as Lancashire slacks average about 1·3 per cent. nitrogen, the gross return will be between 11s. and 12s. per ton of coal. The few examples given at the end of this paper will roughly indicate how this works out in practice.

Producer gas provides a much more satisfactory means of transmitting heat through a straggling works than steam. The mains are probably less costly and there are no losses corresponding with steam condensation, while for furnace work, high temperature drying, and evaporating, it offers great convenience and an all round economy, which may be set down, from general experience, as equal to 30 per cent. over the direct burning of coal under such apparatus. Where steam is essential for process work it might often be better to generate it by gas firing at the point of utilisation. In works spread over a large area also gas can be advantageously carried to isolated gas engines, which, unlike small steam engines, do not fall off in efficiency in the small sizes.

As to motive power and its transmission, small non-condensing engines should be avoided. Power transmission by shafting, ropes, belts and the like is often inconvenient in chemical works of a scattered nature. Electrical transmission is generally to be recommended; the losses are small and conveniences very great. When cheap public supply is available it can be turned on just when and as required and is paid for as used, saving also in space and capital account. But as a rule it will pay in a large works to put down a private central plant for generating the works current, either by steam, gas, or Diesel engines.

For purposes of comparison the following is an approximate table showing the performance and cost of modern prime movers:—

(a) The most economical form of modern steam engine (for example the "Uniflow") in conjunction with modern boiler plant.

(b) A steam turbine of highest class with modern boiler plant.

(c) Gas engine with "bituminous" gas plant.

(d) Diesel oil engine.

Type.	B.T.U. per B.H.P. hour.	Fuel cost per B.H.P. hour.	Capital cost per B.H.P.
		penny.	
(a) Steam engine	19,000	·102	£7
(b) Steam turbine	21,000	·112	£6
(c) Gas engine . .	15,000	·08	£8
(d) Diesel engine	9,000	·18	£8

In the above 70 per cent. efficiency is assumed for boiler and gas plant.

Coal of 12,000 B.T.U. value at 12s. per ton.

Diesel oil of 18,000 B.T.U. value at 70s. per ton.

I cannot attempt in this paper to give data for full analysis of the comparative merits of different power schemes, but, primarily to outline how these comparisons may be made, and secondly to illustrate shortly how we stand to-day I close with a few examples. In each case a works is assumed requiring 2,000 brake horse-power, working full load day and night—say, 7000 hours per annum. I also assume the following:—

Electricity obtainable at ¾d. per unit.

Coal with 1·3 per cent. nitrogen and 12,000 B.T.U. value at 12s. per ton.

Diesel oil of 18,000 B.T.U. value at 70s. per ton.

Ammonium sulphate worth £12 10s. per ton.

Tar worth £1 per ton.

Air-dried peat 40 per cent. moisture, 9000 B.T.U. value 2·3 per cent. nitrogen (on sample from West of England recently tested).

Example 1.—2000 H.P. of purchased electricity at three-farthings per unit.

Cost per H.P. hour	·56 penny
Cost per H.P. year	£16 6s. 4d.
Cost per unit	·75 penny

Example 2.—A Steam Turbine Plant of high economy with condensing plant and modern Lancashire or water tube boiler plant.

Capital Costs.

2000 H.P. of Steam Turbines at £4	£8000
2000 H.P. of Steam Boilers at 35s.	3500
Buildings, foundations and chimney	2300
	£13,800

Running Costs.

10,720 tons of coal at 12s.	£6432
Oil and stores, say	643
Labour, 14 men at £70	980
Maintenance at 2 per cent.	276
Interest and Depreciation at 10 per cent.	1380
Total running cost per annum	£9711
Cost per H.P. hour	·166 penny
Cost per H.P. year	£4 17s. 1d.
Equivalent cost per unit at switchboard	·248 penny

Example 3.—Steam Turbine as in Example 2. Ordinary Lancashire boilers fired by Recovery Producer Gas with normal allowance for Producer Steam.

Capital Costs.

55 ton Recovery Plant at £250	£16,250
Boiler plant in proportion	7000
2000 H.P. of Steam Turbines at £4	8000
Buildings, foundations and chimney	4687
	£35,937

Running Costs.

	Equivalent cost per unit		nil

With a clear profit of 21 per cent. on capital outlay.

In regard to these examples, ideal conditions are assumed, namely a 100 per cent. load factor with no allowances for standby or breakdown. If working on day load only, or with variable and intermittent load, the power costs will obviously be less satisfactory and will, incidentally, show a better case for purchased current.

The examples are worked out for power load only. If heating processes are large in proportion to motive power required it is obviously greatly in favour of any of the gas recovery schemes.

The capital costs given are in some cases based upon actual costs and quotations, but in other cases are only roughly approximated, and should not be accepted too literally.

Much difference of opinion exists as to allowance to be made for interest, depreciation, and maintenance. The rates chosen appear to meet with general acceptance, though personally I would prefer them taken at a more liberal figure.

The main object has been to provide a general scheme for comparative analysis, and if those interested will take the trouble to substitute their own figures for my assumptions where necessary they will find these examples useful for comparative purposes.

Discussion.

Mr. E. G. **Hiller** said that broadly speaking most people would agree with the estimates given by the author. The question of power production, he presumed, was not one of the most important things chemists had to consider. He gathered from the Census of Production figures that the total power in chemical trades was 215,000 H.P., the total power of the United Kingdom being about ten millions. The gross output of the works included in those trades was £75,000,000, and 215,000 H.P. at £4 per H.P. per year for fuel represented £860,000, that was about 1·1 per cent. on the gross output, whilst in other trades in the country it was about 2 to 3 per cent., so, as one would naturally expect, in chemical works the power required was on a lower scale than it was in textile works, ironworks, etc. The figures given as to the production of steam from a steam boiler, viz., 20 tons evaporating 30,000 gallons (6·7 lb. of water per lb. of coal) was about the average result.

Mr. J. H. **Lester** did not quite understand the suggestion to use the recovery gas producer along with the burnt gases for steam production. If it was proposed to utilise heat from the producer which generally went in radiant heat and to use the burnt gases in addition to that, he was not quite sure that the author had taken into consideration the amount of water which had been already converted into steam and the enormous amount of loss thereby occasioned. A very large amount of water had to be evaporated to keep the producer going; that had to be condensed again, and the whole of it was lost so far as heat was concerned. The cost of oil for the Diesel engine was put at 70s., but he believed that it was considerably more and had been quoted as high as 90s.

Mr. **Mills** referred to the difficulty of working a fire properly by either hand firing or mechanical firing. Having tested many fires under various conditions he had come to the conclusion that, as in many metallurgical industries, the best method was to turn the fuel into gas and then burn it. It had been tried before without success, but with a furnace—really a gas producer—put on a double-flued Lancashire boiler, 30 by 8, a number of tests had showed a saving of from 18 to 24 per cent. as compared with other boilers, or the same boilers, burning the same fuel. The difficulties, both chemical and mechanical, had been considerable, but he thought they had been overcome.

Dr. J. **Grossmann** said he had always contended that the production of 7lb. of steam to 1lb. of coal was an excellent result which was seldom obtained in actual work, though fancy results might be produced in special tests. Producer gas, if it could be made cheaply enough, was an ideal fuel for boilers. The recovery of by-products from coal and similar fuel would have to be confined to very large works for some time at any rate; he did not think in smaller works the recovery processes had shown any advantage. The smaller the actual quantity of by-products obtained, the greater was the working expense. He could not agree with the author's absolute condemnation of non-condensing engines. In chemical works a great deal of heat was required, and the waste steam from non-condensing engines should not be lost. In nearly every works there were a great many drying operations to be carried out, and the waste steam could be utilised for that purpose. Where it was possible to have one central engine that was the best form of using power, but in many chemical works, especially old ones, it was not feasible. Mr. Wollaston had also mentioned the desirability of preventing steam losses by condensation by covering the pipes. He (Dr. Grossmann) had frequently suggested that a slight superheating of the steam, where it had to be carried for some distance, would be very advantageous.

Mr. R. H. **Clayton** remarked that the author stated that of 100 tons of coal only 20 went for power, which showed pretty well the condition chemical works were in; that although the small pumps and engines were very inefficient, yet, as the main volume of steam was used for boiling purposes, the loss through small inefficient pumps was not so great as it would be if all the steam were taken for power purposes.

It was rather difficult in chemical works to utilise the knowledge one got from the CO_2 recorder. If the men were dealt with too harshly in the matter of CO_2 analyses, it would be found that though a few pounds of coal might be saved, it was lost in other ways. The principal trouble they had had in connection with the CO_2 recorder was in the small pipe conducting the gases to the instrument. The ordinary filter supplied with it was so large that it rapidly condensed moisture and clogged the apparatus. When the recorder was not working properly it was probably due to some condensation water in the tube which caused it to register low. The question of the lagging of pipes was a very great problem in connection with chemical works. The action of the steam upon them was so very great, and they were put down and pulled up so often, that it was best to use very cheap material rather than high class, and that perhaps led to loss of heat. He thought the price of oil for the Diesel engine was excessive, and with regard to dried peat 9000 B.T.U., with 4 per cent. moisture, seemed very high to him. There was bound to be 10 or 15 per cent. of water in peat although it was dried. Was the figure of 5s. the price on the peat field or delivered at the works?

Mr. J. E. **Christopher** was surprised to see that the fuel cost per B.H.P. for steam turbines was put down as being greater than the cost for steam engines, which was scarcely his experience. He also enquired as to the applicability of producer gas for the Diesel engine.

Mr. F. H. **Terleski** said it was quite common to find the CO_2 recorder an hour and a half behind the chimney. With regard to the weighing of cinders, the combustible left in them would vary from 5 to 20 per cent. with different firemen, but a company had brought out a patent firebar and guaranteed that the combustible matter in cinders would not exceed 2·5 per cent. In his opinion, the use of draught recorders in chemical works should receive more attention than it had done in the past. It was quite a small matter to place one practically on the boiler front, behind the breeches, or in the side flues, and another at the chimney base; they would be found very effective. Comparing types of boilers, he observed that the Babcock boiler certainly steamed quickly, but there was no great reserve of steam. The Lancashire boiler was *par excellence* where a reserve of steam had to be relied upon. One matter which he should like to see taken up strongly by chemical manufacturers in the North of England—it was already done in the South, where coal was a more important item—was the buying of coal on a calorific and ash basis. Colliery owners would sometimes send coal which varied between 17 and 18 per cent. in ash, which meant a tremendous difference when the cleaning out of fires had to be taken into account. Nothing was said in the paper about the internal condition of boilers, which, to the steam user, was a most important point, especially when the life of the boiler had to be taken into consideration.

Mr. H. J. **Bailey** said it was a matter of national importance that the coal resources of the kingdom should be used with the greatest economy. There were hundreds of works where chemists were employed who were capable of testing coals, and if they took up the problem they would make their position more favourable. Where there was a high ash in coal there was almost invariably a high carbon content in the clinker. He had seen clinkers containing 25 per cent. of combustible matter when the ash had run anything from 18 to 20 per cent. High ash meant excessive clinker, which considerably reduced the efficiency of the coal.

Dr. G. J. **Fowler** was surprised at the figures given in the table dealing with the results from using peat. He asked to what extent the peat was dried and whether it underwent any preliminary process before being distilled. In a discussion on the subject some years ago, the general conclusion seemed to be that owing to the chemical composition of the peat the high expectations entertained of it were doomed to disappointment. Therefore he should like to know whether the figures were for peat in the ordinary air-dried state, and whether they were applicable to practically any description of peat. If such figures were obtainable on a large scale there were, no doubt, great possibilities in chemical development in that direction.

Mr. **Paton** thought the figure of 12s. for coal was very high. Coal had been available for chemical industries at somewhere nearer 2s., and there were thousands of tons lost every day in the Lancashire area without any attempt being made to get value out of it. Taking the country through the national loss must be from 20 to 30 millions. He thought Societies like theirs could make suggestions to those in power to the effect that taxes could be materially reduced by the application of scientific methods to the country's resources.

Mr. **Bramhall**, dealing with the question of loss in transmission, said that during the last year he had installed electric power in one case where they were transmitting steam about 500 yards, with the result that it was costing one-third of what it cost before, and in 18 months it had paid the whole cost of the plant. With regard to the use of peat he noticed that by burning the gas with the peat, a profit of about 21 per cent. was made, but if the gas was thrown away and the peat was burnt, the profit would be between 40 and 50 per cent.—assuming all the author's figures were correct—because instead of allowing a capital expenditure of £47,000, only about £28,000 would be needed. If those results could be guaranteed it was a very tempting proposition and money could easily be found to put down works for the purpose of simply destroying the peat and making the sulphate of ammonia. An enormous amount of dirty and inferior coal was wasted, and if it could be applied in the same way as the peat, the results would be very beneficial.

Would it be very costly to fix a gas-firing apparatus on an ordinary Lancashire boiler, because that had been the one thing against any sort of by-product treatment? If the gas was a waste product, a large part of the profit was blown away, but if it could be used economically with the ordinary Lancashire boiler, one of the main difficulties was got over.

Mr. **Hoseason** said that as electrical power was likely to take the place of other motive powers he would like to ask the author the average cost of that power as compared with those he had dealt with in the paper.

As regards gas-fired boilers, he had made a test on a big scale, and he thought the chief trouble would be the difficulty of producing a gas free from dust. That was one of the great drawbacks in gas engines, and would probably be a great drawback in connection with the gas-fired boiler.

Mr. E. Ardern considered that coal contracts should be based on actual composition. Very few works laboratories had the necessary instruments to determine the calorific value of coal, and he asked how far the estimates of the thermal value as determined from certain equations based on the ash value and the volatiles, etc., were in agreement, or how far they varied, from estimates determined by total combustion of the coal.

Mr. Terleski replied that the difficulty could easily be overcome by following the example of the wool manufacturers in Bradford, and establishing a "Coal Conditioning House" where tests could be made. He noticed, too, that Boiler Insurance Companies were willing to carry out coal analyses for their clients.

Mr. J. Baddiley suggested it might be profitable to burn peat for ammonia alone, and stated that on one of the islands off the coast of Sweden a large works had been started for that purpose.

Mr. Moffatt asked what the author considered was the smallest size of plant on which it would pay to install a recovery process. There was a good profit from the 2,000 H.P. plant running continuously, but would it pay to install it with, say, 100 H.P. He thought ¾d. a unit with 100 per cent. load factor was a very high figure for the cost of electricity; any power company would quote one-third of a penny with 100 per cent. load factor, and 2,000 H.P.

Mr. L. E. Vlies asked if the acid used for the recovery of ammonia would be the ordinary B.O.V. of commerce; if it was so, the price to-day was 42s. and not 30s.

Mr. Julius Hübner said that an enormous amount of heat was wasted continuously, especially in the smaller bleachworks, dyeworks, and printworks, and in no part of the works was it more apparent than in the different drying operations. Whilst drying in large chemical works was effected on more or less scientific principles, in the types of works mentioned it was carried on without consideration of loss of heat.

Mr Wollaston, replying to the discussion, said that one of the main objects of the paper was to try to induce chemical manufacturers and others not to think of efficiency in pounds evaporated per lb. of coal, but to think of it on the basis of efficiency in B.T.U.'s. Nowadays coal was bought at the lowest price without regard to the difference in value of coals. It was most misleading to say that 6 or 7 lb. was evaporated per lb. of coal. That meant nothing unless it was considered on the basis of the heat purchased in the coal, and the heat actually obtained in the steam got from that coal. Reference had been made to the use of high pressure engines and utilising the exhaust from those engines for heating purposes. He believed very excellent results were being obtained by that method in bleachworks, dyeworks, and paper works, but he had always looked with some suspicion upon that method, for this reason, that a certain amount of power and heat were wanted, each of which varied from time to time, and it was rather difficult to regulate the one to the other. It had always seemed to him preferable to generate power separately as economically as possible, and to generate the steam independently in separate boilers at low pressure. He offered that as a suggestion only, for he had not studied the question closely.

He was sorry he could not give any further details of peat plants. A firm with which he had been associated had three installations. At one in Italy, where peat was used, electricity was generated over a very large area and he believed it was produced for nothing, in fact he believed there was a credit balance. The peat which he had taken as the basis for his estimates was not being utilised at present, but there was a scheme on foot for doing so. It could be gasified in air-dried condition with a moisture content up to 50 per cent., but it was preferred to get it about 40, which, he understood, was comparatively easy.

He had based his figures for the comparative economies of steam turbines and steam engines on two sets of quotations he had received, one for a turbine, and one for a uniflow steam engine, and they showed about the rates of guaranteed economy he had given. He had heard it stated that with a turbine designed by Mr. Ferranti they were running on 6 lb. of steam per H.P. That was inconceivable to him: he had never heard of such a result previously. On the other hand he had been told of steam engines with very high superheat getting below 9 lb. of steam.

As to the application of gas to Lancashire and water tube boilers, he did not think the results were very different, but better results could be obtained by the application of producer gas to water-tube boilers than to Lancashire boilers becauses a very large amount of gas could be burnt through a Lancashire boiler, but there was not heating surface enough to take it up. Broadly speaking, he did not think it was a good proposition to burn producer gas in either of those types of boiler. They were not built for that, and if producer gas was to be largely used in boilers in the future they would be especially built to take that gas and utilise it to the best advantage.

As to the smallest size plant that could be used for a recovery process, that depended on many points. There was no reason why the ordinary yield of sulphate of ammonia should not be obtained from 100 H.P. gas plant, only the capital cost would be so high in proportion to the output that it would take away the profit. Working say 10 hours a day, it had been proved that it was not worth while putting down a recovery plant to work with gas engines under 2,000 H.P., but if they could get up to 100 per cent. load factor, 24 hours a day, and working continuously, it could be done on a great deal less.

He could not follow Mr. Bramhall's argument as to throwing the gas away, and getting a higher return. It must be taken into account that 2,000 H.P. for 7,000 hours per annum was being produced for nothing, with a profit of 21 per cent. The Directors of the Power Gas Corporation along with other people, had purchased a property in Natal, and floated a company to gasify outcrop coal. Experts had asserted that the coal could be fed to the producer at 1s. 8d. a ton. It contained about 2·2 per cent. of nitrogen, and according to the estimates there would be a handsome profit. The gas was burnt to waste because it was valueless at present, but they hoped soon it would be possible to utilise it profitably. If coal or peat rich in nitrogen could be obtained at a low price there was no doubt it was highly lucrative to put it through a producer and recover the by-products. In the case he had mentioned, it was proposed that the producer should be put down right by the side of the peat field, and the price of 5s. a ton was the price for delivery at the producer.

Meeting held on Friday, January 23rd, 1914.

PRESENTATION OF THE PERKIN MEDAL T MR. JOHN WESLEY HYATT.

In the condensed report of the proceedings of th above meeting (see this Journal, March 16th, 191 pp. 225—229), that portion of Prof. Chandler's speec which dealt with the priority of Mr. Hyatt's inventic of celluloid, was omitted.

Scottish Section.

Meeting held at Glasgow on Tuesday, 25th November, 1913.

DR. THOMAS EWAN IN THE CHAIR.

NOTES ON NAPHTHALENE IN COAL GAS.

BY JAMES MACLEOD, F.I.C., AND JAS. A. RUSSELL HENDERSON, D.SC.

The data contained in this paper were collected by the authors during last summer (1913) at the Gas Works, Greenock.

Stoppages owing to the deposition of naphthalene in the service pipes, induced the Greenock Corporation to introduce into their works a Livesey washer for the purpose of eliminating naphthalene from the gas. The washer was placed between the purifiers and the station meter so that by the time the gas reached the washer it was freed from its principal impurities (cf. J. of Gaslighting, 1913, **123**, 682).

Two oils were experimented with for use in the above washer; of these one was a shale oil (750 naphtha) and the other a coal tar distillation product, "Special solvent for naphthalene."

It is to be pointed out that these costs are based on the complete extraction of the naphthalene from the gas which is of course unnecessary as all that is required is to lower the naphthalene content sufficiently to prevent its deposition in the mains and service pipes.

Freezing experiments. "Special solvent for naphthalene." When a test tube filled with this oil was immersed in melting ice no naphthalene separated. When a sample of this oil saturated with naphthalene was treated in a similar way naphthalene began to separate in a few minutes and in a short time the contents of the test tube became solid.

From "750 naphtha" saturated with naphthalene large crystals of naphthalene separated after several hours' immersion in melting ice.

Taking all things into consideration it appears that the "Special solvent for naphthalene" is more suitable than the "750 naphtha." The following points may be noted:—The special oil is not so volatile and dissolves a larger quantity of naphthalene than the naphtha, and consequently when the special oil is used the work of renewing the oil in the washer is not required so frequently as when naphtha is used. The special oil, being a distillation product of coal tar, has little or no effect on the quality and nature of the tar when run into the tar well, whereas naphtha, being a paraffin product, alters the nature of the tar. There is not much difference in the relative costs of washing the gas per 1000 cub. ft.

	750 Naphtha.	Special oil.	
Colour	Water clear	Reddish	
Sp. gr. at 15° C.	0·750	1·000	
Distillation—Below 100° C.	17 per cent.	23·5 per cent. (1)	(1) Benzene, toluene.

The method the authors used for estimating the amount of naphthalene in coal gas is as follows :—The gas was passed at the rate of about 0·7 cub. ft. per hour through a saturated solution of citric acid and then through a ten-bulbed absorption tube containing 2·6 grams of re-crystallised picric acid and about 100 c.c. of water and finally through an experimental meter. The experiments were allowed to run overnight. The naphthalene picrate and picric acid in the absorption tube were washed into a 250 c.c. flask and heated to 40° C. on a water bath till all the picric acid had dissolved. After cooling the naphthalene picrate was filtered off and the amount of unused picric acid determined by titration with $N/10$ sodium hydroxide in 50 c.c. See Coleman and Smith (this Journal, 1900, **19**, 128), Dickenson Gair (this J., 1905, **24**, 1279), Jorissen and Rutter (this J., 1909, **28**, 1179), and Schlumberger (this J., 1913, **32**, 76).

Amount of naphthalene required to saturate a gas.

Temperature.	Grains per 100 cubic feet.	
°C.	I.	II.
0	6·0	2·0
5	9·8	3·2
10	14·1	6·7
15	19·0	10·9
20	24·6	16·5
25	30·9	24·7

I. According to Allen (this J., 1900, **19**, 209).
II. According to Schlumberger.

If the figures given by Schlumberger are correct then the coal gas entering the naphthalene washer must have been supersaturated with naphthalene on several occasions ; if, on the other hand, the figures obtained by Allen are accurate then the gas entering the washer has never been saturated.

On no occasion has the gas leaving the works been saturated with naphthalene. It was observed that on disconnecting the tube from the inlet of the naphthalene washer to the absorption apparatus some crystals of naphthalene had formed. It appears probable that Allen's figures are not quite accurate.

The greatest amount of naphthalene found in the gas entering the washer was 24·7 grains per 100 cubic feet, on July 15—16, and the lowest amount, 11·2 grains per 100 cubic feet, on August 22—25. The figures obtained for the naphthalene at the inlet of the washer during July were greater than those for August. The averages for these months were respectively 19·7 and 15·2 grains per 100 cubic feet.

The amount of naphthalene in the gas depends upon many factors and it is almost impossible to find any relations between the figures given in the tables. The amount of naphthalene depends first of all on the coal used in the retorts. Some coals especially the coking coals, seem to yield a gas rich in naphthalene. As naphthalene is a pyrogenetic substance the amount of it present in the gas will depend upon the temperature at which the coal is carbonized and also upon the time during which the gas remains in contact with the hot coke and walls of the retorts. The amount of free space in the retort has also a marked influence on the amount of naphthalene formed.

The rate at which the gas is cooled in the condensers seems to effect the naphthalene content of the gas. It is to be noted that during July the average cooling of the gas during its passage through the condensers was 44·9° F. and in August 55°, and during these months the amounts of naphthalene were 19·7 and 15·2 respectively. On July 7—8 the cooling amounted to 55° and the amount of naphthalene fell to 13·9 grains per 100 cubic feet. From the 9th to 22nd July the cooling at the condensers was not so efficient and there is an accompanying rise in the amount of naphthalene.

The dependence upon the rate of cooling is not general as is seen in the figures. However, the figures obtained seem to indicate that it would be well to let the gases enter the condensers as hot as possible and cool them there as effectively as possible.

An attempt has been made to correlate the amount of naphthalene in the gas with the vacuum at the exhauster. By keeping the exhaust low it was thought that perhaps less naphthalene would evaporate into the gas ; on the other hand a strong exhaust would draw the gases away from the retort more rapidly and so lessen the time during which the gas is in contact with the hot coke and the walls of the retorts.

One of the coals in use was considered to be the cause of some of the naphthalene trouble. Experiments were carried out in the coal testing plant with this coal with the following results.

The charge of coal consisted of 2 lb. of coal and the time of heating was one hour.

Temp. of retort	840° C.	960° C.	1040° C.
Vol. of gas per ton....	8,133 c. feet	9,327 c. feet	11,083 c. feet
Wt. of coke per ton ..	12·5 cwt.	12·25 cwt.	12·25 cwt.

In none of the above cases was there any indication of naphthalene on passing the gas through a solution containing picric acid in suspension. In these experiments the gas was not long in contact with the hot coke and the cooling was very efficient. Lime was used in the purifying box. No tar was present in the gas on arrival at the holder. This is striking evidence of the elusive character of naphthalene, as naphthalene was generally troublesome when this coal was in use in the works.

The figures given in the tables indicate that there is some relation between the amount of naphthalene in the gas leaving the works and the daily temperature provided account is taken of the efficiency of the washer for any particular day.

Oil has to be added to the washer every few days. The results of the experiments show that the day after the oil has been added to the washer there is a decrease in the amount of naphthalene per 100 cubic feet. Thus on July 14—15 the amount of naphthalene leaving the works was 11·9 grains per 100 cubic feet; on the 15th oil was added to the washer and on the 15th—16th the amount of naphthalene fell to 5·7. Similar results are to be observed on July 24th and 25th.

During the period of the tests in August the amount of gas passed through the washer was 23,172,000 cubic feet. The amount of oil added in the same period was 170 gallons. The average weight of naphthalene extracted by the oil was 8·5 grains per 100 cubic feet. This gives a total quantity of naphthalene extracted of 1,969,620 grains, or 11,586 grains per gallon of oil used. Experiments showed that the oil was capable of dissolving 14,000 grains per gallon. This extraction works out at an efficiency of 82·7 per cent.

It was meant to carry out experiments on the effect of back pressure or varying seal in the washer on the efficiency of the extraction, but this could not be undertaken although it is hoped to carry out tests at a future date. The naphthalene content of the gas has, as usual with the advent of colder weather, fallen to a very low figure and in any case tests would not have been exactly comparable with those done previously.

FIRST REPORT OF THE COMMITTEE ON THE NOMENCLATURE OF ALLOYS.

See under Class X. of the Journal and Patent Literature, page 318.

Obituary.

CHRISTOPHER CLARK HUTCHINSON.

The death occurred on March 7th from heart failure of Mr. C. C. Hutchinson, K.C., one of the founders of this Society.

Born in 1854, the second son of Mr. William Hutchinson of Burnside, Westmorland, he was educated at the Royal College of Science, Dublin, and soon afterwards became an engineer in partnership with the late Mr. S. H. Johnson. He served as an abstractor for the Society's Journal from 1885 to 1891, on the Publication Committee from 1891 to 1899, and on the Council from 1891 to 1895. He was called to the bar at the Middle Temple in 1896 and took silk in 1910. His experience as an engineer was of great service to him at the Parliamentary Bar, where he soon obtained a large practice. He drafted the Charter of Incorporation and By-laws of this Society.

Journal and Patent Literature.

PATENT SPECIFICATIONS may be obtained by post by remitting as follows:—

English.—8*d.* each, to the Comptroller of the Patent Office, W. Temple Franks, Esq., Southampton Buildings, Chancery Lane, London, W.C.

United States.—1*s.* each, to the Secretary of the Society.

French.—1 fr. 05 c. each, as follows: Patents dated 1902 to 1907 inclusive, Belin et Cie., 56, Rue des Francs Bourgeois, Paris (3e.); Patents from 1908 to date, L'Imprimerie Nationale, 87, Rue Vieille du Temple, Paris.

German.—1 mark each (with full particulars) to Kaiserlich Patentamt, Berlin, Germany.

I.—GENERAL PLANT; MACHINERY.

"*Mammoth-pump*"; *Use of the —— in chemical industry.* K. Meerbach. Chem.-Zeit., 1914, 38, 274—275.

MAMMOTH or air-lift pumps are constructed in antimonial lead, stoneware, and ebonite, for lifting acid and alkaline liquids as well as for the transportation of guncotton suspended in liquids, and several have been installed for this purpose.—A. S.

Air; Moisture in compressed —— [for pneumatic tools]. A. Hofmann. Eng. and Min. J., 1914, 97, 366—367.

To avoid condensation of the moisture in it, when compressed air is utilised in pneumatic tools it is advantageous first to cool the compressed air, and then to reheat it before it enters the tool.—T. St.

PATENTS.

Cooling, cleansing and drying gases; Apparatus for ——. T. R. Wollaston, Manchester. Eng. Pat. 2114, Jan. 27, 1913.

THE gas passes downwards through a vertical conical chamber, the wide lower end of which terminates in a fluted comb partially immersed in a liquid seal. The washing liquid is sprayed into the top of the chamber. Owing to the increasing cross-sectional area of the chamber the speed of the gas steadily decreases, whilst that of the liquid particles remains almost constant. The washed gas passes between the teeth of the comb into an enclosing chamber, which may be provided with radial, vertical, fluted metallic strips, having ragged holes punched in them, or with other suitable means for separating liquid from the gas, which latter is finally discharged through a pipe in the upper part of the outer casing.—W. H. C.

Drying machines; Rotary ——. F. J. M. Millar, London. Eng. Pat. 2463, Jan. 30, 1913.

A continuously operating and discharging machine of the rotary type, consisting of a combined conical cylinder and automatic reversing gear; it is rotated within an outer casing by suitable machinery. A current of hot air is passed through the outer casing, and the material is fed into the smaller end of the drum and discharged from an opening in the side near the larger end.—W. H. C.

Drying by passage of hot air through the material and evaporation in vacuo; Process of ——. A. Blavinhac and H. D. N. Teisseire. Fr. Pat. 462,273, Nov. 18, 1912.

The material is passed downwards between two vertical perforated plates each of which forms one side of a chamber. A supply of heated air is delivered to the chamber on one side and passes horizontally through the layer of material to the chamber on the other side, which communicates with a suction device. The material is in this way exposed both to a partial vacuum and to a current of heated air.—W. H. C.

Filters. H. E. Hughes, London. Eng. Pat. 6958, March 22, 1913.

The flanged edges of an upper and a lower casing are clamped together with a cloth of felt or other suitable filtering material between. The liquid is fed into the upper vessel which has a removable cover and an internal inverted conical partition with a circular opening at the apex of the cone. A vertical perforated cylinder fits into this opening and serves to retain any coarser particles. The filtered liquid is withdrawn from the lower vessel through an opening at the side.—W. H. C.

Filtering, removing gases from, and distilling liquids; Apparatus for ——. M. Kirschner, geb. Wachsmuth. Ger. Pat. 268,880, Nov. 17, 1912.

The liquid is projected in the form of a fine shower over the filtering layers, which are disposed one above the other, and wide-mouthed pipes connected with an exhauster are disposed in several of the compartments between the filtering layers in such a manner that the liquid throughout its course remains under a practically constant degree of suction. In this way the speed of filtration is accelerated and gases are removed from the liquid.—A. S.

Separating solid substances contained in liquids or liquid masses; Process and apparatus for ——. H. Hencke. Fr. Pat. 462,288, Sept. 8, 1913.

A horizontal perforated drum covered with suitable filtering material is rotated partly immersed in a tank. The interior of the drum is divided into several compartments which are in communication with a vacuum pump so that as the drum rotates an increasing suction may be applied, whilst as successive portions of the periphery reach the discharge position the vacuum is cut off. The discharge of the cake is effected preferably by a roller carrying an endless band which works against the periphery of the drum and is rotated in the opposite direction.
—W. H. C.

Chemical reactions; Process for carrying out ——. Soc. Générale des Nitrures. Fr. Pat. 462,464, Nov. 22, 1912.

The solid or gaseous particles which are to react are projected through a chamber, heated to the necessary temperature, at such a speed that they pass out of the heated space before they have time to attain the temperature at which the products of the reaction are decomposed. The process may be applied to the manufacture of aluminium nitride, calcium carbide, cyanides, etc.—W. H. C.

Packing absorption or reaction towers. R. Moritz. Fr Pat. 462,877, Sept. 23, 1913.

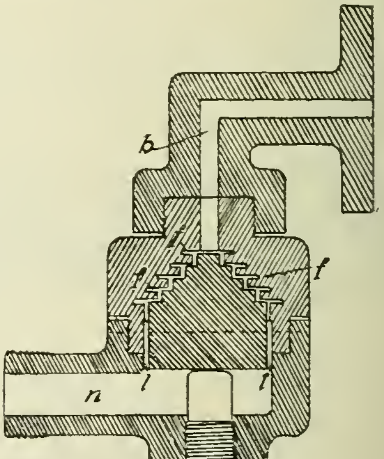
Vertical or horizontal partitions are provided so that although the liquid can pass freely downwards the gases are compelled to take any desired tortuous course. The partitions are supported entirely by the packing material.
—W. H. C.

Dialysing membranes; Preparation of ——. R. Hömberg, C. Brahm, and H. Mühsam, Ger Pat. 269,115, April 16, 1913.

Films of Norgine or other substance prepared from seaweed, preferably spread on suitable supports (metal wire gauze or the like, perforated plates, unglazed porcelain, etc.) are hardened by treatment with metallic salts, acids, or acid substances. The strength of the films may be increased by incorporating insoluble substances, such as barium sulphate, talc, kieselguhr, etc., with the Norgine or producing precipitates of such substances during the hardening process.—A. S.

Homogenising liquids; Method of ——. F. M. Berberich. Ger. Pat. 269,540, July 30, 1911.

The apparatus used is shown in the figure. The liquid enters under pressure through the channel, *b*, and after passing through the narrow passages shown, escapes by way of the grooves, *l*, and channel, *n*. The provision of the narrow annular channels, *f*, ensures that each portion of the liquid comes repeatedly in contact with another portion moving in the opposite direction The pressure on the liquid is greatest at the narrowest portion of the device.—A. S.



Solution of solid substances; Apparatus for the continuous ——, *especially for slaking lime with sugar juice or water.* H. Eberhardt, Maschinen- und Armaturenfabrik. Ger. Pat. 270,045, Nov. 3, 1912. Addition to Ger. Pat. 268,442.

The perforated cylinder through which the material descends, as described in the chief patent (this J., 1914, 127), is fixed eccentrically within the dissolving vessel, and below the cylinder but above the scraper which directs the undissolved material into the worm elevator, is an agitator which forces the solvent liquid upwards and laterally through the perforated cylinder.—A. S.

Agglomerating finely divided granular or friable materials; Processes of ——. V. A. M. Kroll, Luxembourg. Eng. Pat. 27,762, Dec. 2, 1912. Under Int. Conv., Dec. 9, 1911.

See Fr. Pat. 452,631 of 1912; this J., 1913, 757.—T. F. B.

Rectifying apparatus. A. Golodetz, Berlin, Assignor to B. Benedix, Hamburg. U.S. Pat. 1,086,452, Feb. 10, 1914.

See Eng. Pat. 18,711 of 1912; this J., 1913, 351.—T.F.B.

IIa.—FUEL; GAS; MINERAL OILS AND WAXES.

Coal: Absorption of gases by ——. F. Leprince-Ringuet. Comptes rend., 1914, **158**, 573—576.

Gases (fire-damp, carbon dioxide, air, oxygen, and methane, at pressures ranging from 0·25 to 80 atmos.) were absorbed by coal to a much less extent than by charcoal, but the absorption in both cases was of the same general character; a state of equilibrium existed for each temperature and pressure, and the absorption markedly decreased as the temperature rose; the increased absorption with rise of pressure was rapid at first but gradually tended to a limit. Equilibrium was reached very slowly and, especially in the case of carbon dioxide, evolution of the absorbed gas, however slowly effected, was spasmodic. Results of the same order of magnitude were obtained with coals of widely different composition and size of grain; they afforded no explanation of the large evolution of fire-damp observed in very gassy mines. —F. Sodn.

Surface combustion. W. A. Bone. Roy. Inst., Feb. 27, 1914. J. Gas Lighting, 1914, **125**, 572—573. (See also this J., 1911, 527; 1912, 61, 524.)

Tests made with the 110-tube boiler at the Skinningrove Iron Works (see this J., 1912, 61) after it had run for 5 months showed that with a total evaporation of 5000 lb. of water from and at 212° F. (100° C.) per hour, the ratio of heat utilised to net heat supplied, was 0·927 : 1, and that the mechanical properties of the tubes were not in any way impaired. In a test of a "Bonecourt" boiler recently installed in connection with Krupp's coking plant in the Ruhr district, Westphalia, an evaporation of 6750 lb. of water per hour from and at 212° F. (100° C.), with an efficiency ratio of 0·925 was realised. In regard to surface combustion in a bed of granular refractory material for melting metals, etc., it is stated that without regeneration it should be possible easily to obtain temperatures up to 2000° C. with coal gas, coke-oven gas, or water-gas, or about 1500° C. with low-grade producer gas, such as Mond gas. Heating by means of diaphragms has been employed for more than a year for boiling and concentrating sugar solutions in a confectionery factory, the boiling being effected in a copper pan over a circular diaphragm of 13 ins. diam. Some of the diaphragms have been in continuous day use for about one year, and it is stated that the gas consumption is about one-half of that obtaining when ordinary flame burners were used. Very rapid and efficient evaporation of liquids can be effected by the use of overhead diaphragms. —A. S.

Hydrocarbon flames; Water-gas equilibrium in ——. G. W. Andrew. Chem. Soc. Trans., 1914, **105**, 444—446.

The equilibrium conditions of the reversible system $CO+H_2O \rightleftharpoons CO_2+H_2$ in hydrocarbon flames have been examined by exploding hydrocarbons with oxygen insufficient in quantity for complete combustion, but sufficient to prevent the deposition of carbon. The ratio $\frac{CO \times H_2O}{CO_2 \times H_2}$ was found to be practically constant and independent of pressure and of the maximum flame temperature, since the gases react during cooling and the equilibrium constant, "k," corresponds to some lower temperature at which the gases cease to react rapidly. This temperature lies between 1500° and 1600° C. at which "k" as determined by other investigators has a value of 4·0. This is in close agreement with the values obtained by exploding the following gaseous mixtures: CH_4+O_2, $k=3·98$; $2CH_4+3O_2$, $k=3·98$; $2C_2H_6+3O_2$, $k=4·12$; $2C_2H_6+5O_2$, $k=3·63$; $2C_2H_4+5O_2$, $k=3·47$. Even the deposition of carbon, or the recurrence of considerable quantities of methane had but little influence on the equilibrium.—G. F. M.

Soot: Products isolated from ——. E. Knecht and E. Hibbert. Proc. Manchester Lit. and Phil. Soc., 1913, **58**; Reprint, pp. 1—5.

Ten lb. of household soot from the Warrington district yielded, when extracted with benzene, 2 lb. of a semi-solid, pitchy mass. By extraction of this with petroleum spirit, and re-crystallisation from alcohol or methyl acetate, a hydrocarbon, $C_{27}H_{54}$, probably cerotene, was isolated in the form of white crystals, m. pt. 65 C. The same substance was isolated from soot derived from another source. The original pitch also contained an oxygenated compound, probably $C_{15}H_{16}O$, b. pt. 300° C. under reduced pressure, sparingly soluble in alcohol and benzene, more soluble in ether, chloroform and glacial acetic acid, $[a]_D = +8°$ in chloroform solution, and an organic acid, $C_{10}H_{10}O_2$, m.pt. 135 C. (See also this J., 1905, 818.) —W. P. S.

Asphaltum in dark petroleums; Determination of ——. D. Holde and G. Meyerheim. Chem.-Zeit., 1914, **38**, 241—244, 264—265.

Hot ethyl acetate, recommended by Kantorowicz (this J., 1914, 66) was found not to be a suitable reagent for precipitating asphaltum from petroleums. It did not precipitate the ceresin, and it dissolved both soft and hard asphaltums more readily than ether, and hard asphaltum more readily than petroleum ether. In a considerable number of cases, ethyl acetate precipitated no asphaltum from oils from which asphaltum was precipitated by petroleum ether. The quantity of asphaltum precipitated by ethyl acetate was not the same as that obtained by means of ether or petroleum ether after removal of ceresin. The use of ether or petroleum ether is recommended. —A. T. L.

Patents.

Washing apparatus [*for coal*] *with multiple ascending currents.* P. Habets and A. France. Fourth Addition, dated Aug. 6, 1913, to Fr. Pat. 435,720, Oct. 17, 1911.

In order to reduce the quantity of the water used in the apparatus described in the original patent, the shale compartments are arranged in direct or indirect communication with an overflow chamber provided with suitable valves by which the speed and level of the current may be regulated. (See also this J., 1914, 241.)—W. H. C.

Peat; Production of briquettes and of coke from ——. W. I. St. J. and J. R. H. Prioleau. Fr. Pat. 462,980, Sept. 25, 1913. Under Int. Conv., Sept. 12, 1913.

Peat is disintegrated and heated to about 30° C. in a steam-jacketed hopper arranged above a pair of hollow steam-heated rollers. These rollers feed the peat into a briquetting machine, which discharges it under slight pressure through suitable orifices. The compressed peat is cut into blocks, which are dried at 30° C. in chambers through which a current of air is passed. The briquettes may be carbonised in retorts for the production of coke, the distillation gases being used for heating the drying chambers.—A. T. L.

Fuel: Process of burning solid ——. O. B. Evans, Lansdowne, Pa., Assignor to The United Gas Improvement Co., Philadelphia, Pa. U.S. Pat. 1,085,806, Feb. 3, 1914.

The formation of clinkers during the combustion of a bed of fuel yielding a fusible ash is prevented by supplying the air in such a manner that there are produced in the mass of fuel superposed zones of temperature, one above and the other below the fusing temperature of the ash. Unconsumed carbon is fed through the hotter zone so as to prevent the agglutination of the fused ash therein, and is subsequently burnt out in the cooler zone.—H. H.

Combustion of gaseous mixtures. Bonecourt Surface Combustion, Ltd. Fr. Pat. 462,775, Sept. 19, 1913. Under Int. Conv., Sept. 21, 1912.

A combustible mixture is projected against the incandescent surface of a refractory mass, and burns at the hot surface, the products of combustion escaping through the pores of the material or through passages formed in it. The mixture is discharged through a passage of such cross-section that the flame cannot strike back through it, and the velocity of the gases is such that combustion does not take place until they spread out over the surface of the material.—A. T. L.

Gas producer. E. A. W. Jefferies, Assignor to Morgan Construction Co., Worcester, Mass. U.S. Pat. 1,085,686, Feb. 3, 1914.

An annular cooling jacket surrounding the lower part of a gas producer contains a coil of pipe through which the water passing to the air and steam inlet pipe of the producer is conducted, so that it becomes heated by contact with the heated water in the cooling jacket.—H. H.

Retort oven for the production of lighting gas. Stettiner Chamotte-Fabrik Akt.-Ges., vorm. Didier. Fr. Pat. 461,685, Aug. 21, 1913. Under Int. Conv., Feb. 14, 1913.

In order to keep the whole of the retorts in work throughout the year, the gas generator for heating the retorts is thrown out of operation in the summer when the demand for gas is small, and a part of the retort gases is used for heating the retorts. The gas conduits for this purpose are formed in the upper part of the lateral walls of the generator.—A. T. L.

Gas for heating ; Production of ——. Athion Ges. m. b. H. Fr. Pat. 462,740, Sept. 18, 1913. Under Int. Conv., Sept. 21, 1912.

Carbon dioxide extracted from combustion gases in the known manner by means of alkali carbonate solution or water, is used in place of steam in generators for making producer gas. Gases rich in carbon monoxide are thus obtained, and nitrogen compounds as well as carbon dioxide can be recovered from the products of combustion of these gases. The surplus quantity of carbon dioxide not required to be passed again through the generators, is liquefied.—A. T. L.

Water-gas producer. A. Bormann, geb. Baeumcher. Ger. Pat. 269,349, March 16, 1913.

The producer shaft is divided by means of a partition into an upper distillation and gas-producing chamber and a lower combustion chamber. In the partition are openings through which part of the carbonised fuel falls from the upper chamber into the combustion chamber, and the combustion gases pass through other openings in the partition into heating tubes disposed within the upper distillation and gas-producing chamber.—A. S.

Gas-purifying material ; Process for the revivification of spent ——. H. Frank and K. Kallenbach. Ger. Pat. 269,764, June 4, 1912.

The mass is treated with compressed air, then passed on to a shaking screen, and the portion which passes through again treated with compressed air. The larger particles retained by the screen are ground in an edge-runner and then mixed with the finer portion.—A. S.

Fuel for explosion engines. J. de Cosmo and H. Quinaux. First Addition, dated Aug. 8, 1913, to Fr. Pat. 459,857, April 10, 1913 (this J., 1913, 1150).

A naphthalene mixture which remains liquid at ordinary temperatures consists of crude naphthalene, 400, refined mineral oil, 600, nitronaphthalene, 10, naphthylamine, 5, and cresol 5 grms. The naphthalene is mixed first with half of the oil, then with the nitronaphthalene and naphthylamine, and after heating to 23°—30° C., with the remainder of the oil. The mass is vigorously stirred, mixed with the cresol, allowed to stand, decanted and filtered.—A. T. L.

Alcohol for motors : Manufacture of ——. Mme. la Marquise Veuve de Ahumada, née M. Baratoff. Fr. Pat. 462,909, Dec. 3, 1912.

Denatured or pure alcohol, 840 grms., is mixed with 150 grms. of a mixture containing 2 parts of petroleum spirit and 1 part of ether, and with 10 grms. of a solution of white phosphorus (8 per cent.) in carbon bisulphide. —A. T. L.

Peat fuel or coke ; Process for producing —— and apparatus therefor. W. L. St. J. Prioleau, Boncath, South Wales, and J. R. H. Prioleau, London. Eng. Pat. 20,668, Sept. 12, 1913.

See Fr. Pat. 462,980 of 1913 ; preceding.—T. F. B.

Burning finely divided fuel ; Method of ——. *Apparatus for burning finely divided fuel.* D. J. Irish, New York, Assignor to The Babcock and Wilcox Co., Bayonne, N.J. U.S. Pats. 1,086,712 and 1,086,715, Feb. 10, 1914.

See Eng. Pat. 18,712 of 1911 ; this J., 1912, 864.—T. F. B.

Air-deflecting plate. Apparatus for burning finely divided fuel. D. J. Irish, New York, Assignor to The Babcock and Wilcox Co., Bayonne, N.J. U.S. Pats. 1,086,713 and 1,086,714, Feb. 10, 1914.

See Eng. Pats. 27,673 and 27,674 of 1911 ; this J., 1912, 1021.—T. F. B.

Ammonia and other products in gas producers ; Manufacture of ——. H. Wade, London. From "Montania" Brennstoffverwertung Ges. m. b. H., Berlin, Charlottenburg. Eng. Pat. 9499. April 22, 1913.

See Fr. Pat. 452,648 of 1912 ; this J., 1913, 648.—T. F. B.

Mineral hydrocarbons (petroleum and the like) ; Process for converting —— into oils having a lower boiling point. H. Zerning, Halensee, Germany. Eng. Pat. 731, Jan. 9, 1913.

See Fr. Pat. 452,919 of 1913 and Addition thereto ; this J., 1913, 781.—T. F. B.

Separation of the so-called acid tar formed in refining mineral oils or tar oils with sulphuric acid. Ger. Pat. 270,074. See III.

Treating waste acid and acid effluents from tin-plate works. Eng. Pat. 3505. *See* VII.

Hydrogen from iron and steam. Fr. Pat. 461,623. *See* VII.

Hydrogen by the alternate oxidation and reduction of a contact mass containing spongy iron, by means of steam and a reducing flame. Fr. Pat. 461,624. *See* VII.

IIb.—DESTRUCTIVE DISTILLATION ; HEATING ; LIGHTING.

Patents.

Wood ; Method of distilling ——. F. Pope, New York, and G. M. Pope, Mount Pleasant, Ga., Assignors to E. M. Pope, Boston, Mass, and Southern Manufacturing Co., Pittsburgh, Pa. U.S. Pat. 1,085,875, Feb. 3, 1914.

Wood is placed in a closed vessel and hot liquid pitch is caused to circulate upwards and over it ; the air is exhausted from the upper part of the vessel, whilst a current of steam is introduced in order to carry off the distillation products.—W. P. S.

Filaments for tungsten lamps; Manufacture of ——. G. P. Scholl, New York, Assignor to Westinghouse Lamp Co. U.S. Pat. 1,086,088, Feb. 3, 1914.

A paste of tungsten and casein is formed into filaments which are heated by means of an electric current in a non-oxidising atmosphere containing hydrogen in order to remove the carbonaceous material.—H. H.

Filaments; Process of treating incandescent lamp ——. R. H. Henderson, East Orange, N.J., Assignor to Westinghouse Lamp Co. U.S. Pat. 1,086,171, Feb. 3, 1914.

Metallic filaments are heated to a temperature in excess of the normal operating temperature in an atmosphere of phosphorus vapour whereby the surface of the filament is rendered compact and smooth.—H. H.

III.—TAR AND TAR PRODUCTS.

Tar; Use of —— *in the production of basic linings of steel furnaces.* J. Wagner. Rev. Mét., 1914, **11**, 211—220.

The constituents of coal tar which are beneficial in preparing furnace hearths of dolomite and tar are coal-tar acids, anthracene oils, and non-volatile pitch. The prejudicial constituents are light oils, naphthalene, free carbon in too high a proportion, and coal-tar bases. Tar intended for the purpose named should yield on fractionation, not more than 8 per cent. below 230° C., and not less than 30 per cent. between 230° C. and 350° C., and the loss on distillation should be about 3 per cent.—T. St.

Patents.

Mineral oils and tar oils; Process for the separation of the so-called acid tar formed in refining —— *with sulphuric acid.* A. Burkhardt. Ger. Pat. 270,074, May 25, 1912.

The reaction mixture after the treatment with sulphuric acid, is treated directly, or after separation of the acid tar, with a current of an inert gas at the ordinary temperature, until sulphur dioxide is no longer evolved. It is claimed that in this way the acid tar remaining dissolved in the oil can be removed in the cold and without the use of alkali or water, thus avoiding the formation of troublesome emulsions.—A. S.

Polynitro- and polyamino-carbazoles; Manufacture of ——. R. B. Ransford, London. From L. Cassella und Co., G. m. b. H., Frankfort, Germany. Eng. Pat. 7882, April 3, 1913.

See Ger. Pat. 268,173 of 1912; this J., 1914, 193. The nitro compounds can be reduced to the corresponding polyamino compounds by the usual methods.—T. F. B.

IV.—COLOURING MATTERS AND DYES.

Indigo; Solubility of —— *in dimethyl sulphate.* S. J. Peachey. J. Soc. Dyers and Col., 1914, **30**, 84.

Commercial dimethyl sulphate dissolves indigo freely, even in the cold, with production of a deep blue solution from which the indigo is completely precipitated by excess of alcohol. Prolonged heating at 100° C. causes decomposition and the blue solution turns brown. Commercial dimethyl sulphate contains a small quantity of free sulphuric acid which is necessary for its action upon indigo, since the pure reagent does not dissolve the dyestuff until it has been warmed for some time or about 0·5 per cent. of sulphuric acid has been added. No sulphonation in the indigo, however, takes place. A solution of indigo of 80 per cent. sulphuric acid is miscible with dimethyl sulphate, but on the addition of a little water the ester separates as a dark blue oil, removing a considerable portion of the dyestuff from the acid. Certain other vat-dyestuffs dissolve more or less freely in dimethyl sulphate. —J. F. B.

Indigo; Some new derivatives of ——. F. Kunckell. J. prakt. Chem., 1914, **89**, 324—328.

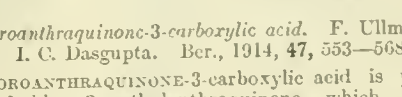
In continuation of previous work (this J., 1912, 1072) the author has succeeded in preparing indigo derivatives by reducing compounds containing a substituted benzene nucleus having a nitro-group and a chloroacetyl residue in the ortho position. 4-Acetamino-*p*-methyl-*o*-chloro-*m*-chloroacetophenone, $C_6H_4(CH_3)Cl(NH.CO.CH_3)(CO.CH_2Cl)$, was prepared by the action of aluminium chloride on a mixture of *m*-chloro-*p*-acetotoluide and chloroacetyl chloride in presence of carbon bisulphide, and was converted into 5-nitro-6-chloroacetyl-3-chloro-*p*-acetotoluide by nitration with fuming nitric acid. The nitro-compound when reduced with zinc and acetic acid on the water-bath yielded 4·4′-dimethyl-6·6′-dichloro-7·7′-diacetaminoindigo, a dark blue compound insoluble in alcohol, ether, benzene, petroleum spirit, and xylene. In a similar manner, 6-chloroacetyl-5-nitro-*m*-bromo-*p*-acetotoluide, obtained by nitration of chloroacetyl-*m*-bromo-*p*-acetotoluide, gave on reduction the dark blue 4·4′-dimethyl-6·6′-dibromo-7·7′-diacetaminoindigo. The latter when dissolved in cold concentrated sulphuric acid and the solution poured into ice water yielded the monosulphonic acid, which dissolved to a blue solution in water, alcohol, ether, and benzene. —A. S.

6′-Aminoquercetin. E. R. Watson. Chem. Soc. Trans., 1914, **105**, 338—349.

6′-Aminoquercetin was obtained by completely methylating quercetin, nitrating, reducing and de-methylating. It dyes on mordants almost the same shades as quercetin. The amino-group could not be converted into a hydroxyl-group by decomposing the diazo compound, although pentamethylquercetin-diazonium chloride combines with β-naphthol to give a crimson azo-compound. The salts of quercetin pentamethylether are intensely yellow coloured substances, which leads the author to assign to them a quinonoid structure (*i.e.*, oxonium salts).—J. B.

Quercetin; Dyestuffs derived from ——. E. R. Watson and K. B. Sen. Chem. Soc. Trans., 1914, **105**, 389—399.

The object of the authors was to obtain from the abundantly occurring quercetin, dyestuffs having deeper shades than the yellows of the parent substance. By the action of magnesium-ethyl iodide on pentaethylquercetin the crimson oxonium salt 3.5.7-triethoxy-2-*m*-*p*-diethoxyphenyl-4-ethyl-1.4-benzopyran anhydroiodide was produced, which on de-ethylating gave a dyestuff having the constitution :—



$$(HO)_2C_6H_2\begin{cases} OI\text{——}C.C_6H_3(OH)_2,H_2O. \\ \qquad\qquad\quad \| \\ (C_2H_5).C(OH) \end{cases}$$

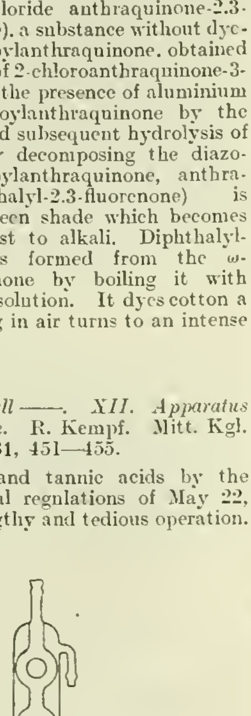
The free base dissolved in caustic potash with a blue colour and dyed a violet on chrome and alum and a crimson on tin mordants. A substance which dyed slaty-blue shades was obtained by condensing quercetin with dimethylaniline in the presence of phosphoryl chloride. It appears to be 3·5-dihydroxy-7-keto-4-*p*-dimethylaminophenyl-2-*m*-*p*-dihydroxyphenyl-1·4-benzopyran.—J. B.

2-Chloroanthraquinone-3-carboxylic acid. F. Ullmann and I. C. Dasgupta. Ber., 1914, **47**, 553—568.

2-Chloroanthraquinone-3-carboxylic acid is prepared from 2-chloro-3-methylanthraquinone, which, together with the more soluble 2.1-derivative is obtained from phthalic anhydride and *o*-chlorotoluene by the Friedel-Craft reaction, by converting it into 3-ω-dibromomethyl-2-chloroanthraquinone by treatment with bromine in nitrobenzene solution, hydrolysing to the aldehyde and oxidising this with sodium bichromate in acetic acid solution. The 2-chloro-3-carboxylic acid when condensed with aniline gives 2-anilinoanthraquinone-3-carboxylic acid, from which by the action of phosphorus pentachloride anthraquinone-2.3-acridone is produced, a substance which dyes cotton a brownish yellow. 2-β-Naphthylaminoanthraquinone-3-carboxylic acid is obtained in an analogous way and it forms an acridone which dyes cotton a greenish-yellow, becoming violet, however, in the presence of alkali. 1′.2-Dianthraquinonylimide-3-carboxylic ester is formed by condensing the ester of 2-chloroanthraquinone-3-carboxylic acid with α-aminoanthraquinone and it undergoes an acridone condensation to give 1.2-anthraquinonyl-2.3-anthracridone (diphthalyl-3.4.6.7-acridone), which dyes cotton a brown shade becoming orange on standing but changed to a violet by alkali. 2-Phenoxyanthraquinone-3-carboxylic acid results when the 2-chloro-3-carboxylic acid is condensed with phenol and from it is obtained by the action of phosphorus pentachloride anthraquinone-2.3-xanthone (phthalyl-2.3-xanthone), a substance without dyeing properties. 2-Chloro-3-benzoylanthraquinone, obtained by condensing the acid chloride of 2-chloroanthraquinone-3-carboxylic acid with benzene in the presence of aluminium chloride, gives 2-amino-3-benzoylanthraquinone by the action of toluenesulphamide and subsequent hydrolysis of the sulphamide-derivative. By decomposing the diazo-compound of 2-amino-3-benzoylanthraquinone, anthraquinone-2.3-fluorenone (phthalyl-2.3-fluorenone) is obtained. It dyes cotton a green shade which becomes on standing a weak yellow fast to alkali. Diphthalyl-4.5.4′.5′-dichloro-2.2′-stilbene is formed from the ω-dibromomethylchloroanthraquinone by boiling it with copper powder in nitrobenzene solution. It dyes cotton a brown shade, which on standing in air turns to an intense yellow not fast to light.—J. B.

Inks; Examination of iron-gall ——. XII. Apparatus for extraction with ethyl acetate. R. Kempf. Mitt. Kgl. Materialprüfungsamt, 1913, 31, 451—455.

The determination of gallic and tannic acids by the method proposed in the official regulations of May 22, 1912 (this J., 1913, 281) is a lengthy and tedious operation. Difficulties are also encountered in hot weather owing to the hydrolysis of the ethyl acetate and consequent extraction of other matters, principally the colouring matter of the ink. An automatic extraction apparatus, now approved, is illustrated in the figure. The liquid to be extracted (10 c.c. of ink and 10 c.c. of 20 per cent. hydrochloric acid) is placed in the cylindrical vessel, *e*, which is provided with a cooling-jacket, *e′*. The flask *a*, of a capacity of about 150 c.c., is charged with 100 c.c. of ethyl acetate which is kept in brisk ebullition. The vapours ascend through the tube, *b*, to the condenser, *c*, and the condensed drops fall into the funnel, *d*, which is connected with a spiral tube standing loosely in the cylindrical vessel. From the rose-shaped bottom of this tube, the solvent ascends in drops through the ink. The spiral form of the tube has the effect of cooling the solvent before it comes in contact with the ink and of presenting a hindrance to the upward passage of the drops through the ink. The extract overflows through the tube, *f*, into the flask, any traces of ink carried over being collected in the small trap in this tube. From time to time samples of the extract standing above the ink are tested in order to see whether the extraction is complete. It has been found that this apparatus performs the extraction four times as rapidly as the shaking method and the results are equivalent. An extraction lasting 1—1¼ hour is amply sufficient to exhaust the ink. —J. F. B.



1.4-*Chloromethylanthraquinone; Unusual behaviour of —— with concentrated nitric acid. Formation of* 1.2-*dihydroxy*-3-*nitro*-4-*methylanthraquinone.* O. Fischer and H. Rebsamen. Ber., 1914, **47**, 461—466.

Twenty grms. of 1.4-chloromethylanthraquinone of m. pt. 164° C., were treated with 160 grms. of nitric acid of sp. gr. 1·52, free from chlorine, added gradually, with shaking and cooling in water. After standing for some hours the mixture was heated for a short time to 60°—70° C., poured into water, and the orange precipitate separated and crystallised from its deep red solution in glacial acetic acid; a yield of 5 grms. of red needles, or leaflets, of m. pt. 217°—218° C. was obtained. The product was easily soluble in ether and alcohol and dissolved in dilute alkalis with violet-blue colour; it was a mordant dyestuff dyeing almost exactly like β-nitroalizarin, and analysis proved it to be 1.2-dihydroxy-3-nitro-4-methylanthraquinone.—G. H. F.

Patents.

Colouring matters; Production of new sulphur —— which dye cotton brown. J. Y. Johnson, London. From Badische Anilin u. Soda Fabrik, Ludwigshafen-on-Rhine, Germany. Eng. Pat. 17,317, July 28, 1913.

Amino- or hydroxy- derivatives of acridines, or their leuco-compounds, for instance, Acridine Yellow (prepared from *m*-toluylenediamine and formaldehyde), are converted into fast brown sulphur dyestuffs by melting with sulphur and sodium sulphide or preferably by melting first with sulphur and subsequently treating with sulphide.—J. B.

1.4-*Di[hydr]oxy*-2-*nitroanthraquinone* [2 *nitroquinizarin*]; *Manufacture of* ——. P. A. Newton, London. From Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. Eng. Pat. 17,780, Aug. 2, 1913.

See Fr. Pat. 461,094 of 1913; this J., 1914, 19.—T. F. B.

V.—FIBRES; TEXTILES; CELLULOSE; PAPER.

Wool: The development of the amido group in ——. M. Fort and L. L. Lloyd. J. Soc. Dyers and Col., 1914, 30, 73—77.

The potassium salt of β-naphthoquinone-4-sulphonic acid condenses with a variety of simple amido compounds with elimination of the sulphonic group, giving coloured products. This compound may be utilised as a colourimetric reagent for the free amido and amino groups developed in wool under various conditions. If wool scoured with benzene or slightly warm, neutral soap solution be boiled with a solution of the quinonesulphonate a faint permanent brown stain is produced, but in the case of wool boiled for a long time with alkaline scouring agents a deeper shade of brown is developed, corresponding to a more advanced condensation with amido groups. Treatment with boiling dilute alkalis increases the reactivity of the wool with the quinonesulphonate and this effect is not appreciably modified by subsequent treatment with warm acetic acid. Treatment with cold strong caustic soda produces some development of amido groups but not to so high a degree as boiling with dilute sodium carbonate. The effect of cold strong sulphuric acid is to suppress free amido groups and wool so treated is not stained by the reagent. A short treatment with a hot mixture of equal parts of sulphuric acid and water, followed by washing, greatly increases the staining capacity of the wool and more dilute solutions of acid produce a similar effect in a less degree. The reaction of wool with potassium naphthoquinonesulphonate is of the same order as with acid dyestuffs and both effects are due to the same cause, except that acid dyestuffs are capable of replacing sulphuric acid combined as an additive salt with the fibre, whereas sulphuric acid in this state partially hinders the condensation with the naphthoquinonesulphonate. The effect of severe steaming or decatising is to increase the staining effect with the reagent. The yellowing or browning of wool under the influence of various agencies appears to be accompanied by the development of free amido groups and long exposure to the action of light has a similar effect.—J. F. B.

Fibres ; Tests of the relative strengths of ——. C. Beadle and H. P. Stevens. J. Soc. Dyers and Col., 1914, **30**, 92—96.

Rope-making fibres generally show a considerable diminution in tensile strength in the wet state, as compared with their strength when dry, increasing with the time of steeping. Experiments with *Hedychium coronarium* in the green state, however, show a tensile strength equal to that of the fibre in the dry state thus : breaking length of fibre-vascular bundles, green plant, 58 kilom.: after extraction and drying, 57—59 kilom. ; after re-wetting for 24 hours, 29 kilom., all values being calculated on dry weights. Some of the measurements recorded for tensile strengths of various fibres are given in the following table :—

Fibre.	Calculated cross-sectional area.	Breaking strain per sq. mm. cross-section.	Breaking length.
	sq. mm.	kilos.	kilom.
Sisal	0·0240	57·3	38·2
Sanseviería (dressed) ..	0·0224	57·5	38·4
Manila (dressed)	0·0181	91·4	60·9
Hedychium (dressed) .	0·0093	89·3	59·1
Cotton	0·00026	31·4	22·8
Cellulose monofil	0·0140	21·0	14·0

—J. F. B.

Ropes and twines : Characteristics and properties of eight foreign fibres used for ——. F. Kœrner. Mitt. kgl. Materialprufungsamt, 1914, **31**, 405—436.

An account of the complete examination of 8 rope-making fibres obtained from foreign and colonial sources. The details of longitudinal and cross-sectional structures are described and the tensile strengths determined on filaments with a space of 20 mm. between the clips. The cross-sectional area of the filaments was calculated from the weight of the filament and the mean sp. gr. of 1·5. Tensile tests were repeated after exposure to the weather for 6 weeks in mid-winter and after immersion in sea water for 72 hours on two occasions, with intermediate drying in the air. The results are summarised in the table below ; the tensile strengths, as compared with that of Russian hemp = 83 kilos. per sq. mm., are relatively low but still practically useful.

Soda cellulose spent lyes ; Recovery of by-products from ——. A. Langlet. Papierfab., 1914, **12**, 212—215.

Further trials on a semi-industrial scale with Rinmann's process for the recovery of by-products from the black lyes (this J., 1912, 183, 279, 532, 812) have been carried out on lyes from the digestion of wood by the soda sulphate process. The hope that the lye could be regenerated to serve for two or three digestions, merely by precipitation and re-causticisation, was not realised, on account of the large proportion of impurities remaining unprecipitated. The lyes from the digester were treated with flue gases at 95°—100° C. and the humic substances precipitated in a sintered condition. The liquid was pressed through an externally cooled screw conveyor into a filter which separated the humic substances in a form containing 60—65 per cent. of dry substance and 7—8 per cent. Na_2O (referred to the dry substance). The humic substances were burnt in the smelting furnace with the addition of sodium sulphate. The filtered lye was concentrated *in vacuo* and mixed with about 1·5 times as much sodium hydroxide as was originally present in the lye and about half the equivalent of powdered lime. The solution was filtered, evaporated in the retort under a pressure of 2·5 atmos. and thrown by a centrifugal distributor on to the externally heated walls of a conical pan from which the dry mass was removed by a scraper. Destructive distillation was completed by passing the mass on through a heated cast-iron pipe. The distillation products (steam, acetone spirit, aldehydes, hydrocarbons) passed first through washers and were then condensed. The soda was recovered by lixiviating the charred residue. Acetone was the most important by-product. On rectification, there were obtained per ton of pulp : 18 kilos. of pure acetone, 27 of motor spirit, 11 of motor oil and 41 of inferior motor oil. These products were valued at about 20s., whilst the extra cost of materials, fuel and plant for obtaining them worked out at about 16s. 6d. per ton of cellulose. Laboratory trials however indicated that the yield of acetone spirit might be increased by 50 per cent. with improved apparatus. The process was hardly practicable with lyes from the sulphate process of digestion and the next trials will be made in Germany on pure caustic soda lyes from the digestion of straw.

—J. F. B.

Celluloid : Absorption of gases by ——. V. Lefebure. Chem. Soc. Trans., 1914, **105**, 328—337.

Films of celluloid absorb considerable quantities of gases, *e.g.*, carbon dioxide diffuses through such films quite rapidly. The effect is relatively specific as it is not shown by gelatin, viscoid, etc. Precipitated celluloid does not absorb much gas. Experiments are in progress on the rate of absorption and the equilibrium attained. Adsorption appears to be an important factor especially in the thinner films : this probably does not occur on the extreme outer surface but at the surfaces of a disperse system lying just below.—H. E. P.

Hedychium paper; Effects of mineral loading on the physical qualities of ——. C. Beadle and H. P. Stevens. J. Soc. Dyers and Col., 1914, **30,** 89—92.

The strength of *Hedychium* papers is largely dependent on the peculiar glutinous qualities of the parenchyma cells and these cells possess extraordinary affinity for the particles of mineral matter, so that papers may be made containing as much as 40—50 per cent. of loading. In the case of the bursting strain per unit substance of paper the diminution is directly proportional to the decrease in percentage of fibre by weight. The diminution of bursting strain per unit volume of paper is also proportional to the decrease in percentage of fibre by volume.—J. F. B.

Paper; Microscopical examination of ——. L. Kollmann. Papierfabr., 1914, **12,** 241—246. (See also this J., 1912, 714.)

Experiments are described for the microscopic identification of the amorphous constituents of papers by staining them with selective dyestuffs and examining them *in situ.* Paper, after removal of the resin with ether, is stained first with a solution of Erganon Violet and subsequently with one of Capri Blue. The violet stain is absorbed by the amorphous particles of precipitated aluminium compounds of the sizing, while the blue is absorbed by the china clay, the two being easily distinguishable. With the correct concentration of the blue dyestuff (about 0·1 per cent.), not too prolonged action of the same and sufficient washing, it is possible to ensure that the fibres remain practically colourless. By drying the prepared specimen and examining after mounting in petroleum spirit, the fibres become more transparent and the stained particles easily visible.—J. F. B.

Patents.

Carbonisable material; Rendering acid-proof ——. G. G. M. Hardingham, London. From The Western Precipitation Co., Los Angeles, Cal., U.S.A. Eng. Pat. 8036, April 5, 1913.

Woven cotton fabric intended for the filtration of furnace gases is rendered proof against the acid contained in and the high temperature of such gases by heating to a high temperature, preferably in a closed vessel. For instance, a few minutes heating at 300° to 350° C. or a treatment for several days at 200° to 250° C. will suffice. Fabrics thus treated, and having lost 68 to 76 per cent. of their original weight, showed tensile strengths of "30 to 85 kilos. per metre" ("originally 2300 kilos. per m."). They resisted boiling sulphuric acid up to strengths of 50 to 64 per cent. The compounds obtained are possibly "pseudo-carbons," comparable with coal and asphaltum. Other carbonisable material than cotton can be used.—J. B.

Textile fibre from Epilobium angustifolium; Production of ——. K. Schumann. Ger. Pat. 269,350, Jan. 6, 1912.

By manuring the growing plants with, for example, ammonium salts, or gas liquor of 1°—2° B. (sp. gr. 1·007—1·014), the seed hairs are rendered stronger, longer and more elastic; and subsequently the surface of the seed hairs is roughened by subjecting them to the action of superheated steam.—A. S.

Concentrating, washing or bleaching cellulose-pulp, etc.; Apparatus for ——. G. Gunn, Heywood. Eng. Pat. 2629, Feb. 1, 1913.

The wet pulp is fed upwards between two revolving cylinders covered with wire cloth, whereby it is drained, and, after passing under a metal roller, it is removed by means of a doctor from the cylinder to which it is adhering, this cylinder being allowed to move transversely, whilst the other remains relatively fixed.—J. B.

Plastic fabric; Treatment of continuous sheets of ——. W. F. Fuller, jun., Fall River, Mass. U.S. Pat. 1,086,762, Feb. 10, 1914.

Dissolved plastic material is made to flow continuously on to a travelling belt on which it is first allowed to become partially solidified by evaporation of the solvent and finally hardened by complete evaporation of the solvent by a current of hot air in a chamber. The solvent is recovered from the air by condensation and the air then reheated and returned to the chamber.—J. B.

Furs, skins, and similar objects; Process for protecting —— against the attacks of moths or other insects or for killing these pests. Act.-Ges. f. Anilinfabr., Treptow, Germany. Eng. Pat. 19,688, Aug. 28, 1912. Under Int. Conv., Oct. 26, 1911.

See Fr. Pat. 442,719 of 1912; this J., 1912, 1026.—T.F.B.

Acetylcellulose; Manufacture of ——. Knoll und Co., Ludwigshafen on Rhine, Germany. Eng. Pat. 2491, Jan. 30, 1913. Under Int. Conv., Feb. 1, 1912.

See Fr. Pat. 453,835 of 1913; this J., 1913, 785.—T. F. B.

Paper suitable for security-cheques; Manufacture of ——. R. C. Menzies and J. E. Aitken, Musselburgh. U.S. Pat. 1,086,386, Feb. 10, 1914.

See Fr. Pat. 439,426 of 1912; this J., 1912, 714.—T. F. B.

VI.—BLEACHING; DYEING; PRINTING; FINISHING.

Bleaching agents; Action of —— on various natural colouring matters. R. L. Taylor. J. Soc. Dyers and Col., 1914, **30,** 85—88. (See also this J., 1912, 429.)

The colouring matter of raw linen cannot be bleached completely by solutions of free chlorine or hypochlorous acid; a hypochlorite must be present. The most rapid and complete bleaching effect is obtained when sufficient alkali is added to neutralise the chlorine or hypochlorous acid, almost but not quite, completely. The colouring matters of linen appear to exist in two varieties, one of which is bleached rapidly by chlorine or hypochlorous acid but very slowly by hypochlorites, whilst the other resists the acid reagents but is bleached by an alkaline hypochlorite. The colouring matters of cotton also exist in two varieties, similarly differentiated. The activity of bleaching liquors upon natural colouring matters therefore cannot be measured by their activity towards simple dyestuffs such as Turkey Red or Indigo. In the latter cases the bleaching activity is directly dependent upon the amount of free chlorine or hypochlorous acid present in the liquor and any agent which increases the degree of acidity would stimulate the bleaching; this is not the case with the bleaching of textile fibres. In both cases an excess of alkali exerts a powerful retarding influence on the bleaching. The author describes experiments which show that the optimum effect is produced when acid is added to the bleach liquor in quantity slightly in excess of that necessary to neutralise the free alkalinity of the solution.—J. F. B.

Sulphur blacks; Process for improving the tone of ——. G. Saget. Sealed note No. 1630, dated May 7, 1906. Report thereon by T. Stricker. Bull. Soc. Ind. Mulhouse, 1913, **83,** 803—804.

The difficulty of the bronzing of sulphur blacks is overcome by after-treating with a cold solution containing 15 c.c. of acetate of alumina of 16° B. (sp. gr. 1·125) per litre, rinsing, squeezing, padding with a 10 per cent. solution of Turkey red oil and drying without washing. The report states that this method gives a much better result than the usual one of simply oiling after dyeing.—J. B.

Para-red; A method of preventing the oxidation of the β-naphthol in dyeing ——. G. Saget. Sealed Note No. 1400, dated July 1, 1903. Report thereon by F. Binder. Bull. Soc. Ind. Mulhouse, 1913, **83**, 801—803.

The addition to the padding liquor of 10 per cent. of sodium sulphite crystals on the weight of the β-naphthol enables the pieces to be kept several days without becoming discoloured.—J. B.

Logwood Black; Production of —— applicable to silk, wool or cotton by direct oxidation on the fibre. A. Romann. Sealed Note No. 702, dated Oct. 4, 1892. Report thereon by J. Zubelen. Bull. Soc. Ind. Mulhouse, 1913, **83**, 807—808.

Logwood extract is printed directly on to the material which is then steamed for 30 seconds, and passed into a bath of bichromate, with or without the addition of ammonia, at 50° C. The white is cleared by means of bisulphite. The report states that the process gives good results on cotton and silk, but not on wool.—J. B.

Indigo discharges with the aid of bromine compounds. M. Freiberger. Sealed Notes Nos. 714 and 715, dated Dec. 19, 1892, and 1780 of Nov. 11, 1907. Bull. Soc. Ind. Mulhouse, 1913, **83**, 811—814.

Ammonium bromide is used in conjunction with chlorates (of aluminium, barium, etc.) and an agent to promote the oxidation, *e.g.*, chromium hydroxide, ferric chloride or copper salts. It can also be used in conjunction with the very active aluminium chlorate and sodium bichromate mixture, where it acts in preventing the burning of the piece during drying. This chromate discharge is greatly improved by the addition of lead sulphide and barium sulphate to the mixture, the colours being rendered more stable and the rollers less liable to attack. Lead sulphate is formed on steaming.—J. B.

Drying pieces after printing. Koechlin Frères. Sealed Note No. 726, dated March 22, 1893. Report thereon by L. Bloch. Bull. Soc. Ind. Mulhouse, 1913, **83**, 809—810.

The method of drying consists in presenting, during as great a part as possible of the passage of the piece through the hot flue, the printed side of the cloth to the heated surface. This constituted a reversal of contemporary practice, and had for its object the securing of clearer prints by a rapid drying of the surface of the colour, thus preventing running.—J. B.

Patents.

Dyeing of hair. C. Monnet. Fr. Pat. 462,577, Nov. 25, 1912.

The diamines used for dyeing are applied simultaneously with soap, thus avoiding intimate contact with, and their fixation on, the living tissue, and permitting the rapid removal of excess of colouring matter by washing with water.—B. N.

Dyeing of fur and hair. Act.-Ges. für Anilin-Fabrikation. Fr. Pat. 462,824, Sept. 20, 1913. Under Int. Conv., Dec. 11, 1912 and March 22, 1913.

The fur or hair is dyed with a mixture comprising an aromatic *m*- or *p*-diamine or a derivative thereof, *e.g.*, *p*-phenylenediamine, *p*-toluylenediamine, *p*-aminodimethylaniline, *p*-aminodiethylaniline, *p*-diaminodiphenylamine, *m*-toluylenediamine, with an aromatic dihydroxy compound, such as resorcinol, pyrocatechol, 1-methyl-3.5-dihydroxybenzene, dihydroxynaphthalene, etc., and an appropriate oxidising agent, such as hydrogen peroxide. —B. N.

Prints; Production of fast coloured ——. H. Levinstein and Levinstein Ltd., Manchester. Eng. Pat. 3427, Feb. 10, 1913.

A non-substantive dyestuff containing resorcinol as a component is printed together with a thickening agent and formaldehyde, or a substance capable of liberating formaldehyde when heated, such as, for example, hexamethylenetetramine. After steaming, shades are obtained which are fast to boiling soap solution. The mono-azo dyestuff from 2-amino-5-naphthol-7-sulphonic acid and resorcinol gives a brown, that from *p*-aminoacetanilide gives an orange shade.—J. B.

Printing sarees, scarves, shawls, etc.; Machines for ——. The Calico Printers' Association Ltd., Manchester, and J. Muir, Glasgow. Eng. Pat. 5278, March 3, 1913.

An improved mechanism for automatically arresting and re-starting in correct register the tappets and their tappet shafts in machines for intermittent printing, particularly such as are described in Eng. Pats. 22,678 of 1902, 25,088 of 1903 and 27,668 of 1907 (this J., 1904, 933).—J. B.

Flame-extinguishing material [for fibres and fabrics]. Fire-extinguishing compound. J. W. Aylsworth, East Orange, N.J., Assignor to Condensite Co. of America, Glen Ridge, N.J. U.S. Pats. 1,085,783 and 1,085,784, Feb. 3, 1914.

(1). Fibres or fabrics are impregnated with a solution in water of a higher halogen substitution product of a phenol and then treated to precipitate the body in an insoluble form, the material being thus rendered non-inflammable and water-repellent. (2). An aqueous solution of an alkali salt of a higher halogen substitution product of a phenol or an organic acid, capable of producing flame-extinguishing vapours at a temperature of from 400° to 700° F. (204° to 371° C.), together with a mineral salt having combustion-retarding properties.—H. H.

Fabrics incombustible and fire-resisting; Rendering ——. L. Böhler. Fr. Pat. 456,589, Feb. 20, 1913.

Tissues of all kinds are treated in a solution of alum, squeezed, dried, then soaked in a solution of ammonium sulphate and finally dried slowly.—J. B.

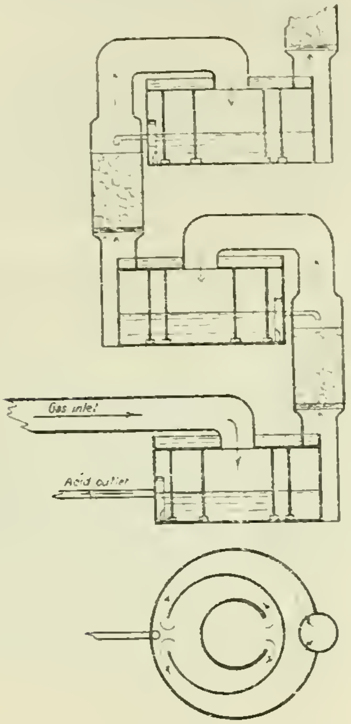
VII.—ACIDS; ALKALIS; SALTS; NON-METALLIC ELEMENTS.

Sicilian sulphur trade. Chem. Trade J., March 7, 1914. [T.R.]

According to the official report of the Compulsory Sicilian Sulphur Combine for the seventh working year from August 1, 1912, to July 31, 1913, the total production of sulphur in Sicily was 351,752 tons, against 366,457 tons in 1911—12 and 391,908 in 1910—11. The failure to reach a normal production of 400,000 tons is again attributed to the general conditions and to the closing, in 1913, of 7 mines in addition to the 16 mines closed in 1912. The total sales during 1912—13, including sales for future delivery, amounted to 497,246 tons, against 603,255 tons in 1911—12 and 816,818 tons in 1910—11. The total exports declined from 447,638 tons in 1911—12 to 434,473 tons in 1912—13. The most striking decline in the exports is that to France, which has always imported the largest quantity, and which took 32,970 tons less than during the preceding year. This decline is believed to be due to the establishment by the Union Sulphur Company of large refineries in that country. On the other hand, the exports to Germany increased by 6,222 tons, to Norway by 5,278 tons, to Russia by 4,520 tons, to Turkey by 4,352 tons, and to Sweden by 3,422 tons. The exports to the United States further declined from 7,125 tons in 1912 to 1,792 tons in 1913.

Hydrochloric acid; New apparatus for the condensation of ——. H. Friedrich. Chem. Apparatur, 1914, **1**, 38—39.

The apparatus comprises a combination of "tourilles" and absorption towers, extending in a vertical direction so as to economise ground space: for a daily output of 5000 kilos. of saltcake, the whole of the condensing plant does not require more than 4 sq. m. of ground space. The "tourilles" (see Fig.) consist of cylindrical vessels, 120 cm. diam. by 50 cm. high, filled with the absorbing liquid



to a height of 20 cm., and each having a layer (10 cm. high) of cooling water on the cover. Inside each "tourille" are 2 cylindrical partitions, with vertical slits on opposite sides, to cause the gas to take a tortuous path. The "tourilles" are connected by short towers with stoneware packing, over which the absorbing liquid trickles in passing from one "tourille" to the next lower one.—A. S.

Perchromic acid; Preparation of blue ——. Higher oxidation products of chromium. VI. E. H. Riesenfeld and W. Mau. Ber., 1914, **47**, 548—553.

PERCHROMIC acid was obtained as a dark blue crystalline mass by the oxidation of chromic anhydride, dissolved in methylic ether, with 97 per cent. hydrogen peroxide at —30° C. The composition of the acid was independent of the amount of peroxide used; the ratio of active oxygen : Cr : H_2O was 3·44 : 1 : 3·45, as compared with 3·5 : 1 : 3·5 required for $H_3CrO_8,2H_2O$. The water is not regarded as merely water of crystallisation, but of constitution, as expressed by the suggested formula, $Cr(OH)_4(O.OH)_3$. The acid decomposes at temperatures above —30° C.; it appears to be of about the same strength as acetic acid. —G. F. M.

Nickel sulphide and cobalt sulphide. A. Thiel and H. Gessner. Z. anorg. Chem., 1914, **86**, 1—57.

EXPERIMENTS in an atmosphere of nitrogen in a special apparatus showed that the anomalous behaviour of nickel sulphide to dilute mineral acids is due to its existence in three forms. The α-modification is dissolved by strong mineral acids of 0·01 *N* concentration and upwards, and is easily oxidised; glacial acetic acid rapidly, or water slowly, converts it into the β-modification, soluble in hot 2 *N* hydrochloric acid, and the γ-modification, soluble only with the aid of oxidising agents. The β- and γ-sulphides are formed chiefly or exclusively on precipitation from very dilute solutions; from hot, strongly acid solutions the γ-modification is formed, while all three occur in the precipitate obtained in ordinary analysis. The fall in solubility of fresh precipitates on exposure to air is due to the oxidation of the sulphide to compounds soluble with difficulty, and conversion of these by the hydrogen sulphide present to β-or γ-sulphides. The three modifications are polymerides, of which the first is amorphous, and the other two of different crystalline form. An apparently true equilibrium is reached with dilute hydrochloric acid and β- or γ-sulphide, but not on starting from a nickel salt and hydrogen sulphide.—O. E. M.

Bromination of manganese in ethereal medium. F. Ducelliez and A. Raynaud. Comptes rend., 1914, **158**, 576—578.

MANGANESE did not unite with dry bromine at the ordinary temperature, but in presence of anhydrous ether, two compounds, $MnBr_2.(C_2H_5)_2O$ and $MnBr_2.3(C_2H_5)_2O$, were obtained. The former, a deliquescent crystalline substance, yielded manganous bromide on heating.—F. SODN.

Gases; Influence of colloids and fine suspensions on the solubility of —— in water. IV. Solubility of nitrous oxide at pressures lower than atmospheric. A. Findlay and O. R. Howell. Chem. Soc. Trans. 1914, **105**, 291—298.

FROM the present results and those obtained previously (this J., 1910, 350) complete solubility curves for nitrous oxide in water in presence of colloids have been plotted for pressures varying from 250 to 1400 mm. of mercury. In all cases there was a minimum, well marked with solutions of gelatin, dextrin, and ferric hydroxide, but shallow with silicic acid solutions. (Cp. the solubility of carbon dioxide, this J., 1913, 486.) In starch solutions also distinct indications of a minimum solubility were obtained, though this was not observed in the case of the solubility of carbon dioxide. The solubilities obtained with suspensions of silica did not appreciably differ from those in pure water. With charcoal suspensions an ascending solubility curve was obtained throughout the whole range of pressures employed.—G. F. M.

Chlorine water; Decomposition of —— in the light. J. Milbauer. Z. physik. Chem., 1914, **86**, 564—566.

EXPERIMENTS with a considerable number of substances, showed that none of them, with the exception of bromine, notably accelerated the photochemical decomposition of chlorine water, when added thereto in small quantity (0·001 grm. per 10 c.c.). Mixtures of chlorine water and bromine water in all proportions decomposed more rapidly on exposure to light than either of the pure solutions. —A. S.

Formates; Decomposition of —— in relation to the technical production of hydrogen. M. G. Levi and A. Piva. Annali Chim. Appl., 1914, **1**, 1—24.

ONE of the processes proposed for the technical production of hydrogen from water-gas consists in passing the latter, together with steam, over lime heated to about 500° C., when, it is stated, hydrogen is produced according to the equation: $CaO+CO+H_2O=CaCO_3+H_2$. In view of the known analogous reactions with alkali hydroxides, the reaction may be regarded as proceeding in two stages, with intermediate formation of calcium formate:—

$$2CO+CaO+H_2O=(HCOO)_2Ca;$$
$$(HCOO)_2Ca=CaCO_3+CO+H_2.$$

The authors have studied the decomposition of anhydrous sodium and calcium formates by heat. In an atmosphere of nitrogen, decomposition of sodium formate began at 300°—310° C. and became vigorous at 400° C. Between 330° and 600° C. the gases produced consisted of carbon monoxide (22·9—40·2 per cent.) and hydrogen (53·4—77·1 per cent.), with a small proportion of carbon dioxide increasing with the temperature (up to 6·4 per cent.). The yield of hydrogen was highest at the lower temperatures (330°—370° C.). The residue consisted of carbonate and oxalate, the latter predominating at temperatures up to about 500° C., and a small quantity of carbonaceous matter, increasing with the temperature. Small quantities of condensable volatile products were also formed. Calcium formate in an atmosphere of nitrogen showed appreciable decomposition at 400°—410° C. and decomposed vigorously at 550° C. Larger quantities of volatile condensable products were formed, the gases contained more carbon dioxide and also notable quantities of methane, increasing with the temperature up to about 500° C. In an atmosphere of carbon monoxide, larger quantities of carbon dioxide were produced from sodium formate than in an atmosphere of nitrogen, and methane was also formed, whilst from both formates the yield of hydrogen was less. The gases were in all cases tested for unsaturated hydrocarbons by means of bromine water and fuming sulphuric acid, and with both reagents, a small diminution of volume occurred, but similar results were obtained in control experiments with test mixtures of pure carbon monoxide and nitrogen.—A. S.

Nitrogen: Oxidation of —— under the influence of the electric discharge. II. Activation of nitrogen and oxygen by the direct current arc. A. Koenig and E. Elöd. Ber., 1914, **47**, 516—522. (See also this J., 1913, 82, 194 and 288).

The experiments described show that nitrogen and oxygen can actually combine outside the path of the discharge at relatively low temperatures to give appreciable quantities of nitrogen peroxide. This points to an activation of one or both of the gases, the activity being retained after the gas has been removed from the effect of the discharge. (See also following abstract.)—W. H. P.

Nitrogen: The after-glow of ——. A. Koenig and E. Elöd. Ber., 1914, **47**, 523—529.

The after-glow in nitrogen will take place even after the most thorough removal of all traces of oxygen, provided that the gas is also free from metallic vapours (*e.g.*, mercury) (see Tiede and Domcke, this J., 1914, 76 and 254). A small trace of mercury vapour extinguishes the after-glow, but the addition of a little oxygen by oxidising the metal restores it, while a further addition of oxygen weakens and finally again extinguishes it. In experiments with Tiede and Domcke's apparatus the pump and the manometer were sufficient to provide the mercury vapour to extinguish the discharge if no oxygen was present. The authors' conclusions are strengthened by spectroscopic observations of the discharge.—W. H. P.

Nitrogen; Phenomena exhibited by highly rarefied ——. J. de Kowalski. Comptes rend., 1914, **158**, 625—627. (Compare this J., 1914, 76, 254; also preceding abstract.)

A repetition of Strutt's work on the production of "active nitrogen" has yielded results in agreement therewith, notwithstanding that the gas was carefully purified, with a special view to the elimination of the last traces of oxygen, by the methods of Rayleigh and Gehlhoff (see this J., 1911, 683). At pressures below 5×10^{-4} mm. and under the influence of an intense electric field a previously unnoticed preliminary phenomenon was remarked upon breaking the current: numerous minute explosions accompanied by an intense violet luminescence were visible for a brief period, after which the characteristic orange glow of the "active nitrogen" alone remained. The violet light gave the mercury spectrum, and the author attributes the phenomenon to the presence of an explosive nitride of mercury, the formation of which is due to the action of "active nitrogen" upon traces of mercury from the vacuum pump.—J. R.

Determination of free caustic alkali in commercial soda compounds and soaps by the barium chloride method. Kling and others. *See* XII.

Detection and determination of nitrates by means of diphenylbenzidine. Marqueyrol and Muraour. *See* XXIII.

Erratum.

This Journal, March 16, 1914, page 254, col. 1, lines 22 and 23 from the bottom should be transposed.

Patents.

Nitric acid; Process and apparatus for the manufacture of highly concentrated or of monohydrated ——. Verein Chemischer Fabriken in Mannheim. Fr. Pat. 462,290, Sept. 8, 1913. Under Int. Conv., Sept. 16, 1912.

Mixed nitric and sulphuric acids flow in a continuous stream (preferably not more than 3—4 cm. deep) through a still, in which a current of air or analogous gas passes over the mixture so as to carry the volatilised nitric acid towards the vapour exit. The still described is circular and very shallow; it is heated at the bottom only, and the mixed acids, introduced through a central pipe, are made to follow a protracted path by directing walls attached to the bottom plate. Dry air enters from an annular space near the periphery of the still, formed by a depending apron reaching to the surface of the acid, and passes out through the still head.—F. Sodn.

Nitric acid; Manufacture of —— from calcium nitrate. Traine und Hellmers, H. Weyer, and F. Brandenburg. Ger. Pat. 269,656, Oct. 22, 1912.

In the manufacture of nitric acid by igniting calcium nitrate and treating the resulting nitrous fumes with moist oxygen or air, an inert refractory substance such as burnt lime is added to the calcium nitrate before or during decomposition. The lime is added in such quantity that the fused calcium nitrate is absorbed by or envelops the pieces of lime; it can then be readily kept in motion by the stirring apparatus and does not remain in contact with the heating surface and form a crust thereon.—A. S.

Acid vapours; Apparatus for the condensation of [nitric and hydrochloric] ——. E. Leblanc. Fr. Pat. 462,712, Sept. 17, 1913.

Internal cooling of condensing plant is secured by arranging within the apparatus groups of tubes of glass or other acid-resisting material, so supported that the acid vapours may circulate around them. Each tube encloses an inner metal tube reaching almost to its lower end which is closed, the inner tube serving for the introduction of water which passes up the outer tube and thence to another member of the group. The upper ends of the tubes and the connecting pieces are exposed.—F. Sodn.

Atomiser for lead [sulphuric acid] chambers. J. Parent. Fr. Pat. 462,349, Aug. 1, 1913.

A channel, oblique to the axis, leads from the feed tube to the central passage of the atomiser, so that, when liquid is forced through under pressure, a very rapid rotary motion is acquired and a powerful spreading effect produced at the bowl-shaped nozzle.—F. Sodn.

Sulphuric acid; Construction for lead chambers in the manufacture of ——. Z. Littman. Fr. Pat. 462,668, Sept. 5, 1913.

The roofs are step-like in construction so that the height of the chamber diminishes in the direction of flow of the gases; also the end chambers are divided by diagonal partitions into compartments (communicating with each other) of decreasing section from entry to exit of the gases. In the principal chamber the cooling effect is increased by valved pipes above the roof, connecting the steps one with another, and a secondary system of gas passages (also valved) connects the floor of the principal chamber with the roofs of subsequent chambers, without disturbing the principal gas circulation.—F. Sodn.

Pyrites; Method of roasting —— whereby the accompanying metals, such as copper, zinc, and lead, are converted into sulphates. C. P. Debuch. Ger. Pat. 269,774, July 26, 1912.

Instead of the pyrites being transferred as usual from the first hearth to the second, from the second to the third, and so on, a portion is transferred from the first hearth to the third, from the second to the fourth, and so on. In this way the quantity of sulphur burnt per unit of time on each hearth, and hence the temperature, is diminished, whilst at the same time the material transferred carries with it sufficient heat to ensure the continuation and completion of the roasting of the partially roasted material. It is stated that by this means efficient oxidation of the pyrites and simultaneous conversion of the copper, zinc and lead into sulphates are attained. A similar result can be obtained by mixing inert material (*e.g.* pyrites cinder) with the raw pyrites.—A. S.

Waste [sulphuric] acid and acid effluents from tin-plate works and the like; Treatment of ——. F. A. Anderson, Newcastle-on-Tyne. Eng. Pat. 3505, Feb. 11, 1913.

The acid effluent is treated with excess of cream or milk of lime, thoroughly agitated for 2—3 hours, and the precipitate, containing ferrous hydroxide, calcium sulphate, and a little calcium hydroxide, settled, collected, and pumped into filter-presses. The resulting cakes are stored for a few days, until the ferrous hydroxide has been completely oxidised, and are then used for coal-gas purification or plaster of Paris manufacture, according as ferric hydroxide or calcium sulphate is the predominating constituent.—O. R.

Barytes from ores; Method of separating ——. C. J. Greenstreet, St. Louis, U.S.A. Eng. Pat. 16,273, July 15, 1913.

See U.S. Pat. 1,069,545 of 1913; this J., 1913, 871. Sodium chloride may be replaced by potassium, magnesium, calcium, strontium, or barium chloride, sodium, magnesium, or potassium sulphate, or potassium or sodium bisulphate.—T. F. B.

Chalk; Process of manufacture of [precipitated] ——. L. Negro. Fr. Pat. 462,329, June 21, 1913.

Gases produced during lime burning are passed, after purification, into milk of lime (made from the quicklime or lime residues), and the resulting calcium carbonate is filtered off and dried.—F. Sodn.

Alkali and alkaline-earth chlorides; Means for the electrolysis of ——. A. Clemm, Mannheim, Germany. Eng. Pat. 21,462, Sept. 23, 1913. Under Int. Conv. Dec. 3, 1912.

In the electrolysis of alkali and alkaline-earth chloride solutions by processes using vertical diaphragms and circulating electrolytes, a powder, such as barium sulphate, which is proof against chlorine, hydrochloric acid, and caustic alkali, is interposed in the diaphragms between an alkali-resisting material, such as asbestos fabric on the cathode side, and an arrangement of acid- and chlorine-resisting material, such as glass, ebonite, stoneware, or the like, on the anode side. With such diaphragm arrangement, high yields of concentrated hydroxide lyes and very high current efficiency can be obtained.—O. R.

Aluminium nitride; Process and electric furnace for the manufacture of ——. G. Coutagne. Fr. Pat. 462,462, Nov. 22, 1912.

A mixture of carbon and alumina (or material containing alumina, such as bauxite), travelling slowly through a furnace, is heated, in one zone, to a temperature (not necessarily uniform) sufficiently high to reduce the alumina more or less completely, whilst nitrogen (as producer gas, for example) slowly passes in the opposite direction, so as to meet the deoxidised material beyond the zone of irregular temperature. The process may be carried out in a vertical tubular furnace, of which the carbon lining constitutes one electrode; the second electrode is suspended axially, and the surrounding space is filled with the material to be treated, this being heated directly by the passage of a low-tension current

—F. Sodn.

Ammonia; Process of synthesis of —— by means of carbon. A. Serret. Fr. Pat. 462,683, Nov. 27, 1912.

A mixture of nitrogen, hydrocarbons, and steam is brought into contact with alkalinised carbon ["charbon alcalinisé"], at a temperature ensuring the formation of ammonia from the nascent hydrogen produced, but below that at which ammonia is decomposed.—F. Sodn.

Salt similar to light cooking salt; Production of —— from fused sodium chloride. G. Bergen and L. Stolz. Ger. Pat. 269,427, Dec. 10, 1912.

Compressed air or other gas or steam is blown into the molten salt, and after solidification of the salt the blowing is continued to cool the solid salt.—A. S.

Chlorides of the rare earths; Preparation of anhydrous —— free from oxychlorides. Deutsche Gasglühlicht A.-G. (Auerges.). Ger. Pat. 268,827, Nov. 24, 1912.

A mixture of anhydrous chloride and oxychloride, obtained by heating the hydrous chloride to a high temperature, is treated with alcohol, the solution separated from the insoluble residue containing the oxychloride, and the anhydrous chloride recovered by evaporating the solution. In order to free it from traces of organic matter, it is heated in a current of hot dry air.—A. S.

Mesothorium and radium; Separation of salts of —— in the extraction of thorium from minerals containing it. K. Schwab. Ger. Pat. 269,541, April 23, 1911.

Barium salts are added to the concentrated sulphuric acid used for decomposing the mineral (*e.g.* monazite sand), the reaction product is worked into a sludge with water, and is then treated with a large quantity of water to which has been added a quantity of barium salts sufficient to ensure the complete retention of radioactive substances in the insoluble residue. It is stated that without this second addition of barium salts, up to 60 per cent. of the radium and mesothorium may pass into solution, barium-radium mesothorium sulphate being considerably more soluble in dilute solutions of cerium and didymium salts than in water.—A.S.

Radiothorium or substances containing it; Process for obtaining —— for the preparation of solutions containing thorium X. Deutsche Gasglühlicht A.-G. (Auerges.). Ger. Pat. 269,692, March 22, 1912.

The solution of the material freed as far as possible from impurities, especially barium, calcium, iron, lead, phosphoric acid, and if practicable, cerite earths, is treated with pure ammonia, the precipitate washed, dissolved in dilute nitric acid, evaporated to dryness to expel the excess of acid, the residue dissolved in distilled water, and the solution treated with excess of pure ammonia. The precipitated hydroxides, containing radiothorium, are evaporated to dryness together with the solution of ammonium salts, and the ammonium salts are removed from the residue by repeated washing with distilled water or a dilute solution of sodium chloride free from carbon dioxide. For the preparation of solutions containing thorium X, the residue obtained as described above is left in contact with pure distilled water or a dilute solution of sodium chloride free from carbon dioxide until a sufficient quantity of thorium X has passed into solution.

—A. S.

Aluminium sulphite; Oxidation of —— to aluminium sulphate by means of air. C. A. Beringer. Ger. Pat. 269,794, Feb. 11, 1913.

The aluminium sulphite solution is treated with air under a high pressure (5 atmospheres) and at a high temperature (130° C.), whereby a quantitative yield of aluminium sulphate is stated to be obtained.—A. S.

Peroxide of hydrogen; Compound for making ——. C. B. Jacobs, Port Chester, N.Y. U.S. Pat. 1,076,039, Oct. 21, 1913.

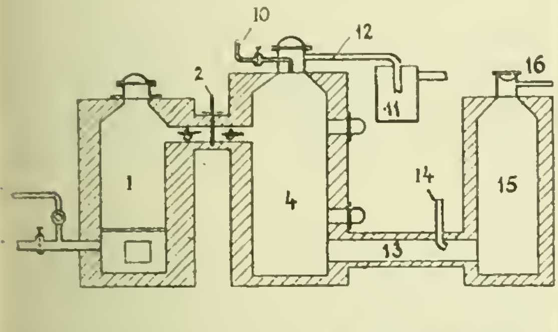
An anhydrous peroxide salt of an alkali metal, especially metaborate of sodium peroxide, made by adding sodium peroxide to a solution of metaboric acid at 5°—10° C., crystallising at 0° C., and dehydrating over sulphuric acid. The compounds are quite stable and may be made up into tablets, suitable for preparing, with water, alkaline non-caustic solutions of hydrogen peroxide, of known strength, for medicinal and other purposes.—F. Sodn.

Bromine; Process for the recovery of ——. A. E. Schaefer, Saginaw, Mich. U.S. Pat. 1,085,914, Feb. 3, 1914.

A solution of ferrous bromide is brought into contact with gases containing bromine, and the resulting ferric bromide solution, after reduction by metallic iron, is again exposed to the gases, the process being continued until a solution of desired strength is obtained.—F. Sodn.

Hydrogen from iron and steam; Process for the production of ——. A. Messerschmitt. Fr. Pat. 461,623, Aug. 4, 1913.

The contact mass of iron, is heated, directly or indirectly, by means of a gas of low calorific value, whilst reduction takes place with a gas of high calorific power. In this way reduction is completely and rapidly effected, whilst overheating of the contact mass in the other stages of the operation is avoided. Thus, in the first or heating stage, a gas of low calorific value passes from the producer, 1, into the contact chamber, 4, into which a current of air is simultaneously directed through the conduit, 10, the hot gases traversing the contact mass downwards, and escaping by way of the conduit, 13, into the superheater, 15. In the reducing phase, steam is admitted into the producer to form a gas rich in carbon monoxide and hydrogen, which, following the same course as in the first stage, reduces the contact mass, and is burnt in the superheater, with the help of air admitted through the conduit, 14. In the oxidising phase, the damper, 2, is closed, and steam, admitted by way of the conduit, 16, passes through the superheater, 15, into the contact chambor, 4. The hydrogen, which is generated, passes through the conduit, 12, into the collector, 11. When several reaction chambers are employed, one set can be employed as superheaters for the other set, the gases, escaping from the first set in the reducing phase, being mixed with air and burnt in contact with the reaction masses contained in the second set, and then reversed, after the first set have passed through the oxidising stage.—O. R.



Hydrogen; Process for the preparation of —— *by the alternate oxidation and reduction of a contact mass containing spongy iron, by means of steam and a reducing flame.* A. Messerschmitt. Fr. Pat. 461,624, Aug. 4, 1913.

The simultaneous heating and reduction of the contact mass is effected by mixing a certain amount of air with the reducing gases, and burning a definite proportion of the latter in a preliminary mixing chamber, before passing the excess of reducing gases and products of combustion into the reaction chamber. The composition of the mixture, and the temperature at which it is admitted to the contact mass, are kept as constant as possible, and the gases issuing from the reaction chamber are mixed with an excess of air and completely burnt in a regenerator, the reaction chamber being preferably annular in form and the regenerator disposed inside it. Using a pair of such appliances, the gases are passed first in one direction and then reversed, the regenerator of one system after one operation serving to pre-heat the mixture of air and reducing gases before these enter the mixing chamber of the second system for the next operation. The mixing chamber may take the form of an annular space outside and near the bottom of the reaction chamber, or the regenerator of one system may at the same time act as preliminary mixing chamber for the twin system.—O. R.

Hydrogen; Process for the production of —— *by means of hydrocarbons and steam.* Badische Anilin und Soda Fabrik. Fr. Pat. 463,114, Sept. 30, 1913. Under Int. Conv., Nov. 30, 1912.

A mixture of hydrocarbons and steam is passed over an inactive, refractory oxide, such as magnesia, which is covered with a catalyst, such as nickel or a nickel oxide, and heated above a dark red heat, say to 800°—1000° C. The resulting gaseous mixture is freed from carbon monoxide and dioxide, leaving substantially pure hydrogen, suitable for the catalytic production of ammonia.
—O. R.

Oxygen; Process for preparing ——, *especially for baths, from peroxides or per-salts, by catalytic decomposition.* F. Michel. Ger. Pat. 269,852, Oct. 26, 1912.

The decomposition of the peroxides or per-salts is effected by compounds of elements of the chromium group, such as molybdenum, tungsten, uranium, chromium, and vanadium, in combination with iodine-compounds. It is stated that the action of the two classes of compounds used together is many times more powerful than that of the components. The method may be applied to the decomposition of residual peroxides, in bleaching works, etc., in cases where the usual reagents, such as permanganate, cannot be used.—A. S.

Nitric acid; Manufacture of —— *from nitrates and sulphuric acid.* C. Uebel. Heidelberg, Germany. Eng. Pat. 19,881, Sept. 2, 1913. Under Int. Conv., March 11, 1913.

See Fr. Pat. 461,452 of 1913; this J., 1914, 200.—T. F. B.

Iron in liquids; Process for the oxidation and separation of ——. Bayerische A.-G. f. Chemische und Landwirthschaftlich-Chemische Fabrikate, H. Hackl, and H. Bunzel, Heufeld, Upper Bavaria. Eng. Pat. 4371, Feb. 20, 1913. Under Int. Conv., June 25, 1912.

See Fr. Pat. 459,576 of 1913; this J., 1913, 1156.—T. F. B.

Nitrides such as that of aluminium; Process for the manufacture of ——. Soc. Générale des Nitrures, Paris. Eng. Pat. 11,091, May 10, 1913. Under Int. Conv., May 13, 1912.

See Fr. Pat. 457,723 of 1913; this J., 1913, 1010.—T. F. B.

Process for the execution of chemical reactions. Fr. Pat. 462,464. *See* I.

Element for the electrolysis of water. Fr. Pat. 462,394. *See* XI.

VIII.—GLASS; CERAMICS.

Clays and kaolins; Causes of plasticity and allied properties of ——. P. Rohland. Silikat-Zeits., 1914, 2, 30—33.

The author contends, in opposition to the views of Brown and Montgomery (Technol. Paper, Bureau of Standards, Washington, 1913), that all clays lose their plasticity when heated to a temperature at which combined water begins to be evolved (590—620 C.). Above about 950° C., when the combined water has been driven off, the amount of heat absorbed by clays corresponds with the contraction, which increases progressively with the temperature, well-defined contraction taking place only in the cases of substances of marked colloidal nature. The plasticity, however, is dependent not on the combined water, but on the free water, which develops the colloidal properties latent in air-dry clays. The contraction on drying of clays is also a function of their colloidal nature, and therefore of their plasticity, this contraction not taking place with crystalloids. In many cases the colloids of clays are of organic nature, but some clays, which contain practically no organic matter, owe their plasticity to the formation of the colloidal hydroxides of aluminium, silicon, or iron, when the clays are brought into contact with water. The well known effects of caustic alkalis on the plasticity, not only of clays, but also of cements, trass, zeolites, and the like, are due to the development of colloidal properties by hydroxyl ions, every substance of a plastic nature requiring a definite concentration of hydroxyl ions to produce the maximum proportion of colloidal constituents.—O. R.

Leadless glazes in commerce. L. Petrik. Sprechsaal, 1914, **47**, 147—148.

Further work on the lead problem for the Hungarian Ministry of Commerce (see this J., 1914, 80) has comprised the examination of powders sold for the production of leadless glazes. A sample proved on analysis to have the molecular formula : 0·26 BaO, 0·23 CaO, 0·14 K_2O, 0·36 Na_2O, 0·04 Al_2O_3, 2·15 SiO_2, 0·5 B_2O_3. Its barium oxide content was 14·78 per cent., all of which was found soluble by the official test which approximates to the conditions of digestion (*loc. cit.*). The author points out that barium is as poisonous as lead.—H. H. S.

Patents.

China-clay ; Apparatus for washing and separating ——. W. J. Gee, London, and M. Coulson and Co., Ltd., Spennymoor. Eng. Pat. 5442, Mar. 4, 1913.

The material is fed together with a suitable supply of water into an inclined, rotary cylinder provided with spiral ribs. Light material is washed down by the current of water, whilst heavier and coarser particles are caught by the ribs and conveyed in the reverse direction. A trough extends centrally through the cylinder, and an endless conveyor belt, fitted with prongs or scrapers, continuously delivers raw material from a feeding hopper into the trough, subjecting it at the same time to a raking and disintegrating action. The bottom of the trough is formed of removable plates, one or more of which may be removed at any point at which it is desired to discharge the raw material into the cylinder.—O. R.

Enamels, particularly zircon enamels ; Clouding agent for the manufacture of white ——. Vereinigte Chem. Fabr. Landau, Kreidl, Heller und Co. Fr. Pat. 462,587, Sept. 16, 1913. Under Int. Conv., Oct. 1, 1912.

A clouding agent, consisting of an alkali metal salt, especially a zirconate, to which has been added an acid possessing a weak capacity for electrolytic dissociation, especially an organic acid, which is eliminated on heating. —O. R.

IX.—BUILDING MATERIALS.

Wood ; Preservation of ——. A. J. Wallis-Tayler. J. Roy. Soc. Arts. 1914, **62**, 286—315.

Wood should be seasoned for at least 6—12 months before treatment. (1). *Kyanising* consists in steeping timber in a 1 per cent. solution of mercuric chloride for 7—11 days. (2). *Burnettising* comprises preliminary steaming, followed by impregnation in a 2—2½ per cent. solution of zinc chloride under a pressure of 7—8 atmospheres. In the *zinc-tannin* or *Wellhouse* process, treatment in a partial vacuum follows the preliminary steaming, a small percentage of glue is added to the zinc chloride, and after impregnation for 2½—6 hours at 100—125 lb. per sq. in., the timber receives a final treatment with a 0·5 per cent. solution of tannin under the same pressure for two hours. (3). *Creosoting* usually involves steaming of the dried timber, heating under reduced pressure, and treatment with creosote oil under a pressure of 100—180 lb. per sq. in. The amount of creosote absorbed by the timber varies from 7 to 20 lb. per cb. ft., and the temperature of treatment should be between 100° and 130° C. In the *Curtis-Isaacs* process, the timber and creosote are heated to above the boiling point of the sap at ordinary pressure, in a retort having vents open to the air ; the vents are then closed and the creosote is forced into the wood under pressure. The *Rueping* process consists in forcing, first compressed air at a pressure of 80—100 lb. per sq. in. into the pores of the wood, and then at a higher pressure creosote oil, without relieving the air pressure. In the *Lowry* process, treatment with creosote oil at 77°—82° C. under a pressure of 180 lb. per sq. in. is followed by draining and a rapid vacuum treatment. In the *zinc-creosote* or *Rutger* process, an emulsion of ½ lb. of "dry zinc" and 1·5—4 lb. of creosote oil per cubic foot of timber is used, the emulsion being kept continuously agitated, *e.g.*, by means of a centrifugal pump. The *Hasselmann* process makes use of a solution containing cupric, aluminium, and potassium sulphates, heated to 118°—126·6° C., under a pressure of 35 lb. per sq. in. In the *creo-resinate* process (specially suitable for wood paving-blocks), air at 121° C. under a pressure of about 100 lb. per sq. in. is substituted for steam ; the antiseptic agent consists of 50 parts of creosote oil, 48 of resin, and 2 of formaldehyde, and impregnation is followed by a treatment with lime water at 100° C. and under 150 lb. pressure. The *Guissani* process makes use of a mixture of anthracene and pitch heated to 140° C., in which wood is submerged until it is free from moisture and sap, after which it is successively treated with cold, heavy tar oil, and cold zinc chloride solution. In the *saccharine solution* or *Powellising* process, suitable for the treatment of green wood, a solution consisting mainly of sugar with a small percentage of arsenic, is used. The *vulcanising* or *Haskinising* process consists in roasting wood, which has been previously dried by steaming, to a temperature high enough to coagulate its contained albumins (71°—94° C.), and to resolve some of the fibre and sap with the production of wood creosote. In addition to the use of definite antiseptics and of a large number of metallic salts for wood preservation, mineral oils, preferably mixed with asphaltum, can be used to stop up the open wood cells, thus protecting timber from the action of heat, moisture, and air. By the zinc chloride process the life of wood is more than doubled ; creosoted wood lasts 25—50 per cent. longer than wood treated with zinc chloride, but costs three or four times as much. The amount of preservative injected into 1 cb. ft. of various classes of timbe ranges from about 3 lb. of mercuric chloride in the cas of hard woods, to about 6 lb. for moderately hard woods and 10 lb. for soft woods, the corresponding amounts o creosote oil being 3, 10, and 20 lb. respectively. Th average costs of preserving timber with zinc chloride creosote oil, and mercuric chloride, are approximatel 1·25d., 5d., and 8d. per cb. ft. respectively.—O. R.

Lime-silica bricks ; Action of heat and furnace gases on —— E. Damour. Rev. Mét., 1914, **11**, 203—210.

Lime-silica bricks of the composition, CaO 14·1, SiO_2 78· H_2O+CO_2 6·8 per cent., were heated for two hours in muffle at temperatures ranging from 100° C. to 1000° and the loss of weight, and the strength after heatin determined. The loss of weight increased with t temperature up to 550° C., when it remained practical constant, showing that at this temperature the mo complete decomposition of the hydrates or hydrosilicat forming the cement of the bricks took place. The crushi strength decreased comparatively slowly as the temper ture increased up to 500° C., but at higher temperatu the strength fell rapidly. At a temperature approachi that of the dissociation of calcium carbonate, the bric fell to dust. When the bricks were heated at 300 and 400° C. for varying lengths of time, and exposed directly to the muffle gases, the maximum loss in weight occurred between 2 and 6 hours' heating. Absorption of carbon dioxide thus began to take place rapidly after the third or fourth hour. After the heated bricks had been exposed to the air for several days, they regained a part of the weight lost on heating. The longer the exposure to the hot gases at a given temperature, the weaker the bricks became. Tho bricks heated to the same temperatures inside a muffle, and thus protected from the action of carbon dioxide, had an average strength nearly three times that of the bricks which had been exposed to the heating gases. The author considers that the tests demonstrate the unsuitability of lime-silica bricks for the construction of chimneys and furnaces.—T. St.

Portland cement clinker ; The compound, $8CaO,Al_2O_3,2SiO_2$, *and the alite of* ——. H. Kühl. Tonind.-Zeit., 1914, **38**, 365—368.

Janecke's compound, $8CaO,Al_2O_3,2SiO_2$, was prepared at a sintering temperature (compare this J., 1912, 491). It was found to be extraordinarily quick-setting and to have low tensile and crushing strengths ; its specific gravity, when ground so as to leave a residue of 15 per cent. on a sieve with 4900 meshes per sq. cm., was 2·91. The view that it constitutes the alite of Portland cement clinker is rejected, in favour of the hypothesis that alite is a solid solution of which this compound forms the basis.
—F. Sodn.

Ultramarine ; Behaviour of —— in cement ware. O. Jordan. Tonind.-Zeit., 1914, **38**, 450—451.

The decomposition of ultramarine in cement (see Haerting, this J., 1914, 81) was artificially stimulated by prolonged gentle heat and continuous moistening in a series of experiments on eight kinds of cement, four ultramarine blues and one green, and eight varieties of silica such as quartz, kieselguhr, trass, etc. The results showed that decomposition occurs when carbon dioxide is lacking, and that atmospheric carbon dioxide plays a part in preventing surface decomposition (*loc. cit.*). The addition of silica (*e.g.*, the residue obtained in the manufacture of aluminium sulphate from kaolin and termed "Kaolinkieselsäure") as recommended also by Rinne (Tonind.-Zeit., 1913, 1656), is suggested as the remedy which can be used in tropical as well as in temperate climates.
—H. H. S.

Patents.

Wood ; Apparatus for impregnating ——. H. L. Galloway, Kilmacolm, Renfrew, and W. J. Frame, Glasgow Eng. Pat. 25,029, Nov. 1, 1912.

A number of cylindrical containers are mounted round a central axis, about which they can revolve and intermittently occupy a number of operative positions. In the course of rotation, each cylinder in turn is submerged in a tank containing the impregnating liquid, the latter flooding the cylinders through their open ends, and being forced through the material in the cylinders by means of a pump. Means are provided for charging and discharging the cylinders with the material to be treated, and for subjecting the contents of the cylinders to the action of a vacuum and of hydraulic pressure, each process taking place as the cylinders in their turn reach suitable, successive, operative positions, provision being made for the formation of fluid-tight joints, when the ends of the cylinders register with valve-controlled pressure and vacuum chambers.—O. R.

Portland and similar cement ; Method of treating [preparing for testing] ——. H. J. Force, Scranton, Pa. U.S. Pat. 1,085,977, Feb. 3, 1914.

In preparing cement bodies for testing, they are boiled under a pressure exceeding 50 lb. (preferably about 285 lb.) per sq. in.—F Sodn.

Cement and the like ; Drying apparatus for ——. Buhler Frères. First Addition, dated Aug. 19, 1913, to Fr. Pat. 392,743, July 27, 1908 (this J., 1909, 21).

A number of additional conduits for the hot gases are provided, of which at least one serves as an extra drying chamber ; by means of dampers this chamber is sealed both from the gas conduits and from the moisture-collecting chamber, when its doors open for the admission or the withdrawal of the trucks, the current of drying gases then passing through an auxiliary conduit.—O. R.

Asphalt ; Process of the manufacture of —— for compressed asphalt pavements. R. Wallbaum. Fr. Pat. 462,658, Sept. 1, 1913. Under Int. Conv., Dec. 4, 1912.

Limestone, chalk, trass, or the like, is moistened and incorporated with an emulsion of asphaltum and water.
—O. R.

Calcareous stone ; Process for the manufacture of synthetic ——. A. Venturi. Fr. Pat. 463,004, Sept. 26, 1913. Under Int. Conv., Oct. 18, 1912.

Calcareous material is calcined, slaked, ground, mixed with filling or colouring material, moistened, moulded, dried and hardened in an autoclave by means of carbon dioxide under pressure and steam.—O. R.

Treating waste acid or acid effluents from tin-plate works. Eng. Pat. 3705. *See* VII.

X.—METALS ; METALLURGY, INCLUDING ELECTRO-METALLURGY.

Titanium and vanadium ; Determination of —— in iron alloys. H. König. Stahl u. Eisen, 1914, **34**, 405—409

Investigation has shown that although the volumetric determination of titanium is not entirely satisfactory, yet it is more rapid in presence of elements which interfere in precipitation processes. Details are given of a modified form of Cain's volumetric process for the estimation of vanadium (this J., 1911, 658). There is an extensive bibliography.—J. L. F.

Molybdenum in cyanide solutions. J. E. Clennell. Eng. and Min. J., 1914, **97**, 363—364.

Samples of ore and solution from a mine in Central America were found to contain molybdenum and tellurium. In tests molybdic acid and ammonium molybdate acted like acids towards the cyanide, but not in presence of excess of alkali.—T. St.

Silver and cuprous oxide. C. H. Mathewson and C. H. Stokesbury. Int. Zeits. Metallog., 1914, **5**, 193—212.

Cuprous oxide dissolves freely in molten silver but is practically insoluble in the solidified metal. The authors describe the thermal characteristics and microstructure of alloys containing Cu_2O up to 20 per cent., the constitutional relations of which are similar to those of the Cu—Cu_2O system. When a silver-copper alloy poor in copper is melted and solidified with free access of air, cuprous oxide is found between the grains of silver.—W. R. S.

[Copper] Converting ; Selective ——. A. P. Selby-Davidson. Eng. and Min. J., 1914, **97**, 357—358.

Copper produced at the O.K. mine in northern Queensland assayed Au 0·16 to 0·79 oz., and Ag 6·42 to 12·23 oz. per ton. About 50 per cent. of the gold and 15 per cent. of the silver were obtainable in 10 per cent. "bottoms." The charge was converted into blister copper. The "bottoms" melted up weekly with added matte, yielded second "bottoms" when a total concentration of 86·6 per cent. of the gold and 23·67 per cent. of the silver was effected.—T. St.

Copper; Metallurgy of —— in the basic (Peirce-Smith) converter. B. de Saint-Seine. Rev. Mét., 1914, **11**, 145—164.

Basic differ from acid converters in the character of the lining, but in either the same matte yields a similar product. Basic converters are those generally employed in America, producing 1000 tons of copper monthly (40 tons per charge), and are 25 ft. long and 10 ft. in diameter. The lining of magnesite bricks is only very slightly attacked and the action is independent of the nature of the slag; 6000 tons of copper have been produced without any repairs being necessary. In the basic converter, mattes with copper ranging from 8 to 70 per cent. can be treated economically with a yield of 90 to 95 per cent. of the copper introduced. The temperature should not exceed 2100° F. (1145° C.). It is this comparatively low temperature which, by reason of the correspondingly long life of the lining, makes the Peirce-Smith converter practicable, and differentiates it from the Knudsen converter. In the latter the temperature is raised to the melting point of the added ores, whilst in the former the additions are brought into fusion by the solvent action of the charge.—T. St.

Zinc; Assay of —— by ferrocyanide methods. Min. and Eng. World, 1914, **40**, 55—57. From Report of Assay Sub-Committee of Australasian Inst. of Min. Eng. *Determination of zinc by ferrocyanide in acid solutions.* R. T. D. Williams. Trans. Australasian Inst. Min. Eng., 1911, **15**, 629—644.

Sufficient of the ore to require about 25 c.c. of the ferrocyanide solution (32·5 grms. per litre) is decomposed with nitric acid, potassium chlorate added and the mixture evaporated just to dryness; oxidised ores are dissolved in hydrochloric acid, evaporated to dryness, and boiled with nitric acid before the addition of chlorate. The residue is treated with 100 c.c. of boiling water, 7 grms. of ammonium chloride, 15 c.c. of ammonia (sp. gr. 0·880) and 0·5 grm. of sodium peroxide, the liquid boiled for 5 mins., filtered, the precipitate washed twice with a boiling 1 per cent. solution of ammonium chloride, redissolved in 5 c.c. of hydrochloric acid, re-precipitated by addition of 3 grms. of ammonium chloride, 15 c.c. of ammonia and 2—5 grms. of sodium peroxide, and washed 3 times with the ammonium chloride solution. *Titration in alkaline solution:* The combined ammoniacal filtrates (about 300 c.c.) are heated to 70° C., 30 c.c. of tartrate emulsion (200 grms. of cream of tartar, 2 c.c. of neutral ferric chloride solution containing 10 per cent. Fe, and 1 litre of water) added, and the solution titrated with ferrocyanide until a faint blue colour is obtained by adding a drop of the liquid to a drop of glacial acetic acid, with 0·2 per cent. or more copper in the ore, the ammoniacal solution is acidified with hydrochloric acid and 1 c.c. excess added, the liquid boiled with 20—30 grms. of pure granulated lead, decanted, and titrated after addition of 30 c.c. of tartrate emulsion and 8 c.c. of ammonia. With very low grade ores the excess of ammonia may prevent precipitation of the zinc by ferrocyanide, hence acetic acid is added until a precipitate commences to form, before the titration; but the solution must not become acid. *Titration in acid solution:* To the combined ammoniacal filtrates, whether copper be present or not, 3 grms. of sodium thiosulphate and 5 c.c. of hydrochloric acid in excess of that required to make the solution just acid to methyl orange are added, the solution boiled to expel most of the sulphur dioxide and coagulate the precipitated copper sulphide and sulphur, cooled to 70° C. and titrated (without removing the precipitate) using uranium acetate as external indicator as usual. In either method of titration the ferrocyanide solution is standardised against chemically pure zinc under similar conditions to those of the assay, a blank test being made to determine the volume of ferrocyanide required to produce the end-point in the absence of zinc. Results with the acid method on Broken Hill ores or concentrates, are accurate; results for a concentrate containing 50 per cent. Zn should agree to within 0·5 per cent. The alkaline method is preferred by the Sub-Committee as although the end-point is less sharp the process is more rapid than the acid method and equally accurate.—W. E. F. P.

Muntz metal. The correlation of composition, structure, heat treatment, mechanical properties, etc. J. E. Stead and H. G. A. Stedman. Inst. of Metals, March 1914. [Advance proof.]

Bars of metal containing about 60 per cent. Cu and 40 per cent. Zn was heated for 48 hours at temperatures between 470° and 860° C.; one set was cooled in air, the other quenched in cold water. The bars were submitted to mechanical tests and microscopic examination. Annealing between 750° and 800° C. develops in all brittleness. Heating to 800°—830° C., followed by quenching, leaves the metal as homogeneous β-constituent, tenacity 29 tons per sq. in.; heating to 800°—833° C. and cooling in air gives a tenacity of 25·5 tons. Bars were annealed at 430° C. for 3 months, and this treatment gave the most ductile metal. At about 773° C. a critical or brittle point exists, and brass heated to that temperature has been described as "burnt"; the term is inappropriate, for, on higher heating, the material again becomes ductile. Brass oxidises much less readily than copper, and the scale detached from heated bars consists of zinc oxide free from copper. Brass can be tinted in a few seconds by blowing air containing traces of ammonium sulphide upon the heated specimens; this method is stated to be more delicate than etching.—W. R. S.

Brass; Vanadium in ——. The effect of vanadium on the constitution of brass containing 50—60 per cent. of copper. R. J. Dunn and O. F. Hudson. Inst. Metals, Mar. 1914. [Advance proof.]

The pure vanadian brasses employed were prepared by adding to molten copper a mixture of vanadic acid with a known excess of powdered aluminium and fluxes containing cryolite, oxidising the excess of aluminium by copper oxide, removing the slag from the surface of the metal, and finally adding the zinc. Brasses prepared by the use of commercial cupro-vanadium containing Al 19—25, and Fe 4—6, per cent. were also investigated. The authors are of opinion that if any structural resolution of β into α and γ is effected by the addition of cupro-vanadium, the result is due to the relatively large aluminium content of the commercial alloy rather than to the small vanadium content of the resulting brass.
—W. E. F. P.

Bronze. J. Dewrance. Inst. Metals, March, 1914. [Advance proof.]

At atmospheric temperature, bronze containing Cu 88 Sn 10 and Zn 2 per cent. had a maximum stress of 16·3 tons per sq. in. and an elongation of 11 per cent. on 2 in. at 400° F. (204° C.) and 700° F. (371° C.) the correspondin figures were respectively 9·5 tons and 1 per cent., an 7 tons and 0·25 per cent.; the alloy commenced to los strength above 350° F. (177° C.). When ½ per cent. the copper was replaced by lead, the maximum stress of th alloy at atmospheric temperature was 16·5 tons per sq. i and the elongation 8 per cent., the corresponding valu at 550° F. (288° C.) and 700° F. (371° C.) being 15·8 to and 18 per cent., and 8·25 tons and 2 per cent., respe tively; the critical temperature in this case was abo 600° F. (316° C.). No further advantage resulted wh larger proportions of lead were introduced into the all at the expense of the copper; but with an alloy containi Cu 72, Sn 10, Zn 2 and Pb16 per cent. the maximum str at 500° F. (260° C.) was 12½ tons per sq. in. The results w in no way due to the absorption of atmospheric oxyg by the molten alloys. Further research on similar li is advocated for the purpose of producing a bronze whi can be used with safety at 700° F. (371° C.), *i.e.*, w superheated steam.—W. E. F. P.

Copper-aluminium alloys; Influence of nickel on some — A. A. Read and R. H. Greaves. Inst. of Metals, Mar, 1914. [Advance proof.]

Alloys were prepared containing 10 and 5 per cent. and varying amounts of Ni (1, 2·5, 5, 7·5, 10, and 15 cent.), the balance being made up of copper. The all were submitted to tests similar to those illustrating influence of phosphorus on Cu-Al alloys (see this J., 1 3, 914). *Rolling:* With the exception of the difference in hardness, which increased with the Ni-content, all the alloys tested (1—7·5 per cent. Ni) behaved similarly, yielding perfectly sound rods. *Wire-drawing:* All the wires were sound and smooth. Nickel increased the ductility of the 5 per cent. Al-alloy. *Specific gravity* was increased by the presence of nickel, while the *conductivity* was diminished. *Corrosion* by fresh water was very slightly increased; with sea-water, nickel up to 10 per cent. greatly reduced the corrosion of the alloys. Descriptions and reproductions of micrographs are given. Other tests are tabulated below.

Treatment of alloys.	Effects of Nickel.
Aluminium 10 per cent.	*Tensile tests.*
Cold-rolled	Maximum stress rises considerably, with no reduction in ductility.
Annealed and slowly cooled	Great improvement up to 5 per cent.; above 5, elongation fell off.
Quenched	Maximum stress slightly reduced.
Air-cooled	Properties intermediate between quenched and annealed series.
Chill-castings	Increased maximum stress and yield point up to 10 per cent.; decrease above.
Aluminium 5 per cent.	
Cold-rolled	Maximum stress and yield point raised and above 5 per cent. was more rapid.
Annealed and slowly cooled	
Quenched	
Air-cooled	
Chill-castings	Elongation and reduction of area greatly improved, with maximum stress and yield point unaffected up to 5 per cent. above the latter properties were improved, the former decline of area decreased correspondingly.
Aluminium 10 per cent.	*Alternating stress tests.*
Cold-rolled	Reduced resistance.
Annealed	5 per cent. diminished detrimental effect of annealing.
Quenched	Results irregular (metal coarsely crystalline).
Aluminium 5 per cent.	
Cold-rolled	Diminished resistance.
Annealed	Above 1 per cent. diminished resistance.
Quenched	Quenching increased resistance stress.
	Hardness.
Aluminium 10 per cent.	Diminished hardening capacity.
Aluminium 5 per cent.	
Annealed	More than 5 per cent. rapidly increased.
Cast	More than 7·5 per cent. rapidly increased.
	Melting point.
Aluminium 10 per cent.	Slight fall at first, followed by a rise at about 5 per cent.
Aluminium 5 per cent.	Immediate and considerable rise.

—W. R. S.

Lead; Brittleness of ——. O. Bauer. Mitt. kgl. Materialprüfungsamt., 1913, **31**, 357—369.

The lead covering of an insulated cable had become extremely brittle in course of use: fractures showed an unusually coarse granular structure. There was nothing abnormal in the composition of the metal. Experiments on lead plates showed that when the flexibility was tested at various temperatures by bending to and fro, to an angle of 90° on each side, until the plates broke, there was a slight fall in flexibility up to a temperature of 160° C., above which, up to 260° C., there was a rapid increase. Above 200° C., the flexibility was higher than at the ordinary temperature. Tests carried out at the ordinary temperature, after the lead had been exposed to the influence of various higher temperatures for several days, showed that at 100° C. the flexibility markedly decreased only after 24 days' heating, the original value of about 22 then falling to 17·8—17·1 and remaining at that on further heating. At 145° C. a considerable loss of flexibility was noted after 6 days, the value falling to 12·6; heating, up to 51 days, produced no further perceptible change. At 260° C. a similar behaviour was observed but the minimum value recorded was slightly lower (11·6). The size of the crystalline granules steadily increased with the time and temperature of heating. The average linear dimensions of the granules had increased fivefold after heating for 35 days at 260° C.

—J. F. B.

Type-metal; Cause of the oxidation of ——. R. Meyer and S. Schuster. Z. angew. Chem., 1914, **27**, 121—127.

The results of the examination of ten samples of type, some of which were new and others from forty to seventy years old, indicated that corrosive oxidation does not depend upon the chemical composition of the metal but rather upon:—faults in the founding, the methods adopted for cleaning and imperfect conditions of storage. It is commonly believed that corrosion is due to the presence of arsenic in the metal, but a metal having a porous and irregular fracture will corrode under certain conditions even though it contains as little as 0·1 per cent. Whereas a solid casting containing more than twice as much will remain perfectly sound under similar treatment. Oxidation is mainly to be attributed to the entrance of moisture into the porous body of the type and it is suggested that turpentine or petroleum spirit should be used instead of water for cleaning purposes. The type should also be stored under perfectly dry conditions. The presence of tin in the metal seems to exert a protective influence under conditions which otherwise would bring about corrosion, but type which is free from tin may be kept quite sound if properly treated.—J. A.

Pure metals [titanium and vanadium]; Preparation of ——. M. Billy. Comptes rend., 1914, **158**, 578—580.

Titanium and vanadium were prepared in a state of purity, suitable for physico-chemical determinations, by reducing the vapour of the tetrachloride (made to boil in a current of hydrogen) by contact with sodium hydride, heated to 400°—420° C. The hydride was contained in porcelain boats, lined with fused salt, and could be made *in situ* by enclosing the boats in an apparatus of soft glass. The reaction was accompanied by incandescence, but was not violent. Titanium was obtained as a grey crystalline powder which was purified by treatment with alcohol, 10 per cent. hydrochloric acid, and water, Vanadium was dried in a current of carbon dioxide. The method appears to be capable of general application. —F. Sodn.

First Report to the Beilby Prize Committee of the Institute of Metals on the solidification of metals from the Liquid State. Cecil H. Desch, D.Sc., Ph.D. Offices of the Institute of Metals, Caxton House, Westminster, London. 1914.

The subject is subdivided as follows:—I. Cellular structure of metals. II. Crystallisation from centres and the formation of crystallites on crystal skeletons. III. Foam-structures and Quincke's hypothesis. IV. Cellular structures in cooling liquids. V. Liquid crystals. VI. Influence of surface tension. VII. Undercooling and the existence of a meta-stable limit. VIII. Changes of volume on solidification. IX. The thrust exerted by growing crystals.

Electrolytically deposited metals; Adhesion and alloying of ——. M. Schlötter. Chem.-Zeit., 1914, **38**, 289—291

The degree of adhesion is satisfactorily determined by Burgess's method, in which a copper disc is soldered to the surface of the deposit, the force required to detach the latter from the underlying metal being measured with a spring balance. Several factors influence the degree of adhesion, such as nature and hardness of the deposit and of the cathode metal; generally speaking, a soft metal adheres more firmly to rough surfaces than to smooth ones. The molecular attraction between cathode and electrolyte is increased by the addition of alcohol, which improves some deposits. Several metals occlude hydrogen during electrolysis, part of which is given off subsequently as gas, which accumulates under the deposit and decreases the degree of adhesion. In some cases the deposit alloys with the cathode, and the two cannot be separated. Zinc on being copper-plated first becomes yellow; the thin coating of brass is subsequently covered with copper.—W. R. S.

Surface film produced in polishing metals [copper]; Transparence or translucence of the ——. G. T. Beilby. Roy. Soc. Proc., 1914, A **89**, 593—595.

Copper was polished so as to leave as thin a surface film as possible (see this J., 1901, 992; 1903, 1166) and high-power photomicrographs in natural colours of the surface, before and after treatment with a 10 per cent. solution of ammonium persulphate (which dissolved the surface film) were prepared. Before treatment the small pits under the surface film appeared as blue spots on a pale rose-coloured ground, but with red patches on the blue. After treatment with ammonium persulphate bright spots appeared instead of the red patches. These results show that the surface film is transparent or highly translucent, and that it extends over the smaller pits without any support from below, for the red patches on the blue must have been caused by reflection from the inner concave surface of the pits, which hence must have been practically empty.—A. S.

Alloys; First report of the Committee on the nomenclature of ——. Inst. of Metals, March, 1914. [Advance proof.]

The Committee included representatives of the Inst. of Metals, Inst. of Elect. Engineers, Inst. of Mech. Engineers, Inst. of Naval Architects, Inst. of Eng. and Shipbuilders in Scotland, N.E. Coast Inst. of Eng. and Shipbuilders, and Soc. of Chem. Industry. The retention of existing names, sanctioned by long usage, for use in industrial and commercial practice is advocated, but the coining of new names, adoption of recently coined names, and use of Latin or foreign names or chemical or other symbols is discouraged. As the basis of a system of nomenclature it is recommended that an alloy be denoted by the names, in English, of its component metals, arranged in order of increasing percentage by weight, *eg.* Zn 30, Cu 70 per cent. would be termed zinc-copper, and Sn 1, Zn 29, Cu 70 per cent., tin-zinc-copper. In the case of alloys containing more than three metals, the names of the three metals present in the largest proportions should be used for the name of the alloy, with the prefix "comp." or "complex," but if a small quantity of a metal added intentionally to give the alloy a distinctive character be present, this may be named first; *e.g.* Al 75, Sn 15, As 4, Co 3, Fe 2·75, In 0·25 per cent., might be named "indium complex tin-aluminium, if the indium were regarded as imparting special qualities to the alloy. If the component metals of an alloy be present in practically equal proportions, the names should be arranged in alphabetical order. For ordinary usage the term "brass" is used as an abbreviation of the systematic name zinc-copper, *i.e.* for alloys of zinc and copper containing more than 50 per cent. of copper, and "bronze" as an abbreviation for tin-copper, the presence of additional metals being indicated as in the case of the systematic names; *e.g.*, Sn 1, Zn 29, Cu 70 per cent., would be termed "tin-brass."—A. S.

Use of tar in the preparation of basic linings of steel furnaces. Wagner. *See* III.

Use of the aluminium alloy, duralumin, for the manufacture of domestic and cooking utensils. Fendler and Stüber. *See* XIXb.

Patents.

Cast-iron and process for producing same. R. Anderson, Middlesbrough, Yorks. Eng. Pat. 3354, Feb. 10, 1913.

Cast-iron containing approximately C 2·50, Si 2·00, S 0·03, P 0·05 and Mn 1·00 per cent., is produced by mixing molten, finished, mild steel with molten, hæmatite cast-iron direct from the blast-furnace.—W. E. F. P.

Iron; Process for the manufacture of —— particularly applicable for use in dynamo machines and for like purposes. W. Rübel, Berlin-Westend, Germany. Eng. Pat. 3445, Feb. 10, 1913.

To iron containing not more than 0·5 per cent. of impurities, sufficient aluminium and silicon are added to produce an alloy containing Al 1·3—2·0 and Si 0·8—1·2 per cent. Boron may be substituted for silicon, and beryllium or calcium for aluminium.—W. E. F. P.

Steel and iron; Method of treating ——, in the manufacture thereof. C. R. Gostling, Eustis, Fla., U.S.A. Eng. Pat. 17,869, Aug. 5, 1913.

To remove dissolved gases, the molten metal (in the mould, etc.) is brought into contact with infusorial earth and allowed to solidify in the presence of the same. —W. E. F. P.

[Iron and steel.] Furnaces; Continuous ingot-heating ——. F. K. Siemens, London. Eng. Pat. 17,955, Aug. 6, 1913.

The hottest portion, or finishing hearth, of the furnac is made removable and interchangeable.—W. E. F. P.

Steel; Treating —— in electric furnaces with basic hearths W. R. Walker, New York. U.S. Pat. 1,086,489, Feb. 10 1914.

To refine iron or steel in an electric furnace wit a basic hearth, a practically neutral slag of lime an silica is used in which the proportion of silica whils sufficiently low to avoid serious scorifying of the hearth high enough to avoid notable formation of fumes of lim in the furnace and to provide reduced silicon for inco poration with the metal, whilst the quantity of lime sufficient to ensure elimination of sulphur. For instanc the silica may amount to 25—35 per cent. of the tot weight of the slag.—A. S.

Steel; Special —— of high resistance, and improvemen in the method of manufacture of special steels. Thuaud. Fr. Pat. 462,463, Nov. 22, 1912.

The finished steel has the following composition: C 0· to 0·50 (preferably 0·30—0·35), Ni 11·50 to 17, Mn 0·

to 0·60, Cr 1·70 to 3·25, Si 0·30 to 0·45, V 0·25 to 0·40, Ti 0·40 per cent. The additions are made in a Martin or electric furnace in the following order: 0·25 to 0·30 per cent. of ferrotitanium containing 15 to 20 per cent. Ti, nickel, ferrochrome, ferrosilicon, ferrovanadium; manganese is added as a deoxidiser after addition of the nickel and ferrotitanium after the ferrosilicon.—T. St.

Iron and steel; Welding powder for welding ——. E. Eisengräber, Frankfurt a M., Germany. Eng. Pat. 17,046, July 25, 1913.

A MIXTURE of red hæmatite (previously reduced to the lower oxide) 70, pulverised coal 22, and flux (sodium phosphate) 8, parts by weight.—W. E. F. P.

Iron-silicon-manganese-aluminium alloys; Process for improving the magnetic qualities of ——. R. A. Hadfield, Sheffield. U.S. Pats. 1,086,765 and 1,086,766, Feb. 10, 1914.

To increase the magnetic permeability and electric resistance and reduce the hysteresis of an iron alloy containing Si 2—4·5, Mn not exceeding 0·7 and Al not exceeding 1·3 per cent., it is heated above the γ-critical point (about 900° C. for pure iron) and then cooled slowly, or heated to 900°—1100° C., cooled slowly, reheated to 700°—800° C., and again cooled slowly.—A. S.

Ferromanganese, ferrosilicon, and other alloys: Lining for electric furnaces for the production of ——. Ges. für Elektrostahlanlagen m. b. H. and W. Rodenhauser. Ger. Pat. 269,298, July 26, 1912.

To prevent the penetration of the ferro-alloy into the lining of the furnace walls, the portion of the lining which would otherwise be directly in contact with the molten charge is faced with a mass rich in carbon, *e.g.* a mixture of coke or retort carbon and tar. In working with induction furnaces, when introducing the first charge consisting of the material to be smelted and wrought iron heating rings, sufficient carbon is added to saturate the iron as it melts, so that carbon will not be taken up from the facing material.—A. S.

Iron-nickel-copper alloy; Process of making an ——. G. H. Clamer, Philadelphia, Pa. U.S. Pat. 1,086,314, Feb. 3, 1914.

THE matte obtained by smelting ore containing iron, nickel and copper sulphides is completely oxidised by roasting, and subsequently reduced to metal.—W. E. F. P.

Zinc furnaces; Apparatus for manufacturing receivers for ——. B. Möhring, Dillingen-Saar, Germany. Eng. Pat. 30,061, Dec. 31, 1912.

IN a press for the manufacture of receivers from "dry" clay or loam, the "matrices" containing the latter are made in two parts hinged together, and supported upon a pivoted table, the arrangement being such that the "core" is successively introduced into each by mechanical means. (Reference is directed to Eng. Pats. 1098 of 1880 and 11,316 of 1893.)—W. E. F. P.

Zinc furnace; Electric —— with integral compound resisters and compound condensers. J. Thomson, New York. U.S. Pats. 1,086,414 to 1,086,418, Feb. 10, 1914.

(1) THE furnace, containing a carbon resister bed, comprises an enclosed reaction chamber provided with a series of openings in the side walls, through which the charge is stoked to and upon the upper surface of the resister in transverse ridges alternating with troughs. (2) The carbon resister bed is provided with a series of superimposed spaced bars, forming galleries or slots through which the charge is fed to portions of the upper surface of the resister. The latter is supported upon a spaced grating, through which the products gravitate into a sump, and from which the fumes pass through ports to the condenser. (3) The charge is located between a rod resister and a broken carbon resister, the former acting upon the upper portion of the charge by radiated heat, and the latter upon the lower portion by conducted heat. (4) The charge is supplied to the vertical faces of parallel porous carbon resister beds, the condensing system being disposed along the opposite vertical face of each resister. Each resister is supported upon a perforated hearth above the sump. The charging space between the resisters is divided longitudinally and transversely by electrically non-conducting walls. (5) The furnace is provided with parallel porous resisters and parallel charging pockets, with ports in the furnace side walls for the removal of ash or sinter. Gratings support the resisters above the sumps, and the resisters are connected electrically in series by a carbon connection located above and spanning the sumps. A sump extending longitudinally is filled with granulated refractory material, and has an open tap-end enclosed by a separate refractory plate thrust against an abutment by an outer block.—B. N.

Tungsten; Manufacture of ——. The British Thomson-Houston Co., Ltd., London. From General Electric Co., Schenectady, N.Y., U.S.A. Eng. Pat. 1915, Jan. 23, 1913.

POWDER for the manufacture of ductile tungsten is prepared by incorporating a solution of thorium nitrate with purified tungstic oxide, moulding the mixture before or after drying, firing the mouldings under oxidising conditions and then reducing them with hydrogen. The product should contain not more than 5 per cent. of thorium oxide.—W. E. F. P.

Ores and other substances; Machine for concentrating and separating ——. G. F. Wynne, Wrexham, N. Wales. Eng. Pat. 2564, Jan. 31, 1913.

BY means of a combination of adjustable, rotary and vibratory crank-shafts and cranks, the table of the apparatus, which is carried upon inclined, resilient supports, receives a quick forward motion starting from rest and gradually increasing in velocity, a sudden stoppage and reverse return motion, and also a vertical movement. The apparatus is stated to be specially suitable for the concentration of ores containing both slime and coarser material.—W. E. F. P.

Magnetic separators. Bowes, Scott and Western Ltd., and I. S. Dalgleish, London. Eng. Pat. 3046, Feb. 5, 1913.

THE separator has two converging poles fixed one above the other between which a pulsating or alternating field is set up. The descending material is separated into two streams by the upper pole, the more magnetic portion being deflected, by the influence of the lower pole, to one receptacle, and the less magnetic part falling vertically on to a shoot leading to another receptacle. Direct contact of the material with the poles is prevented by a removable, curved, non-magnetic sheet attached to both poles and bridging the gap between them. The magnet may be removably attached to the wall of a tank for effecting the separation of materials in water.—W. E. F. P.

Ores and the like; Mills for grinding, crushing and pulverising ——. E. S. King, London, and Head Wrightson and Co., Ltd., Thornaby-on-Tees, Yorks. Eng. Pat. 22,476, Oct. 6, 1913.

A PAN mill of the disc type provided with a circumferential overflow for slime and, below the grinding zone, with a central outlet, or series of outlets, for the intermittent discharge of concentrate: the bed of the pan may be of conical shape to facilitate the passage of the concentrate towards the outlets.—W. E. F. P.

[*Lead and zinc.*] *Metallic sulphides; Method for the separation of* ——. L. Bradford. Fr. Pat. 462,580, Sept. 16, 1913. Under Int. Conv., Sept. 19, 1912.

AN aqueous solution containing about 10 per cent. of common salt, and 0·1 to 0·2 per cent. of sulphuric acid, and heated to 48°—71° C., is used to effect a flotation separation of galena from blende and pyrites, the former mineral being left as a residue with the gangue, from which it is subsequently separated; or, as is preferable, the gangue may first be separated from the mixed sulphides. In order to cause a better separation, the action may be retarded by the addition of alkali sulphites or thiosulphates, or sulphurous acid.—T. St.

[*Lead and zinc*] *Metallic sulphides; Separation of ores containing* ——. Minerals Separation, Ltd. Fr. Pat. 462,757, Sept. 18, 1913.

Zinc and lead sulphides are separated by flotation at atmospheric temperature, in neutral or alkaline solutions containing sulphates, chlorides or nitrates of calcium, potassium and sodium, and a froth-producing agent such as eucalyptus oil. Natural mineral waters may also be used. The zinc sulphide, which is left with the gangue, may be separated from the latter by continuing the action with the same solution, or preferably with fresh water. Suitable apparatus for carrying out the process, and for making preliminary laboratory tests, are described, and the compositions of various solutions which have been employed are given.—T. St.

[*Gold and silver.*] *Metals; Process of precipitating and separating* —— *from solutions.* R. S. Towne, New York, and C. Robinson, Mount Vernon, N.Y., U.S.A. Eng. Pat. 2807, Feb. 3, 1913.

A mixture of the solution (*e.g.* cyanide) with a finely divided precipitant (*e.g.* zinc) is passed along a zigzag pipe, to effect mixing and agitation, and conducted into a relatively large volume of solution (cyanide) contained in a vessel of the spitzkasten type. The end of the delivery pipe is situated nearer the bottom than the top of this vessel, in which the precipitate settles by gravity and the solution overflows at the top. A screen supporting a layer of zinc is disposed across the upper part of the vessel to ensure complete precipitation and filtration of the liquid immediately before discharge.—W. E. F. P.

Silver ores; Metallurgical treatment of ——. O. Dyckerhoff, Karlsruhe, Germany. U.S. Pat. 1,085,675, Feb. 3, 1914.

The ore, containing silver, cobalt, nickel and arsenic, is roasted with common salt, clay and pyrites to produce soluble compounds of the metals which are subsequently extracted by leaching with appropriate solvents. —W. E. F. P.

[*Lead pipes, etc.*] *Pumping apparatus for the manufacture of products of indefinite length from molten lead or other metals or alloys.* H. Debauge, Paris. Eng. Pat. 3944, Feb. 15, 1913. Under Int. Conv., Feb. 17, 1912.

A continuously acting apparatus in which the operating mechanism (kept at a low temperature) and the pump proper (immersed in the molten metal) are disposed separately and independently, each piston being connected to its rod by means of spherical bearing surfaces to obviate lateral stresses and consequent friction between piston and cylinder. The suction and pressure valves of the apparatus operate without springs, the necessary pressure on the seats being obtained solely by the difference in density between the molten metal and that of which the valves are composed. An air-bell provided with a safety valve is employed to regulate the delivery pressure of the molten metal.—W. E. F. P.

Slag and the like; New process for pulverising blast-furnace ——. E. A. Bagley and M. E. Feilmann, London. Eng. Pat. 4018, Feb. 17, 1913.

A thin stream of the molten slag is poured on to the upper surface of a smooth, internally-cooled, metal drum rotating at high speed, with the object of producing a very thin, continuous solidified sheet which is subsequently pulverised by projection against a metal plate or slowly-rotating metal cylinder.—W. E. F. P.

Furnace; Muffle ——. E. Curran, Cardiff. Eng. Pat. 6165, March 12, 1913.

In a muffle furnace having alternative paths for the heating gases, the flues and dampers are so arranged that the heat can be uniformly distributed or concentrated at the top, bottom or sides of the muffle.—W. E. F. P.

Furnace; Reverberatory ——. Soc. Française d'Exploit. de Fours Speciaux à Haute Temperature, Paris. Eng. Pat. 11,390, May 15, 1913. Under Int. Conv., June 18, 1912.

A furnace having a fireplace, a reversible regenerator and a draught chimney at each end of the rectangular fusion-chamber, the hearth of which—separated from the sole of the furnace by blocks of refractory material—is formed into a number of basins by transverse, hollow partitions. A lateral chamber, communicating with the regenerators and the fusion-chamber, is situated upon each side of the middle of the furnace, the flow of gases through the apparatus being directed by means of dampers, etc., operated from the exterior.—W. E. F. P.

Blast-furnace. J. Reis, Montclair, N.J. U.S. Pat. 1,086,220, Feb. 3, 1914.

An annular, perforated screen is disposed between the feed hopper and the wall of the furnace to prevent the discharge of coarse, solid material into the gas outlet. The lining of the furnace is provided with shoulders upon which the screen is supported so as to be easily removable. —W. E. F. P.

Metallurgical furnace. U. Wedge, Ardmore, Pa. U.S. Pat. 1,086,494, Feb. 10, 1914.

The furnace comprises a series of superposed treating chambers with intermediate air-heating chambers, all of which are connected by means of a flue. The air passes from the air-heating chambers over electrical heating devices in the flue on its way to the treating chambers. The electrical heating devices are mounted on plugs which fit into openings in the wall of the flue.—A. S.

Casting-furnace. I. Hall. Fr. Pat. 462,568, Sept. 16, 1913. Under Int. Conv., Sept. 16, 1912 and May 21, 1913.

The furnace has an automatic device for regulating the gas supply and indicating the temperature, and a water-cooled mould which can be emptied by tilting.—W. R. S.

Tin or other ores; Automatic process for the recovery of ——, *from rivers, waste sands, and the like.* W. J. Hocking, Camborne, Cornwall. Eng. Pat. 10,936, May 9, 1913.

By means of a centrifugal pump, the material is transferred from a pit (in the river) to an elevated launder provided with a horizontal sieve through which the sand passes to a series of spitzkasten having a peripheral discharge and arranged in parallel. From the bottoms of these vessels the thickened pulp passes to separate concentrating tables.—W. E. F. P.

Detinning; Process of ——. F. von Kügelgen, Holcombs Rock, Va., and G. O. Seward, East Orange, N.J., Assignors to Columbia-Knickerbocker Trust Co. U.S. Pat. 1,086,921, Feb. 10, 1914.

A mixture of dry chlorine gas and air is passed through a series of tanks containing tin scrap in various stages of detinning, the temperature being kept below that at which iron is attacked. The chlorine comes into contact first with scrap which is almost completely stripped and then progressively with scrap containing increasing proportions of tin, so that finally air free from chlorine is discharged from the last tank containing fresh scrap.—A. S.

Wires; Process and apparatus for the subsequent treatment of drawn or rolled ——. W. Frese, Dortmund, Germany Eng. Pat. 19,277, Aug. 25, 1913.

The wire is passed through a receptacle or brush filled with chalk, then wound on a drum, annealed on the latter and placed in an acid bath, unwound, passed in succession through a water-trough, a drying device, one or more alkaline solutions, a second drying apparatus, and finally wound into coils. Several wound drums (of conical shape to facilitate unwinding) may be placed in the acid bath together and the separate wires conducted through the various stages at one operation.—W. E. F. P.

Smelter-fumes; Apparatus for arresting ——, and recovering their values. C. S. Vadner, Salt Lake City, Utah. U.S. Pat. 1,085,712, Feb. 3, 1914.

The fumes are passed upwards through a tower filled with "pieces of insoluble solid material," supported by a perforated, arched partition disposed above the side inlet, and agitated by the rotation of a vertical shaft to which horizontal arms are attached. The chamber beneath the partition is provided with an inclined bottom from which the filtered particles are periodically removed.—W. E. F. P.

Slimes; Apparatus for roasting ——. R. T. Wales, Chrome, N.J. U.S. Pat. 1,085,831, Feb. 3, 1914.

A series of flue-like roasting chambers "arranged in multiple" is heated by gases which, after being mixed with a regulated quantity of air, are passed from a common distributing flue, through the chambers, to a common outlet. The operation of any chamber may be suspended (for inserting or removing trays containing the slimes) without retarding that of the others.—W. E. F. P.

Metals; Extraction of volatile ——. H. Pape. First Addition, dated Sept. 23, 1913, to Fr. Pat. 449,480, Oct. 16, 1912 (see Eng. Pat. 22,715 of 1912; this J., 1913, 1073).

To avoid the partial solidification of molten products below the grate of the furnace described in the principal patent, flame is directed on to the surface of the molten collector which may be used for separating products of different specific gravity.—W. R. S.

Alkali metals by electrolysis. B. Loisel and A. Nacivet. First Addition, dated Nov. 14, 1912, to Fr. Pat. 456,688, June 24, 1912 (this J., 1913, 1074).

The apparatus comprises a metallic vessel with two rows of electrodes separated by a porous diaphragm, each row being connected with an arrangement for reversing the current at predetermined intervals, so that it may serve alternately as anode and cathode. The metal collects in a metallic frame, from which it is ladled out when sufficient has collected.—B. N.

Alkali metals or alloys of the same; Production of ——. Chem. Fabr. von Heyden A.-G. Ger. Pat. 269,712, Nov. 19, 1912.

Fused alkali carbonates, to which salts capable of lowering the melting point but not participating in the electrolysis may be added, are electrolysed with the use of carbon as a soluble anode material. The reactions given are :—

$$Na_2CO_3 \rightarrow 2Na + CO''_3;$$
$$2CO_3'' \rightarrow 2CO_2 + O_2; \; C + O_2 \rightarrow CO_2.$$

—A. S.

Zinc, lead, copper, silver and gold; Method for the extraction of —— from complex sulphide ores. H. E. L. Fiévet. First Addition, dated Nov. 20, 1912, to Fr. Pat. 457,707, July 18, 1912 (this J., 1913, 1018).

The sulphurous acid arising from the pyrites in the ore, or from added iron sulphide, and recovered by washing the escaping gases in coke scrubbers, is utilised to separate the mixed oxides of lead and zinc which are obtained by the process described in the original patent. After the removal of the insoluble lead compounds, the solution is heated to precipitate the zinc as sulphite, which is afterwards calcined. In hot climates, the coke scrubbers may be supplied with a solution of common salt, which reacts with the sulphurous acid in presence of air with the formation of hydrochloric acid and sodium sulphate. With this solution zinc is dissolved as chloride and after separating the solution from lead sulphate is precipitated with lime or magnesia.—T. St.

Mercury, tin, antimony, and arsenic; Extraction of ——. B. Szilard. Fr. Pat. 463,039, Sept. 27, 1913.

The ore is heated under pressure with a solution of sodium and barium sulphides and calcium hydroxide. The metals are recovered from the filtered liquor by precipitation with an acid or sodium bisulphate, or ammonium salts, or by electrolysis, or by addition of a few crystals of the metallic sulphide to be obtained along with ammonium nitrate. Solution of the ore and electrolysis of the liquor may be carried out simultaneously.—W. R. S.

Graphite and metals; Manufacture of electrical conductors composed of ——. G. Preuss. Fr. Pat. 463,132, Oct. 1, 1913. Under Int. Conv., Oct. 2, 1912.

Suitable powdered metals or alloys are mixed with graphite powder, compressed in the cold to reduce the amount of included air and then heated under pressure, to form a homogeneous alloy completely enclosing the particles of graphite.—W. R. S.

Cement steel; Art of manufacturing ——. G. H. Benjamin, New York City. Eng. Pat. 3554, Feb. 11, 1913.

See U S.Pat.1,054,817 of 1913; this J.,1913, 430.—T. F. B.

Armour-plates; Process for the manufacture of —— A. Lucertini, Sampierdarena, Assignor to Soc. Anon. Italiana Gio. Ansaldo Armstrong & Co., Genoa, Italy. U.S. Pat. 1,086,459, Feb. 10, 1913.

See Fr. Pat. 442,299 of 1912; this J, 1912, 929.—T. F. B.

Tungsten and other metals in malleable form; Process and apparatus for producing ——. J. Canello, Paris. Eng. Pat. 5150, Feb. 28, 1913.

See Addition of June 11, 1913, to Fr. Pat. 444,878 of 1912; this J., 1913, 1160.—T. F. B.

Metallic powders or coatings; Furnaces for producing ——. M. U. Schoop, Zürich, Switzerland. Eng. Pat. 5510, March 5, 1913. Under Int. Conv., March 8, 1912.

See Fr. Pat. 441,100 of 1912; this J., 1912, 822.—T. F B.

Retort furnaces [for use in smelting zinc, etc.]. G. Londress and W. Worley, Grafton, W. Va., U.S.A. Eng. Pat. 11,900, May 21, 1913. Under Int. Conv., June 25, 1912.

See U.S. Pat. 1,048,420 of 1912; this J., 1913, 93.—T. F. B.

Reheating furnaces. F. K. Siemens, London. Eng. Pat. 28,048, Dec. 5, 1913.

See Ger. Pat. 268,379 of 1913; this J., 1914, 144.—T. F. B.

Furnaces for heating ingots; Continuous ——. F. K. Siemens. Fr. Pat. 461,937, Aug. 27, 1913.

See Eng. Pat. 17,955 of 1913; preceding.—T. F B.

Reduction furnaces; Muffle for ——. A. Roitzheim, Duisburg-Ruhrort, Germany. U.S. Pat. 1,086,939, Feb. 10, 1914.

See Fr. Pat. 456,636 of 1913; this J., 1913, 1018.—T. F. B.

Treating waste acid and acid effluents from tin-plate works. Eng. Pat. 3505. *See* VII.

XI.—ELECTRO-CHEMISTRY

Patents.

Insulating materials; Manufacture of electric ——. W. Boehm. Fr. Pat. 462,857, Sept. 23, 1913.

Insulators for high-tension work are prepared by impregnating porous porcelain or earthenware with paraffin, oils, lac, mica powder, etc., and then treating, *e.g.*, with ozone, to effect a hardening of the oils in the pores. The powdered ceramic material, before firing, is mixed with a substance, which by combustion or evaporation produces the necessary porosity, and the porous material is first submitted to a reduced pressure, and afterwards impregnated under pressure.—B. N.

Electrical insulation and other purposes ; Manufacture of a material suitable for ——. The British Thomson-Houston Co., Ltd. From General Electric Co., Schenectady, N.Y. Eng. Pats. (1) 3271, Feb. 7, and 22,358, April 9, 1913. (2) 3566, Feb. 11, 1913.

(1) A fusible intermediate reaction product is prepared by slowly heating phthalic anhydride and a polyhydric alcohol, and a clear infusible product free from cavities is obtained from this by heating for some time to about 85° to 135° C., afterwards heating to a higher temperature further to harden and toughen the resin. (2) One part by weight of a polyhydric alcohol, such as glycerol, is heated with two parts by weight of succinic, tartaric or pyrotartaric acid to about 220° C. until the mass becomes viscous, and the heating is continued at about 85° C., until the mass forms an insoluble, infusible, elastic product. Part of the acid may be advantageously replaced by a polybasic aromatic acid.—B. N.

Insulating and fusible powder for electrical applications. H. Grossmann. Fr. Pat. 462,992, Sept. 25, 1913.

A resinous substance of low melting point, such as rosin, pitch, asphaltum, etc., is intimately mixed with a substance, such as glass, porcelain, marble, sand, talc, barytes, etc. The tendency of the powder to brittleness after fusion and solidification may be diminished by mixing with a fusible and malleable substance, such as paraffin, carnaüba or other wax.—B. N.

Electrode ; Storage battery —— and process of making same. H. C. Hubbell, Newark, N.J. U.S. Pat. 1,086,666, Feb. 10, 1914.

Alternate thin layers of iron and a metal like cadmium are arranged closely together face to face, so as to form a plate with the layers disposed edgewise to the faces of the plate. The cadmium is removed by distillation, and the iron layers are formed with electrolytically-active iron compounds on the surface, by making the plate the anode in an aqueous solution of phenol containing an alkali phenolate (phenoxide).—B. N.

Accumulators ; Solution for cells of lead ——. P. Rabbidge. Fr. Pat. 462,663, Sept. 2, 1913. Under Int. Conv., Sept. 2, 1912.

A concentrated solution of potassium permanganate, equal to about 10 per cent. of the electrolyte, is mixed with the latter for the purpose of desulphating or preserving the plates.—B. N.

Cell ; Electrolytic —— for generating hydrogen and oxygen gases. J. B. Burdett, Assignor to Burdett Manufacturing Co., Chicago, Ill. U.S. Pat. 1,086,804, Feb. 10, 1914.

The cell is provided with an electrode-supporting element, comprising a casing with partitions forming gas-tight compartments, and with a continuous diaphragm attached to the partitions so as to form extensions of the compartments. The parts of the diaphragm attached to the partitions form separating walls for the cathode and anode compartments, through which, and the outer cell, electrolyte is automatically circulated. Gas conduits communicate with the compartments, and an adjustable conduit projects into the electrolyte, in order to regulate the pressure of the evolved gas.—B. N.

Water ; Element for the electrolysis of ——. Maschinenfabrik Sürth G. m. b. H. Fr. Pat. 462,394, Sept. 3, 1913.

Each element comprises an iron frame, forged or soldered by autogenous soldering to the electrode, and the upper edge of each element contains two chambers, to collect the gases and separate entrained electrolyte. The sheets of metal forming the electrodes are corrugated, or may be provided with transverse ribs soldered to them, and the diaphragms, separating the electrodes, comprise two series of alternating metallic bands between which is disposed a thin metallic perforated sheet or wire gauze of fine mesh.—B. N.

Anodes of antimonial lead for electrolytic purposes. Siemens und Halske A.-G. Ger. Pat. 270,191, Oct. 6, 1912.

The anode consists of a number of rods, the cross-section of which is circular, oval, or other form free from sharp corners. The rods are fixed at one end to a common conducting and supporting bar, so that they are free to expand in the direction of their axes. The use of anodes of this kind obviates the difficulty experienced with sheet or plate anodes of antimonial lead due to the frequent formation of short circuits owing to bending of the sheets or plates within the bath.—A. S.

Electrolysis of alkali and alkaline-earth chlorides. Eng. Pat. 21,462. *See* VII.

Manufacture of electrical conductors composed of graphite and metals. Fr. Pat. 463,132. *See* X.

XII.—FATS ; OILS ; WAXES.

Cod liver oil [Oleum Jecoris Aselli] ; Content of unsaponifiable matter in ——. H. Thaysen. Ber. Deutsch. Pharm. Ges., 1914, **24**, 136—140.

A number of specimens of cod liver oil were tested by mixing five drops with one drop of sulphuric acid, when a violet colour developed which soon changed to brownish-red. Six of these gave a colour the same depth as that of a mixture of 100 c.c. of water with 2 c.c. of *N*/10 potassium bichromate solution. The acid value of these samples varied between 1·2 and 2·3 and the unsaponifiable matter between 0·70 and 1·02 per cent. The other samples had an acid value varying between 9·0 and 59·0, and unsaponifiable matter 0·64 to 2·30 per cent. The oil with the highest acid value had the darkest colour.
—F. Shdn.

Kickxia elastica and Manihot Glazcovii ; Oil from the seeds of ——. H. Sprinkmeyer and A. Diedrichs. Z. Unters. Nahr. Genussm., 1914, **27**, 120—124.

Kickxia elastica :—The crushed seeds yielded, when expressed and extracted with ether at about 70° C., 28·16 per cent. (54·8 per cent. on the kernels) of a golden yellow oil with a characteristic odour and bitter taste. It had drying properties (9·53 per cent. increase in weight in Livache's test), and yielded 0·48 per cent. of an insoluble bromide. It had the following characters :—Sp. gr. at 15° C., 0·9327 ; refraction at 40° C., 68·8 ; at 25° C., 77·3 ; acid value, 3·33 ; sapon. value, 179·6 ; Reichert-Meissl value, 0·66 ; Hehner value, 95·95 ; iodine value, 130·9 ; Polenske value, 0·30 ; optical rotation (200 mm.) +0·8°. *Fatty acids* :—Refraction at 40° C., 57·3 ; at 25° C., 66·0 ; m. pt. 25·2° C. ; solidif. pt. 23·0° C. ; neutralisation value, 183·0 ; iodine value, 139·7 ; and mean molec. equiv., 312·0. The oil would be suitable for varnishes and paints, whilst the seed hair could be utilised as upholstery material. *Manihot Glazcovii* :—The seed-kernels yielded 50·16 per cent. of a yellow oil with a pleasant nutty aroma and taste. It dried well (Livache test, 7·69 per cent.), and could be used for varnishes, etc. With Bellier's reagent it gave a deep blue colouration. The oil yielded no insoluble bromide, but the fatty acids gave a deposit of linolic acid tetrabromide. The following values were obtained :—Sp. gr. at 15° C., 0·9242 ; refraction at 40° C., 61·8 ; at 25° C., 70·2 ; acid value, 1·74 ; saponif. value, 192·5 ; Reichert-Meissl value, 10·66 ; Hehner value, 95·65 ; iodine value, 117·6 ; Polenske value, 0·50. *Fatty acids* :—Refraction at 40° C., 47·3 ; at 25° C.

55·4; m. pt. 25·8; solidif. pt., 23·5 C.; neutralisation value, 202·6; iodine value, 131·6; and mean molec. equiv., 280·9. (See also Rideal and Acland, this J., 1913, 704.) —C. A. M.

Glycerides and their fatty acids; Applications of the method of determining the difference in the melting points of ——. A. Bömer. Z. Untersuch. Nahr. Genussm., 1914, **27**, 153—172.

Lard:—It is possible to detect 5 per cent. of beef fat in lard containing cocoanut oil, arachis oil or cottonseed oil by the author's m. pt. method (this J., 1914, 38). Any deviation from the normal figures for lard which might be caused by fats such as shea butter could be checked by the phytosteryl acetate test. In the case of hydrogenated arachis and sesamé oils the m. pts. of the least soluble glycerides were very high (70·6° C., and 71·5° C. respectively) whilst the corresponding fatty acids melted at 68·6° C. and 68·5° C.; hence these glycerides apparently consisted of tristearin. Hydrogenated cottonseed oil, however, yielded a mixture of glycerides (m. pt. 61·3° C.), containing fatty acids melting at 38° C. The m. pt. differences ranged from 0° to 0·8° C. for hydrogenated arachis and sesamé oils, and reached 2·8° C. in the case of the cottonseed oil. These hardened fats added to lard depressed the difference in the m. pts. to a greater degree than beef fat, from which however they could be distinguished by the phytosteryl acetate test. The least soluble glycerides of sucking-pigs' fat and of the fat of pigs fed abnormally upon cocoanut, maize, sesamé and cottonseed oil-cakes differed from those of normal lard in containing a smaller proportion of α-palmitodistearin and more stearodipalmitin, but no new glycerides had been produced. Such abnormal feeding did not prevent the detection of beef fat by the author's method.

Detection of lard and tallow in cocoanut oil:—The glycerides of cocoanut oil separated by crystallising 50 grms. of the fat from 50 c.c. of acetone at 10° C. melted at 47·3° C., whilst their fatty acids melted at 44·3° C. In the case of palm-kernel oil the glycerides obtained in two crystallisations melted at 39·9 (I.) and 45·2 (II.), and gave differences of 5·8 and 4·1° C. respectively. Cocoanut oil containing 5 per cent. of lard yielded glycerides melting at (I.) 61·3° C. and (II.) 63·3° C., and showing differences of 7·5° and 7·0° C. respectively. Analogous results were obtained with mixtures of cocoanut oil and beef-fat. A commercial sample of mowrah fat yielded glycerides of m. pt. 61·3 to 66·3° C., with m. pt. differences of —0·7° C. to +2·1° C.

Detection of lard in butter fat:—The palmitodistearin of butter fat melts at 62·9° to 63·1° C. (fatty acids, 62·4° to 63° C.), whilst lard stearodipalmitin melts at 58·0° C. (fatty acids, 55·2° C.). Additions of lard to butter cause the difference between the m. pts. of the more insoluble glycerides and their fatty acids to be greater than normal. In the case of four samples of pure butter the differences in the m. pts. in the last five of eight crystallisations ranged from —0·2° C. to 3·3° C., whilst butter containing 10 to 20 per cent. of lard showed differences of 2·3° to 5·8° C. for the more insoluble glycerides.

Detection of lard in goose-fat:—The most insoluble glyceride melted at 62·4° C. and contained fatty acids of m. pt. 58·2° C. The glycerides separated from mixtures of goose-fat with 20 and 30 per cent. of lard melted at higher temperatures, but the m. pt. differences between glycerides and fatty acids did not differ materially from those given by the pure goose-fat.—C. A. M.

Fatty acids; Catalytic reduction of unsaturated —— by means of nickel and nickel oxide. W. Meigen and G. Bartels. J. prakt. Chem., 1914, **89**, 290—301.

The hydrogenation of fats proceeded much more rapidly at first, and at a lower temperature (180° C.), when finely divided reduced nickel was used as catalyst than when nickel oxide (obtained by ignition of the nitrate) was employed, in which case a temperature of 250° C. was necessary. The view of Bedford and Erdmann (this J., 1913, 611) that a suboxide of nickel (Ni_3O) is formed during the reduction is rejected, and the opinion expressed that metallic oxides do not act as catalysts in the hydrogenation of unsaturated fatty acids but only the metal reduced therefrom. In experiments with nickel oxide, the presence of metallic nickel in the catalyst after use was proved by chemical analysis (the nickel content was higher than corresponded to a suboxide), by its electrical conductivity, and by the formation of nickel-carbonyl on treatment with carbon monoxide. In these tests, it was necessary carefully to exclude air, which very readily oxidised the finely divided reduced nickel.—A. S.

Fatty acids; Decomposition of —— by mould-fungi. A. Spieckermann. Z. Unters. Nahr. Genussm., 1914, **27**, 83—113.

One grm. of each of the pure fatty acids representing saturated, unsaturated, hydroxy- and keto-acids was mixed with 5 to 25 grms. of kieselguhr and 7·5 to 37·5 grms. of nutrient nitrogenous broths, and the mixture inoculated with cultures of *Penicillium glaucum*, *Aspergillus*, *Monilia*, etc. After periods of 2 to 5 weeks the residual fatty acid was recovered. In each case absorption of the fatty acid had occurred, ranging from 3·4 per cent. (arachidic acid) to 91·3 per cent. (myristic acid). The neutralisation values of the recovered acids were invariably lower by a few units, the decrease depending upon the extent of the decomposition. The iodine value of oleic acid was invariably reduced, whilst, on the other hand, the saturated fatty acids frequently showed an increased iodine value, particularly in the case of lauric acid (*e.g.*, 16·6). As a rule, the m. pts. were somewhat lower than before. Lauric acid was completely oxidised to water and carbon dioxide. Oleic, elaidic and erucic acids were decomposed by the moulds more slowly than lauric or myristic acids, but more rapidly than stearic and arachidic acids, whilst brassidic acid was decomposed more rapidly than fatty acids containing 12 to 18 carbon atoms.—C. A. M.

Olive oil; Rancidity of —— and oxidation of oleic acid in presence of sunlight. F. Canzoneri and G. Bianchini. Annali Chim. Appl., 1914., 1914, **1**, 24—32.

Samples of the same olive oil were respectively exposed to air and sunlight, exposed to air under similar conditions in the dark, and exposed to sunlight in a sealed tube from which the air had been exhausted. The first sample became rancid but the other two remained unaltered, indicating that the effect is due not to micro-organisms but to the action of air accelerated or determined by the action of light (see also Scala, this J., 1898, 359; 1908, 819). The action of air and oxygen on oleic acid was also studied. After exposure to air and light for 5 months, there were detected in the reaction product a white solid (m. pt. 50°—51° C.), probably stearolactone, nonylic, formic, azelaic, and dihydroxystearic acids, nonylic aldehyde, and the acids A and B obtained by Molinari by the decomposition of oleic acid ozonide. After exposure to oxygen and light for one week, the presence of nonylic and semi-azelaic aldehydes and azelaic, nonylic, di- and mono-hydroxystearic acids was detected. These results indicate that the decomposition of oleic acid by air or by oxygen in presence of light proceeds along similar lines to the decomposition by means of ozone (see Harries, this J., 1906, 1055, 1158; 1909, 250; Molinari, this J., 1906, 1055; 1908, 1073), the action taking place at the double linkages with a tendency to the formation of peroxides, aldehydes and acids of the type of nonylic compounds and their oxidation products, the latter becoming more complex the more the oxidation is prolonged.—A. S.

Soap solutions; Studies of the constitution of ——. The electrical conductivity of potassium salts of the fatty acids. H. M. Bunbury and H. E. Martin. Chem. Soc. Trans., 1914, **105**, 417—435.

The electrical conductivities of the potassium salts of the saturated fatty acids with an even number of carbon atoms in the molecule, from the stearate to the hexoate, were determined at 90° C.: they were generally higher than those of the sodium salts (this J., 1911, 222), but there was a general resemblance between the curves representing the variation of the conductivity with the concentration of the solution. The maxima and minima were more pronounced in the case of the potassium salts and to a greater extent than could be accounted for by the difference in the mobility of sodium and potassium ions. In the case of potassium palmitate the conductivities found were much lower than those predicted from the values for sodium palmitate. The differences between the maximum and minimum conductivity values were much more marked in the case of the potassium soaps, this being most strikingly seen in the case of the laurates. Potassium hexoate had the characteristic properties of a soap in concentrated solution but these at once disappeared on dilution. Potassium octoate behaved in a similar manner, whilst the decoate was the first to produce a typical though thin lather. The densities of the soap solutions increased very much less rapidly than the concentration. Thus, the excess of density of 2 N potassium laurate over that of water was only two-thirds of that predicted from the density of the 0·5 N solution.—J. A.

Caustic alkali; Determination of free —— in commercial soda compounds and soaps by the barium chloride method. A. Kling, V. Genin and D. Florentin. Bull. Soc. Chim., 1914, **15**, 200—205.

Precipitated barium silicate or borate is soluble in dilute aqueous solutions of barium chloride with the result that the method of determining free caustic alkali in soda compounds or in soaps which contain soluble silicates or borates, by precipitation of their aqueous solutions with barium chloride and subsequent titration of the clear liquid with $N/10$ acid gives inaccurate results. These salts, however, are insoluble in 50 per cent. alcohol and if, after the precipitation, a sufficient quantity of strong alcohol is added to the liquid to bring the alcohol concentration to 50 per cent., accurate results are obtained except in the case of soaps containing oleic acid, since barium oleate is slightly more soluble in 50 per cent. alcohol than in water.—J. A.

Patents.

Wool-grease; Process of treating —— and product thereof. C. Ellis, Montclair, N.J. U.S. Pat. 1,086,357, Feb. 10, 1914.

Wool-grease is heated with hydrogen free from arsenic, at a pressure of about 10 lb., and at a temperature above the temperature of decomposition of nickel soap, in the presence of a nickel catalyst.—E. W. L.

Unsaturated fatty acids, their glycerides and other esters: Process for the conversion [hydrogenation] of —— into corresponding saturated compounds. F. Bedford and C. E. Williams. First Addition, dated Aug. 19, 1913 (under Int. Conv. Aug. 21, 1912), to Fr. Pat. 436,295, Nov. 11, 1911 (see Eng. Pat. 29,612 of 1910; this J., 1912, 398).

A suboxide of nickel is used as the catalytic agent. It may be produced by heating a mixture of nickel oxide or an organic salt of nickel with the oil in a current of hydrogen.—C. A. M.

Unsaturated fatty acids and their esters; Process for converting [hydrogenating] —— into saturated compounds. De Nordiske Fabriker De-No-Fa Aktieselskap. Fr. Pat. 462,905, Sept. 24, 1913.

The basic salt of a heavy metal (*e.g.*, nickel or copper) with a fatty acid of high mol. weight is dissolved in the fatty acids, fat or oil, in the proportion of, say, 0·4 per cent., and the mixture hydrogenated at 100° to 180° C.—C. A. M.

Whale oil or fish oils; Process of removing the disagreeable odour from the fatty acids of ——. W. H. Hofmann. Fr. Pat. 462,763, Sept. 18, 1913. Under Int. Conv., Sept. 28, 1912.

The fatty acids are mixed with a resin and sulphonated at a temperature not exceeding 120° C. The product is repeatedly heated with water (with the addition of salt to prevent emulsification), and is then neutralised and distilled *in vacuo* or with superheated steam.—C. A. M.

Oil; Process for extracting —— from oil seeds and the like. Harburger Oelwerke Brinckman und Mergell. Ger. Pat. 269,195, May 12, 1912.

Before or during the extraction of the oil, preferably by means of solvents, the oil seeds are treated with aliphatic oxygenated compounds containing a methylene group, especially formaldehyde. For example, 2—3 per cent. of formaldehyde or other suitable compound may be added to the solvent used for extracting the oil. It is stated that the oil is extracted more rapidly and is less liable to spoil on keeping. The suitability of the residue for use as fodder is not impaired.—A. S.

Fat for use in the perfume and soap industries and for other purposes. P. de Baudicour and E. Cadoret de la Gabinière. Fr. Pat. 462,794, Nov. 30, 1912.

The resins of indiarubber, gutta-percha or analogous products (*e.g.*, jelutong, almedina) are mixed with castor oil, and subsequently with other resins, to form preparations suitable for soap, lubricants, polishing wax, extraction of perfumes, etc.—C. A. M.

Floating soaps; Process of manufacturing compact —— and products thereof. C. Muller. Fr. Pat. 462,502, Sept. 12, 1913.

A mixture of saponifiable fats (90 per cent.) with wax (10 per cent.) is saponified at about 75° C., and a small proportion of oxygen then introduced to make the soap porous and cause it to float in water.—C. A. M.

Soaps; Preparation of highly antiseptic soluble ——. Schülke und Mayr Nachf. Dr. Raupenstrauch. Fr. Pat. 462,724, Sept. 18, 1913.

p-Chloro-o-cresol or a mixture thereof with m-chloro-o-cresol is dissolved in the soap and water, with the subsequent addition of an alcohol (ethyl alcohol, glycerin or a mixture of the two). Or the antiseptic is mixed with the oil, fat, resin acids, etc., prior to saponification.—C. A. M.

Sulphonated oils and fats; Manufacture of ——. R. Russ, Rumburg, Austria. Eng. Pat. 21,853, Sept. 27, 1913.

See U.S. Pat. 1,081,775 of 1913; this J., 1914, 91.—T. F. B.

Treatment of effluents. [Recovery of grease.] Eng. Pat. 5754. *See* XIXb.

XIII.—PAINTS; PIGMENTS; VARNISHES; RESINS.

Oil from seeds of Kickxia elastica and Manihot glaziovii. Sprinkmeyer and Diedrichs. *See* XII.

Patents.

Oils; Drying ——. L. H. Dyke Acland, London. Eng. Pat. 5347, Mar. 3, 1913.

The drying of linseed oil is accelerated by the addition of ceara or funtumia rubber seed oil either in place of a portion of, or in addition to, the ordinary manganese or lead driers. The proportions recommended are 10—30 per cent. of ceara oil or 50—80 per cent. of funtumia oil. Rapid drying is also obtained by using a mixture of ceara and funtumia oils without linseed oil.—E. W. L.

Varnishes and paints; Antifouling ——. L. Collardon, West Bromwich. Eng. Pat. 9040, April 17, 1913.

A base for use in the manufacture of poisonous antifouling varnishes and paints consists of a compound of the condensation product of a phenol and an aldehyde with arsenic, mercury or copper. It may be prepared by heating together 100 grms. of crystallised phenol, 100 c.c. of 40 per cent. formalin, and 92 grms. of arsenious acid or 50 c.c. of a saturated solution of mercuric chloride. Sulphur dioxide (25 to 50 c.c. of a 10 per cent. solution) or an equivalent agent such as aluminium or magnesium chloride, or urea (25 c.c. of a 10 per cent. solution) may be added. The product is preferably boiled in water for an hour or more, in order to free it from excess of arsenic, or mercury, etc. The poisonous substance may be combined with the phenol first, and the product heated with formaldehyde. The final products are almost colourless, melt at about 90° C., and when heated to about 120° C. are converted into transparent resinous substances. —E. W. L.

Lac; Method of and means for treating ——. J. D. Morrison, Glasgow. From W. A. Freymuth, Umaria, Central India Eng. Pat. 18,563, Aug. 15, 1913.

The lac is placed in a bag and subjected to pressure between rotating buffer-heads; the buffer heads may be heated internally and radiant heat may be applied to the bag by means of a lamp, reflector, or electric radiator. The melted lac passing through the sides of the bag falls into a water-bath and is lifted and replaced on the buffers and bag, being manipulated subsequently until the desired plastic condition is attained.—W. P. S.

Coating composition; Protective ——. L. H. Baekeland, Yonkers, N.Y., Assignor to General Bakelite Co., New York. U.S. Pat. 1,085,100, Jan. 27, 1914.

The composition consists of a solution of a phenolic condensation product which is capable of transformation by heat into an insoluble and infusible body, in water containing the minimum proportion of alkali hydroxide requisite for the preparation of a stable solution. An inert filling material may be added.—E. W. L.

Resinous condensation product. E. S. Dawson, jun., Assignor to General Electric Co., Schenectady, N.Y. U.S. Pat. 1,085,112, Jan. 27, 1914.

Citric acid, a polyhydric alcohol such as glycerol, and an aromatic compound, *e.g.* *m*-dinitrobenzene, having insulating properties, are dissolved in alcohol, and heated to 125°—200° C. to produce a flexible, insoluble and infusible material.—E. W. L.

Wood; Process of extracting products [turpentine and rosin] from ——. W. B. Harper, Lake Charles, La., Assignor to The Castona Improved Process Co., Laino, Miss. U.S. Pat. 1,085,416, Jan. 27, 1914.

The wood is first steam distilled at a low temperature to drive off the turpentine, which is condensed and separated from the water. It is again steam distilled at a higher temperature and pressure sufficient to distil off the oils but not high enough to injure the wood or the rosin. The hot wood is then extracted in the still with a suitable hydrocarbon solvent and the rosin recovered from the solution by evaporation.—W. H. C.

Lacquers and varnishes; Process for the preparation of ——. S. H. Cohn. First Addition, dated Sept. 5, 1913, to Fr. Pat. 441,703, March 25, 1912 (this J., 1912, 886). Under Int. Conv., Oct. 5, 1912.

Oxidised oil of turpentine, pine oil, etc., crude or refined, may be employed as an addition to wood oil for the preparation of lacquers or varnishes, instead of the oils or terpenes of high boiling point referred to in the original patent.—E. W. L.

Frescoes, aquarelles, stereochromes, pictures painted with casein colours or in tempera, photographs, or the like; Process for cleaning or restoring ——. Act.-Ges. f. Anilinfabr., Treptow, Germany. Eng. Pat. 17,531, July 30, 1913. Under Int. Conv., May 15, 1913. Addition to Eng. Pat. 17,523, March 1, 1913.

See Fr. Pat. 459,922 of 1913; this J., 1913, 1163.—T.F.B.

Oil-varnish substitutes from animal oils; Process for the manufacture of ——. W. Kaempfe, Grossenhain, Germany. U.S. Pat. 1,087,064, Feb. 10, 1914.

See Fr. Pat. 445,565 of 1912; this J., 1913, 34.—T. F. B

Manufacture of a material suitable for electrical insulation and other purposes. Eng. Pats. 3271 and 3566. *See* XI.

Fat for use in the perfume and soap industries and for other purposes. Fr. Pat. 462,791. *See* XII.

XIV.—INDIA-RUBBER; GUTTA-PERCHA.

Caoutchouc; Synthetic —— *from isoprene.* C. Harries. Ber., 1914, **47**, 573—577.

The author dissents from Steimmig's statement (this J., 1914, 267) that all synthetic caoutchoucs differ from the natural product. The synthetic product examined in 1909 by the author (see this J., 1910, 502) certainly was an approximately pure polymeride of 1.5-dimethylcyclooctadiene. The product of hydrolysis of the ozonide gave phenylmethyldihydropyridazine almost pure and in high yield. Probably Steimmig's results were due to the use of impure isoprene. It is very difficult to obtain the pure substance, and the polymerisation is very much affected by the manner in which it is performed (cf. the sodium method) and also by factors at present inexplicable. The author obtained different results in parallel experiments with pure isoprene. Steimmig's results certainly explain the apparent loss of hydrolysis-products observed by the author when examining polymerisation-products of isoprene from other sources.—H. E. P.

Oil from seeds of Kickxia elastica and Manihot glazcovii. Sprinkmeyer and Diedrichs. *See* XII.

Transformation of dimethylallene into isoprene. Kutscherow. *See* XX.

Patents.

Rubber latex; Process and apparatus for coagulating and/or curing ——, *and for the antisepticising and drying thereof.* E. J. Byrne, London. Eng. Pats. 3707, Feb. 13, and 5160, March 1, 1913.

Latex passes downwards from a container into a funnel whence it drips on to the upper surface of a dome-topped vertical cylindrical drum, which may be heated by internal steam pipes. Pairs of annular pipes surround the drum, the upper pipe of each pair being designed to direct coagulating and/or curing vapours on to the downward-flowing latex, through horizontal jets, whereas the lower pipe has jets inclined downwards and is used for directing a spray of liquid coagulant on to the latex. The whole is enclosed in an outer casing or jacket. Latex which escapes coagulation falls with excess of acid on to the bottom of the chamber whence it is drained away. The sheet of rubber is removed by lowering the drum and cutting down one side with a knife.—E. W. L.

Rubber latex; Process for the coagulating, and/or curing of ——. E. J. Byrne, London. Eng. Pat. 26,199, Feb. 13, 1913.

Rubber latex is sprayed with a liquid coagulant such as acetic or pyroligneous acid, as it spreads itself or is spread in a thin layer over a surface. Smoke or coagulating (or curing) vapours or gases may be applied simultaneously or otherwise.—E. W. L.

India-rubber; Process for devulcanising and regenerating ——. M. Capel and J. Thiberville. Fr. Pat. 462,328, June 18, 1913.

Ground vulcanised rubber is heated in an autoclave with a mixture of two chemical reagents, one of which dissolves the rubber, whilst the other removes the combined sulphur, converting it into volatile sulphides, and the mass is finally treated with steam.—E. W. L.

Composition of matter [resilient or elastic masses] and method of preparing same. H. A. Gardner, Washington, D.C. U.S. Pat. 1,086,361. Feb. 10, 1914.

A finely-divided, insoluble, inorganic filling material is suspended in wood-oil which is then polymerised. The product, which is insoluble in all ordinary oil and varnish solvents, may be granulated.—E. W. L.

Caoutchouc; Process for promoting the vulcanisation of natural or artificial ——. Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. Eng. Pat. 11,615. May 19, 1913. Addition to Eng. Pat. 11,530 of 1913, dated Nov. 15, 1912.

See Ger. Pat. 266,619 of 1912; this J., 1914, 94.—T. F. B.

Indiarubber substitute; Process for the manufacture of ——. Soc. Thomas, Bazin, Casanova et Cie., Bordeaux, France. Eng. Pat. 19,871, Sept. 2, 1913. Under Int. Conv., Sept. 2, 1912.

See Fr. Pat. 447,904 of 1912; this J., 1913, 245.—T. F B.

India-rubber, gutta-percha, and other crude gum-resins; Process for the treatment of —— in order to obtain pure rubber. P. de Baudicour and E. C. de la Gabinière. Fr. Pat. 462,793, Nov. 30, 1912.

See Eng. Pat. 17,582 of 1913; this J., 1913, 1078.—E. W. L.

Fat for use in the perfume and soap industries and for other purposes. Fr. Pat. 462,794. *See* XII.

XV.—LEATHER; BONE; HORN; GLUE.

Gelatin; The equilibrium of dilute hydrochloric acid and ——. H. R. Procter. Chem. Soc. Trans., 1914, **105**, 313—327.

The swelling of gelatin or other amphoteric protein in dilute acid solutions depends on the osmotic pressures and equality of products of a di acid ionisable salt of the protein as a base and of the external acid with which it is in equilibrium. If the ionisation-constants and the molecular weight are known, all the other quantities are fixed. The ionic-concentrations in the jelly are all functions of that of the equilibrium acid, and independent of the chemical nature of the protein. The theory assumes that the jelly in equilibrium with the acid is a molecular solution, and discards the view of Bütschli and van Bemmelen that it is a two-phased structure. (See also this J., 1911, 226, 818.)—G. F. M.

Patents.

Hides; Method of treating —— before tanning. C. C. Moore and W. Trantom, Lymm, Cheshire. Eng. Pat. 18,890, Aug. 20, 1913.

Sodium chloride free from calcium and magnesium compounds and sulphates is used for preserving hides before tanning. With impure salt the hide-acid and hide-alkali substances react with calcium and magnesium salts present to give complex neutral salt reactions, whereby insoluble protein compounds are formed with the result that the yield of leathers is less, the filling, fatting, etc., of the leather is uneven and there is a liability to stains.
—D. J. L.

Hides and skins; Preparing —— for tanning and dyeing. E. d'Huart, Luxembourg. Eng. Pat. 23,841, Oct. 21, 1913.

The alkaline-earth used for unhairing hides and skins is removed by treatment with the glycerol ester of phosphoric acid or an alkali or alkaline earth salt of the same. The process is particularly applicable when strontium or barium hydroxide has been used as a depilatory. By using either free glycerophosphoric acid or the glycerophosphate of sodium, potassium or ammonium, bating may be carried out either in an acid or alkaline medium or the two may be used in succession. The acid treatment is more suitable for heavy hides containing much alkaline-earth. The action of the compounds of glycerophosphoric acid, which have at the same time a solvent action on albumin, may be increased by the addition of peptone, glue, glycerin, malt extract, bran drench, alkali bicarbonate, ammonium nitrate or ammonium salts of volatile fatty acids. When baryta or strontia has been used, the spent glycerophosphate bath may be revivified by the addition of sulphuric acid and removal of the insoluble sulphates. Glycerophosphoric acid may also be used in the preparation of tanned skins for dyeing where foul urine has formerly been used for the purpose of removing adhering residues of the tanning process and the prevention of penetration of the dyestuff. Particles still adhering to the skin after dyeing are mostly of a starchy nature and may be dissolved by diastase or malt extract.—D. J. L.

Skins; Process for degreasing ——. J. Filhol. Fr. Pat. 462,280, Nov. 18, 1912.

The skins are treated with tetrachloroethane either alone or with the addition of water, at a temperature of 35°—40° C., when the fat passes rapidly into a state of colloidal solution and is coagulated and deposited from the liquid separated from the skins, on cooling. The solvent is recovered by decantation and filtration. Raw skin may be degreased by the process, the solvent penetrating the tissues and facilitating the later penetration of tanning materials. Other solvents which may be used, are di-, tri-, and perchloroethylene and pentachloroethane. Exposure of the solvent to strong light should be avoided.
—D. J. L.

Skins; Treatment of —— with the wool or hair on. L. Beaudry and A. Grenouillet. Fr. Pat. 462,314, Nov. 19, 1912.

The wool-skins after washing are immersed in a bath yielding nascent sulphurous or thiosulphuric acid which may be produced electrolytically. If the wool or hair is required perfectly white, the skin is treated on that side with salts of the alkaline earths, particularly those of calcium, which will fix the acids liberated and cause them to bleach the wool or hair. The skin is then split with a machine specially designed for giving a uniform thickness when used for skins in the wool or hair and then softened, brushed and the wool or hair shaved to an equal and appropriate length.—D. J. L.

Tanning hides; Process of ——. G. S. Kimball, Camden, Ark., Assignor to M. W. Borders, Chicago, Ill. U.S. Pat. 1,086,538, Feb. 10, 1914.

The hides after preparation in the usual manner are immersed in the liquor produced by the destructive distillation of Ouachita cretaceous lignite effected at a temperature of 300°—450° F. (149°—232° C.).—D. J. L.

Tanning; New method of ——, new tanning products and processes for their manufacture. Badische Anilin und Soda Fabrik. Fr. Pat. 462,635, July 30, 1913. Under Int. Conv., Feb. 22, 1913.

Skins are treated with solutions of aromatic sulphonic acids, soluble in water, of amorphous character, not containing a phenolic hydroxyl group and capable of precipitating solutions of glue and gelatin. Such conditions are fulfilled by compounds of high molecular weight containing in the molecule several benzene or naphthalene nuclei and particularly those in which the nuclei are joined by intermediate carbon atoms. Soluble condensation products of formaldehyde and naphthalene are specially mentioned and may be obtained by treating the sulphonic acids of naphthalene or its homologues, in presence or absence of condensing agents, with formaldehyde or products capable of yielding the same. The conditions must be such that products soluble in water are produced. The products, insoluble in water, resulting from the condensation of naphthalene or its homologues with formaldehyde may also be treated with sulphonating agents.—D. J. L.

Leather; Treatment of —— for waterproofing and other purposes. W. C. Matthews, Stafford. Eng. Pat. 3563, Feb. 11, 1913.

The leather is heated or dried by placing on a hot surface and melted wax brushed upon it. Pressure may be applied, if desired, and the wax may be applied to the leather while on a block in the process of shaping.—D. J. L.

Skins; Process for hardening and rendering degrained —— impermeable. K. Hartmann. Fr. Pat. 462,690, Sept. 11, 1913.

The skins prepared in the usual manner are immersed according to their thickness for ½—1 hour in a bath of 4 parts by vol. of formalin to 20 parts of water. They are then immersed, without drying, for ½—1 hour in a bath of 4 parts by vol. of 40 per cent. nitric acid in 20 parts of water. After drying and smoothing it is stated the skin has the appearance of horn and will preserve its important qualities.—D. J. L.

Glue, gelatin, and the like; Process for the manufacture of ——. A. Löw, Vienna, and E. Fischer, Charlottenberg, Germany. U.S. Pat. 1,086,149, Feb. 3, 1914.

Bones are treated for 15 mins. with steam under a pressure of 3 atmospheres and then cooled rapidly under reduced pressure, a quantity of steam being meanwhile admitted so that sufficient condensed water is produced to dissolve the glue.—W. P. S.

XVI.—SOILS; FERTILISERS.

Influence of colloids on microbiological processes. Söhngen. *See* XVIII.

Patents.

Fertiliser from silicious, potassium-bearing rocks and minerals containing phosphoric acid; Process of producing a ——. Chem Fabr. Rhenania and A. Messerschmitt. Fr. Pat. 462,357, Aug. 13, 1913. Under Int. Conv., Aug. 14, 1912, Jan. 31, and June 17, 1913.

The rocks and minerals are mixed with calcareous material containing a quantity of free lime equal to at least two-thirds of the weight of the silicious rock, and are heated to not less than 1100° C. The raw materials should be very finely ground, made into a mud with water, formed into briquettes with a binding material, such as clay, plaster of Paris, or the like, and calcined in the damp state in rotary kilns. The resulting product is a fertiliser containing a high percentage of citric acid-soluble potash and phosphoric acid.—O. R.

Insecticide for plants. U.S. Pat. 1,085,898. *See* XIXb.

XVII.—SUGARS; STARCHES; GUMS.

Table syrup; Manufacture of —— in the West Indies. H. A. Tempany. West Indian Bulletin, 1913, **13**, 324—332.

For some years past table syrup or "fancy molasses" for consumption in Canada and the United States has been manufactured to a considerable extent in the West Indies, chiefly in Barbadoes. The requirements of the product are as follows: The density should not be less than 40° B. (sp. gr. 1·383); the direct polarisation should lie between 32° and 48° V.; it should not ferment or crystallise on prolonged standing; and it should be bright, free from suspended impurities, of a light golden colour when viewed in thin layers, and free from any flavour of acidity, and from all traces of mineral acid. In order that no crystallisation may occur, it is necessary that a certain proportion of invert sugar be present, and this is best ensured by inverting some of the sucrose. As the use of mineral acids contravenes the Pure Food Laws of the United States and Canada, in practice hydrolysis is effected by heating with a definite amount of fermented juice, which is added to the raw juice contained in the clarifier, heating and eliminating being then effected as in making Muscovado sugar. On heating, the proteins are coagulated, and according to the author, this renders unnecessary the addition of lime usually made in manufacturing sugar. While boiling down the acid liquor to the required density in the open pans employed in West Indian factories, more impurities separate, and these are carefully removed by fine mesh wire gauze "skimmers." The syrups should not contain any iron, and on this account the use of iron vessels for heating and concentrating should be avoided. Analyses of the syrups thus made in West Indian factories show the following limiting values: sucrose, 42·1—51·0; reducing sugars 20·0—32·8; ash, 1·3—3·3; water, 19·7—27·1 per cent.; direct polarisation, 35·0°—47·5° V.; density, 39·0°—41·5° B. (sp. gr. 1·370—1·404).—J. P. O.

Starch and the products of its hydrolysis. Behaviour of starch dextrins to different yeasts. Synthetic isomaltose. Von Friedrichs. *See* XVIII.

Patents.

Dextrin; Production of —— from starch of cassava root (Manihot utilissima). E. Riboud and C. Ahnert. Fr. Pat. 462,451, Sept. 11, 1913.

The dried and decorticated roots are powdered and roasted whilst the mass is moistened with water from time to time. The poisonous substances of the root are thus destroyed.—J. H. L.

Apparatus for the continuous solution of solid substances, especially for slaking lime with sugar juice or water. Ger. Pat. 270,045. *See* I.

XVIII.—FERMENTATION INDUSTRIES.

Starch and the products of its hydrolysis. O. v. Friedrichs. Arkiv för Kemi, Min. och Geol., 1913, **5**, Nr. 2. Chem. Zentr., 1914, **1**, 760—762.

Since the starch molecule consists exclusively of maltosans, and maltose is a glucose-α-glucoside, it follows that alternate linkages connecting two glucoside-forming residues in the starch molecule must correspond to the α-configuration. In similar manner the other linkages must correspond to the β-configuration, for starch is hydrolysed only to maltose by amylases and the saccharifying amylase is a β-enzyme. If this conception be correct there should be present three different sugars, viz., dextrose, a glucose-α-glucoside (maltose) and a glucose-β-glucoside in the product of the incomplete hydrolysis of starch by acids, as the action of the latter is not specific and fission could take place at any of the linkages. (See also this J., 1905, 1246.) Potato starch paste (300 grms. per litre) was hydrolysed by means of oxalic acid (0·05*N*) and in the resulting solution, after fractional precipitation and extraction with alcohol, destruction of dextrose and maltose by fermentation with brewer's yeast, and purification by dialysis, the presence of a disaccharide other than maltose was detected. It yielded a phenylosazone, m. pt. 146° C., slightly soluble in ethyl acetate, had $[\alpha]_D = 59 \cdot 1°$, was not fermented by yeast, but was hydrolysed by emulsin with formation of dextrose. It was thus characterised as a glucose-β-glucoside and is considered by the author as being identical with Fischer's isomaltose.

From the products of hydrolysis there were isolated also, by fractional precipitation with alcohol of different concentrations, three achroodextrins, two erythrodextrins

and an amylodextrin. The first achroodextrin ($[\alpha]^{18}_D=162{\cdot}6^\circ$, R=58, mol. wt. 683) was probably identical with Grüter's maltodextrin γ (see this J., 1904, 875). The second ($[\alpha]_D=172{\cdot}8^\circ$, R=42, mol. wt. 1021) was probably identical with Ling and Baker's maltodextrin β (this J., 1897, 154) and Prior's achroodextrin III. (this J., 1900, 549). The third ($[\alpha]^{18}_D=179^\circ$, R=30, mol. wt. 1061) was identical with Ling and Baker's maltodextrin α. The erythrodextrin II. had $[\alpha]_D=193{\cdot}1^\circ$, R=10, mol. wt. 2080; erythrodextrin I. had $[\alpha]^{18}_D=196^\circ$, R=3·6, mol. wt. 3286; and the amylodextrin had $[\alpha]^{18}_D=196$, R=0·6—0·9, mol. wt. 13,630 (*cf.* Baker, this J., 1902, 1087).
—A. S.

Starch dextrins; Behaviour of —— to different yeasts. O. v. Friedrichs. Arkiv. för Kemi, Min. och. Geol., 1913, **5**, Nr. 3. Chem. Zentr., 1914, **1**, 762—763.

The behaviour of the starch dextrins isolated by the author (see preceding abstract) to different yeasts is shown in the following table, in which the numbers indicate roughly the relative amounts of fermentation in the different cases: where no figures appear, no fermentation occurred :—

Kind of yeast.	Achroodextrin, $[\alpha]_D=162{\cdot}6^\circ$.	Achroodextrin, $[\alpha]_D=172{\cdot}8^\circ$.	Achroodextrin, $[\alpha]_D=179^\circ$.	Erythrodextrin, $[\alpha]_D=193{\cdot}1^\circ$.	Erythrodextrin, $[\alpha]_D=196^\circ$.
Mucor Rouxii	3	3	3	2	2
Sacchsia suaveolens	3	3	2	?	?
Schizosaccharomyces Pombe	3	3	3	2	1
Yeast Sinner II...........	2	1	?	?	?
Saccharomyces thermantitonum	1	1	1	—	—
,, *fragilis*......	—	—	—	—	—
,, *exiguus*	?	?	—	—	—
,, *Marxianus* ..	—	—	—	—	—
,, *ellipsoideus II.*	—	—	—	—	—
,, *Pastorianus I.*	?	?	?	—	—

The achroodextrins were fermented more rapidly than the erythrodextrins. The behaviour to *Sacchsia suaveolens*, which, according to Lindner, decomposes β-methylglucoside, indicates the probable presence of β-linkages in the molecules of the dextrins. Yeasts which ferment α-methylglucoside had little action on the dextrins. The achroodextrin with $[\alpha]_D=162{\cdot}6^\circ$ was fermented to the extent of 21·2 per cent. in 60 hours by bottom fermentation beer yeast.—A. S.

Isomaltose; Synthetic ——. O. v. Friedrichs. Arkiv. för Kemi, Min. och Geol., 1913, **5**, Nr. 4. Chem. Zentr., 1914, **1**, 763—764.

A 25 per cent. solution of dextrose in concentrated hydrochloric acid was saturated with hydrochloric acid gas, allowed to stand for 24 hours at 10° C., the acid removed by treatment with lead carbonate and silver carbonate, and the solution neutralised with hydrochloric acid. Experiments with different yeasts and with emulsin indicated that the reaction product contained approximately: dextrose 68, isomaltose 18, maltose 8 and unknown polysaccharides 6 per cent. After removing the dextrose and maltose by fermentation with brewers' yeast, the isomaltose was finally obtained as a glassy solid insoluble in absolute alcohol: its rotatory power was $[\alpha]^{18}_D=72{\cdot}76^\circ$. It was not hydrolysed by the enzyme of kephir, but was more or less rapidly fermented by *Sacchsia suaveolens* and *Sacch. fragilis* and *exiguus*. When hydrolysed by emulsin, in most cases the optical rotation increased instead of diminishing, indicating that emulsin probably contains an enzyme capable of transforming isomaltose into maltose.—A. S.

Yeast cells; Plasmolysis of ——. H. Euler and B. Palm. Biochem. Zeits., 1914, **60**, 97—111.

Yeast is capable of growth in solutions possessing a decidedly higher osmotic pressure than that within the cells. On keeping bottom-fermentation beer yeast for 2 hours in a 25 per cent. solution of glycerol, 71 per cent. of the cells were found to have undergone plasmolysis (complete separation of the plasm from the cell wall); in a 10 per cent. solution, 17·1 per cent. of the cells were plasmolysed. When the yeast was kept in a nutrient solution containing 15 per cent. of glycerol, the cells became acclimatised to the osmotic pressure of the solution, probably owing to a change in the permeability of the cell membrane; the young cells were much more readily acclimatised than the old ones. The rate of plasmolysis of the yeast in a 25 per cent. solution of glycerol approximately followed a logarithmic curve. The yeast employed grew more rapidly in nutrient solutions containing sucrose than in presence of dextrose.—L. E.

Fermentation; Significance of water in the processes of alcoholic —— and respiration of plants. W. Palladin. Biochem. Zeits., 1914, **60**, 171—201.

The actions of zymase, carboxylase, and reductase were retarded or even arrested by partial or complete substitution of other solvents (glycerol, ethyleneglycol, formamide, pyridine, ethyl alcohol) for water. In absence of water, neither the enzymes of alcoholic fermentation, nor those concerned in the anaërobic stage of respiration, exerted any action. In regard to the rôle of water in plant respiration, it is concluded that during this process, water is assimilated, and that in the anaërobic oxidation of the carbon of the sugar (dextrose), half of the requisite oxygen is derived from the sugar and half from the assimilated water, the whole of the carbon dioxide liberated being formed anaërobically. The hydrogen set free from the water assimilated by higher plants combines with respiration pigments (hydrogen acceptors; cp. Wieland, this J., 1913, 1132) which result from the oxidation of chromogens (see this J., 1913, 955). The whole of the oxygen assimilated by the plant during respiration is used in oxidising this combined hydrogen, and the water formed is of aërobic origin; the withdrawal of this combined hydrogen and its oxidation is effected by the agency of peroxydases. Wieland's experiments on the biological conversion of alcohol into acetic acid (*loc. cit.*) indicate that the oxidation is effected by oxygen derived from water, and many, if not all, cases of formation of highly oxidised compounds by plants are also probably due to oxidation at the cost not of atmospheric oxygen but of water, the atmospheric oxygen assimilated at the same time acting only as a hydrogen-acceptor.—L. E.

Alcoholic fermentation. VI. The nature of the reduction of acetaldehyde by living yeast. S. Kostytschew. Z. physiol. Chem., 1914, **89**, 367—372. (See also this J., 1912, 553, 741; 1913, 207.)

In the conversion of acetaldehyde into alcohol by living yeast, equimolecular proportions of ethyl alcohol and acetic acid are produced (*e.g.*, 0·557 grm. of alcohol and 0·729 grm. of acetic acid from 2 grms. of aldehyde in a suspension of 150 grms. of pressed yeast in 1500 c.c. of water). This confirms the hypothesis of a Cannizaro transformation,

$$2CH_3CHO+H_2O=CH_3.CH_2OH+CH_3COOH,$$

first made with respect to alcoholic fermentation by the author, and since included in a scheme of fermentation suggested by Neuberg and Kerb (this J., 1914, 37) who assume that it takes place between acetaldehyde and methylglyoxal.—J. H. L.

Yeast; Rôle of glycogen in fermentation by living ——. H. Euler. Z. physiol. Chem., 1914, **89**, 337—344.

A study of the change in the glycogen-content of yeast during fermentation of dextrose solutions, afforded no definite support for the hypothesis that glycogen is an intermediate product of fermentation. On the contrary, the author concludes that the difference (Δ—C) between the percentage fall in rotatory power of the liquid and the percentage production of carbon dioxide (see this J., 1912, 246, 1142) cannot be due to the formation of glycogen. This difference is independent of the amount of yeast employed for fermentation and is almost the same whether the sugar fermented is dextrose, lævulose or mannose.—J. H. L.

Colloids; Influence of —— on microbiological processes. N. L. Söhngen. Chem. Weekblad, 1914, **11**, 42—59. Chem. Zentr., 1914, **1**, 691.

The fixation of nitrogen by azotobacter was promoted by addition of colloids (colloidal silica, alumina, iron oxide, crude humus) to the nutrient solution. The decomposition of starch by *Bac. ochraceus*, which secretes an amylolytic enzyme very similar to the amylase of malt, was increased by addition of colloidal silica and humus, but diminished by colloidal ferric oxide and alumina. The oxidation of alcohol by acetic bacteria was accelerated by addition of blood charcoal, peat, and filter-paper. Colloids had no perceptible influence on the action of denitrifying organisms. The oxidation of petroleum by micro-organisms was accelerated by blood charcoal and colloidal ferric oxide and silica. (See also this J., 1913, 762.)—A. S.

Brewing; Improved process of ——. A. R. Ling and H. B. Wooldridge. J. Inst. Brew., 1914, **20**, 81—102.

In the process described (Wooldridge, Eng. Pat. 16,744 of 1910) all the brewing operations between mashing and fermentation are conducted in one closed vessel, and the danger of infection associated with the use of wort coolers and refrigerators is thus eliminated. After the mashing process, which is conducted as usual, the wort is run into a closed copper vessel provided with a steam jacket or coil, a false bottom on which the hops can rest, a sparger and the necessary valves, manholes, etc. The cover of the vessel is preferably dome-shaped to avoid loss of wort by "fobbing" during boiling, and from the top of the dome an outlet pipe, which can be closed, communicates with an exhaust pump. The necessary quantity of hops having been introduced, together with sugar or caramel when these are used, the wort is boiled in this vessel under a pressure of 6 lb. per sq. in. In order to maintain the liquid in ebullition during this operation, a small amount of steam is allowed to blow off, but the pressure must be maintained by passing steam through the jacket or coil. After boiling has continued for 15—20 mins. the pressure is reduced to about ½ lb. per sq. in. and the vessel is connected with a vacuum pump, so that the wort is boiled, cooled and concentrated under continuously diminishing pressure. The cooling may be accelerated by passing cold water through the jacket or coil. When the wort has been cooled to the pitching temperature it is run directly into the fermentation vats, the hops remaining in the copper, on the false bottom. For several years the process has been carried out weekly, in a vessel of 10 barrels' capacity. In this case the time required for the cooling of the wort to 60° F. (15·5° C.) by vacuum concentration alone is 4—5 hours, but this period can be reduced to less than 2 hours by running cold water through the coils. Sufficient concentration of the wort to arrive at turning-out gravity and to allow for at least a 10 per cent. hop sparge, is attained within half an hour of starting the vacuum pump. The extraction of resins from the hops is quite as complete as in the ordinary copper, and possibly more complete, provided always that the wort is kept in ebullition as described above. The process is equally suitable for the preparation of running ales, pale ales and stouts. The worts "break" better than those boiled in the ordinary way, the beers rack equally bright, respond much more readily to finings, and are lighter in colour and quite as stable as those prepared in the usual way. They also possess more palate-fulness and appear to be characterised by a somewhat higher content of dextrin. The new process makes no provision for the so-called hot aeration of the wort, which, according to Pasteur, is necessary to ensure proper flocculation or "break." The authors consider, however, and cite H. T. Brown in support of their view (see this J., 1913, 442), that the main condition which determines flocculation of a hot wort is mechanical agitation between certain critical limits of temperature during its cooling, *viz.*, between 120° and 80° F. (49° and 27° C.), and this condition is fulfilled by the vacuum concentration in the new process. The satisfactory character of the beers prepared by the process confirms the authors' view.—J. H. L.

Stout; Use of secondary fermentation yeasts in the preparation of —— and its practical results. W. Rommel. Woch. Brau., 1914, **31**, 88—89.

According to Claussen, the secondary fermentation and characteristic flavour of English stouts is due to certain torulæ, *e.g.*, *Brettanomyces* (this J., 1906, 709). Experiments in the "Versuchs- und Lehranstalt fur Brauerei," Berlin, have confirmed the presence of a number of secondary yeasts (which in form and appearance, however, do not much resemble the better known torulæ) in English stout yeasts. The use of mixed cultures of some of these organisms in the preparation of stout on the practical scale has proved very successful. The organisms are first grown in sterile stout, and then transferred to a few litres of sterilised dark beer wort. After about 8 days, the wort is added to the stout to be treated, which has already been kept in cask for 2—4 months; it is best to add to the stout at the same time, 3—6 per cent. of hopped fresh wort from the cooler. The process has been adopted in a number of breweries in Germany and elsewhere.—L. E.

Ethyl and methyl alcohols; Detection of ——. J. J. Blanksma. Chem. Weekblad, 1913, **11**, 26—29. Chem. Zentr., 1914, **1**, 574.

The method is based on the reaction of sodium methoxide or ethoxide with 1.2.4-chlorodinitrobenzene:

$$C_6H_3Cl(NO_2)_2+C_2H_5ONa=C_6H_3(OC_2H_5)(NO_2)_2+NaCl.$$

The alcoholic liquid is neutralised with magnesia or calcium carbonate, treated with a small quantity of *p*-nitrophenylhydrazine, 25 c.c. are distilled with the aid of Hahn's fractionating device (this J., 1910, 300, 842) and the proportion of total alcohol calculated from the density of the distillate in order to ascertain the quantity of chlorodinitrobenzene required. The remainder of the liquid is brought to an alcohol concentration of 90—95 per cent. by repeated distillation, treated with 12 mgrms. of sodium and 100 mgrms. of chlorodinitrobenzene, warmed, diluted with water, and the precipitated 1.2.4-dinitrophenetol (m. pt. 85·2° C.) or 1.2.4-dinitroanisol (m. pt. 86·9° C.) separated, dried, and its composition determined by mixing with one of the pure components and determining the melting point of the mixture:—

Mols. per cent. of dinitroanisol.	M. pt. of mixture.	Mols. per cent. of dinitroanisol.	M. pt. of mixture.
	° C.		° C.
0	85·2	61·6	61·5
19·5	75	72·4	76
34·4	66·2	90·8	81·8
43·6	54	100	86·9
53·8	53		

—A. S.

Patents.

Amyl alcohol; Manufacture of ——. J. Scheckenbach. Fr. Pat. 462,472, Sept. 11, 1913. Under Int. Conv., Sept. 21, 1912.

Materials such as starch, carbohydrates, or cellulose, saccharified if necessary, are subjected to the action of bacteria resistant to heat (capable of withstanding a temperature of 100° C. for half an hour). Other organisms may first be destroyed by sterilising the material, and pure cultures of the bacteria resistant to heat may be added subsequently.—J. H. L.

Fermentation of juices from beetroots, molasses or grains in presence of sulphurous acid; Process of —— for augmenting the yield of alcohol. V. Martinand. Fr. Pat. 462,967, Sept. 24, 1913. Under Int. Conv., Oct. 28 and Nov. 25, 1912.

The saccharine juices are maintained aseptic before fermentation by addition of sulphurous, thiosulphuric or hydrosulphurous acid or compounds thereof. At the commencement of fermentation ketoses, aldoses or aldehydes are added to combine with the small quantity of free sulphurous acid, whereby it becomes innocuous towards yeast, whilst retaining its antiseptic power towards bacteria, or it may be oxidised to sulphuric acid by addition of peroxides, phenols or polyphenols. Instead of adding to the juice invert-sugar, glucose or other aldehydic or ketonic compounds (*e.g.*, some previously fermented juice), hydrolytic agents such as mineral acids or invertase which will produce aldoses or ketoses from the sucrose present, may be used (cp. this J., 1913, 921).—J. H. L.

Beer; Process of charging ——. O. M. Lamsens, Detroit, U.S.A. Eng. Pat. 11,189, May 13, 1913.

See Fr. Pat. 457,789 of 1913; this J., 1913, 1026.—T. F. B.

XIXa.—FOODS.

Milk; Determination and significance of ammonia in ——. J. Tillmans, A. Splittgerber, and H. Riffart. Z. Unters. Nahr. Genussm., 1914, 27, 59—76.

Fresh milk contains from 3 to 4 mgrms. of ammonia per litre and the quantity increases as the milk undergoes decomposition on keeping. The ammonia-content is not altered by heating, but substances containing ammonia are formed which are precipitated together with the ammonia when the latter is determined by the magnesium chloride precipitation method (see below); these substances do not affect the results obtained by the vacuum distillation process. When heated milk is kept for some time, the quantity of ammonia present increases. The addition of cow-dung to milk does not immediately increase the ammonia-content, but on keeping the quantity of ammonia increases more rapidly than it does in clean milk. Although the amount of ammonia in milk affords no evidence of the presence of added impure water in milk, a large quantity of ammonia indicates that the milk contains an undesirable number of bacteria and, on this account, the authors are of the opinion that any milk containing more than 10 mgrms. of ammonia per litre cannot be considered to be fresh milk. The ammonia may be determined by distilling the milk serum (obtained by treating the milk with mercuric chloride and hydrochloric acid or with basic lead acetate and sodium phosphate) under reduced pressure in the presence of magnesia, or by treating the serum with magnesium chloride and sodium phosphate with the addition of a slight excess of sodium hydroxide, collecting the magnesium ammonium phosphate formed, and separating the ammonia by distillation with magnesia.—W. P. S.

Application of the method of determining the difference in the melting points of glycerides and their fatty acids. Bömer. *See* XII.

Patents.

Milk cultures; Apparatus for preparing ——. F. O. Mott, P. Price, and E. W. Jodrey, London. Eng. Pat. 3138, Feb. 6, 1913.

For the cultivation of lactic acid bacteria in milk an apparatus is employed consisting of a receptacle divided into two compartments; one of these contains the heating liquid (warm water) and the other the milk. This receptacle is enclosed in a casing having heat-insulating walls. A small vessel is provided at the top of the hot-water container for the purpose of reserving a quantity of the milk culture with which the next batch of fresh milk introduced may be inoculated.—W. P. S.

Milk; Method of stabilising —— *and product thereof.* G. W. McMullen, Picton, Ontario, Canada. U.S. Pat. 1,086,385, Feb. 10, 1914.

Milk is subjected to a temperature below 140° F. (60° C.) in an atmosphere saturated with water vapour, the treatment being sufficiently prolonged to render stable the milk without coagulating its proteins. Afterwards the cream is separated, two stable products being obtained.—W. P. S.

Corn, grains, and the like; Process and apparatus for the treatment of ——. J. C. A. Pointe, Dijon, France. Eng. Pat. 8381, April 9, 1913.

The grains are steeped first in sodium chloride solution, then in water at a temperature not exceeding the coagulating point of albumin, and the softened grains are delivered on to a rotating drum covered with perforated sheets. The grains pass between rubber rollers and the perforated surface of the drum, the softer portions passing into the interior whilst the husk is carried off by an exterior perforated travelling band. The material collecting in the drum is transferred to a helical kneader surrounded by a heating jacket and the paste is mixed with other suitable substances, for use in bread-making, etc.—W. P. S.

Flour and grain products; Treatment of ——. B. I. Levin, Manchester. Eng. Pat. 9539, April 23, 1913.

Potassium chlorate, or potassium perchlorate, is incorporated with the flour; other salts may be added simultaneously or separately. It is stated that the presence of potassium chlorate or perchlorate in the flour imparts "a slight and desirable astringency" to the water used in making the dough.—W. P. S.

Fruit and vegetable dust; Manufacture of ——. H. Friedenthal, Berlin. Eng. Pat. 17,723, Aug. 1, 1913. Under Int. Conv., Aug. 14, 1912.

Fruit or vegetables, dried and ground to a powder, are subjected to a current of air whereby the finer particles are separated and removed. The remaining coarser particles are again ground and subjected to a current of air, and the process is repeated until the whole, with the exception of a small quantity of woody tissue, has been converted into a fine powder.—W. P. S.

Tomatoes; Manufacture of an extract, similar to meat extract, from ——. G. Frerichs. Ger. Pat. 269,813, March 23, 1913.

Tomato juice is fermented with yeast, and then concentrated in the usual way. Or, tomato pulp may be fermented, and the fermented juice separated and concentrated.—A. S.

Flour; Method of improving the condition of ——. J. A. Wesener, Chicago. Eng. Pat. 16,938, July 23, 1913.

See U.S. Pat. 1,071,977 of 1913; this J., 1913, 957.—T.F.B.

XIXb.—WATER PURIFICATION; SANITATION.

Permutite; Water softening by ——. A. Bahrdt. Chem. Ind., 1914, 37, 122—130.

Experience at Moscow in the use of permutite for removing the hardness of water, showed that sometimes there was more magnesium in the filtered water than in the untreated water, and that the reactions between the alkaline earth metals and the permutite were reversible; also that calcium could displace magnesium from the magnesium permutite previously formed. When water containing magnesia, but free from calcium, was used in a boiler, the magnesia was deposited as mud without any scale formation. The sodium content of boiler-feed water may be allowed to increase to 5 grms. per litre without harm. Although the permutite process is simple to work and supervise, it is not necessarily the most suitable for use in every case, for with very hard waters the cost of the installation is high and varies with the hardness, whereas in the soda-lime process the cost varies with the quantity of water to be treated. The author recommends a combination of the two processes, in which temporary hardness and most of the magnesium are first removed by lime, and then the permanent hardness, by a permutite filter. Thus a water was obtainable of very slight alkalinity and with but little dissolved solids.—J. H. J.

Water; Removal of manganese from ——. J. Tillmans and O. Heublein. Z. Unters. Nahr. Genussm., 1914, **27**, 253—264.

The removal of manganous salts from drinking water by filtering the latter through material containing manganese dioxide depends on the combination of the manganese dioxide with the manganous oxide with the formation of a mangano-manganite; the acid radical of the manganous salt is, at the same time, liberated. In practice, this acid is always carbon dioxide since, even when manganous sulphate is present, the sulphuric acid reacts with the bicarbonates contained in all natural waters and liberates an equivalent quantity of carbon dioxide.—W. P. S.

Duralumin; Use of the aluminium alloy —— for the manufacture of domestic and cooking utensils. G. Fendler and W. Stüber. Hygien. Rdsch., 1914, **24**, 59—62. Chem. Zentr., 1914, **1**, 693.

Duralumin did not yield recognisable traces of copper to boiling 6 per cent. acetic acid or 2 per cent. sodium chloride solution, or when subjected to the action of these solutions for 4 days at the ordinary temperature. Tea, coffee, cocoa, milk and soup when boiled for ½ hour, or allowed to stand for 4 days at the ordinary temperature, in contact with duralumin, had no greater action than tap water on the alloy.—A. S.

Detection and determination of nitrites by means of diphenylbenzidine. Marqueyrol and Muraour. *See* XXIII.

Patents.

Lime-water, or the like: Apparatus for preparing —— for use in softening or purifying water. F. A. Anderson, Newcastle-on-Tyne. Eng. Pat. 3504, Feb. 11, 1913.

Lime is slaked in a perforated receptacle arranged in a small tank; water is then admitted and is mixed with the slaked lime by stirrers. The "lime cream" is conducted to a tray situated at the top of a cylindrical vessel having a conical lower end, and passes down a tube reaching nearly to the bottom of the vessel. Water is also admitted to the vessel by means of a pipe discharging on to the tray, a regulated proportion of this water being caused to pass down a narrow pipe extending to the bottom of the vessel in order to stir up the lime settling at the bottom. The clear lime-water is withdrawn from the top of the vessel.—W. P. S.

Hardness of water; Compound for removing the ——. Vereinigte Seidenfärbereien C. A. Langenbeck and I. P. Lohe. Fr. Pat. 463,044, Sept. 27, 1913. Under Int. Conv., Jan. 9, 1913.

The compound is prepared by mixing 100 litres of a 10 per cent. solution of sodium phosphate with 1 litre of a solution of sodium silicate, and heating the mixture to boiling; the precipitate obtained is washed, dried at 65° C., ground and sifted.—J. H. J.

Boiler-feed water or other water; Method of and apparatus for treating —— particularly for preventing incrustation. H. Genssen and W. Wiebelitz, Rostock, Germany. Eng. Pat. 5949, March 10, 1913.

The water is passed through an electrolytic tank and then through a number of tubes made of an alloy of copper, zinc, and nickel; these tubes may be inclined so that the rate of flow of the water through them is about 13 feet per second.—W. P. S.

Oxygen; Removal of —— from water which is to be used for industrial and household purposes. R. Gans. Fr. Pat. 462,446, Sept. 11, 1913. Under Int. Conv., Sept. 11, 1912.

A reducing compound of sulphur, such as a sulphite, a thionate or a sulphide is added to the water, with or without a catalyst, for example a salt of iron or copper. When the treated water is caused to boil, it is claimed that there is no corrosion of the iron of the containing vessel by the disengagement of oxygen.—J. H. J.

Effluents; Treatment of ——. [*Recovery of grease.*] E. V. Chambers, T. C. Hammond, and G. G. Jarmain, Huddersfield. Eng. Pat. 5751, Mar. 8, 1913.

The effluent is treated with washed flue gases until all carbonates present are converted into bicarbonates, and is then aerated in an open tank. A greasy scum rises to the surface and is removed by travelling scrapers and delivered into tanks, where it is heated and treated with sulphuric acid in the usual way for the recovery of the grease. The liquid from which the scum has been removed is heated under reduced pressure, or is treated with lime or sodium hydroxide, to convert the bicarbonates into carbonates, and is then again suitable for washing wool, etc.—W. P. S.

Sludge from waste waters; Fermentation and mixing of ——. Comp. Claricite. Fr. Pat. 462,573, Nov. 25, 1912.

Air or other gas is passed under pressure continuously or discontinuously through blowers disposed in the sludge tank in any desired position. The process is applicable to sludge which is capable of undergoing bacterial action, and the complete fermentation of which is desired.—J. H. J.

Insecticide for plants and process of making the same. K. Fischer, Schweinfurt, Germany. U.S. Pat. 1,085,898, Feb. 3, 1914.

Schweinfurt green is mixed with ammonium carbonate and heated until the mixture assumes a blue colour; the ammonium-copper-arsenic compound formed is soluble in water.—W. P. S.

XX.—ORGANIC PRODUCTS; MEDICINAL SUBSTANCES; ESSENTIAL OILS.

Ipecacuanha; The alkaloids of ——. II. O. Keller. Arch. Pharm., 1913, **251**, 701—713. (See also this J., 1911, 1332.)

Methylemetine hydriodide was produced by gently warming emetine with methyl iodide and allowing the mixture to stand. The solid which separated was dissolved in methyl alcohol and precipitated by means of ether. When trimethylemetine hydriodide, or the corresponding quaternary base, was subjected to dry distillation above 300° C., trimethylamine and tetramethylammonium hydroxide were isolated from the basic products by means of their gold salts. Emetine and the quaternary trimethylemetine base were distilled in a current of hydrogen with zinc dust at about 340° C. Guaiacol, ammonia, trimethylamine and another base were produced, the latter giving a gold salt melting at 244°—248° C.
—F. Shdn.

Tetrahydrostrychnine; Some experiments with ——. (*Strychnine alkaloids. XXI.*) H. Leuchs. Ber., 1914, **47**, 536—540.

By the acetylation of tetrahydrostrychnine a colourless crystalline diacetyl derivative was obtained (m.pt. 142°—143° C.). This yielded on saponification with alcoholic potassium hydroxide a N-monoacetyl derivative, and on oxidation in acetone solution with potassium permanganate a small quantity of diacetylhexahydrostrychninonic acid was isolated in crystalline form (m.pt. about 140° C.).
—G. F. M.

Medicinal waters; Changes which take place in distilled —— and method of sterilising them to ensure stability. A. Juillet. Bull. scient. et ind. de la maison Roure-Bertrand fils 1913, [3], **8**, 22—34. Chem. Zentr., 1914, **1**, 569.

The diminution in the content of hydrocyanic acid in distilled cherry-laurel water on keeping is attributed to the action of micro-organisms; it is not observed in the case of sterile preparations. Sterile cherry-laurel, orange-blossom, lime-blossom and rose waters can be obtained by using apparatus which has been previously sterilised, or by sterilising the waters prepared in the usual way, *e.g.* by passing them through a Chamberland filter.—A. S.

Phenol bases. II. J. v. Braun. Ber., 1914, **47**, 492—505. (See this J., 1912, 1051.)

WITH regard to phenol bases homologous to hordenine, it appears that neither methylation of the nitrogen atom nor increasing the length of the side chain alters the principal pharmacological action. When benzoylphenylbutylamine was nitrated, the nitro group entered the *para* position. On reducing the nitro-product with tin and hydrochloric acid and splitting off the benzoyl group by careful heating with hydrochloric acid under pressure, [*d*-*p*-hydroxyphenyl]-butylamine, $OH{\cdot}C_6H_4{\cdot}(CH_2)_4{\cdot}NH_2$, was obtained. After crystalling from ether and light petroleum it melted at 106°—108° C. The hydrochloride melted at 194°—195° C., and the platinum double salt at 212° C. The pharmacological action of *m*-hydroxytetrahydroquinoline and *m*-hydroxydihydromethylketol was similar to that of hordenine but less pronounced. The former base, $C_9H_{11}ON$, was prepared by a series of reactions from 1-benzoyl-7-nitrotetrahydroquinoline. It boiled at 200°—202° C. at 16 mm., and melted at 94°—95° C.; the hydrochloride melted at 159° C. and the picrate at 174° C. Starting from *m*-nitro-N-benzoyldihydromethylketol, *m*-hydroxydihydromethylketol, $C_9H_{11}ON$, was prepared. This distilled at 186°—188° C. at 16 mm., and melted at 86°—87° C. after crystallising from ether and light petroleum. The hydrochloride melted at 165° C. and the picrate at 174° C. *p*-Aminobenzoylhordenine, $NH_2.C_6H_4.CO.O.C_6H_4.(CH_2)_2.N(CH_3)_2$, obtained by careful reduction of the *p*-nitrobenzoyl compound of hordenine (m pt. 89°—90° C.) melted at 156°—157° C. and yielded a picrate m.pt. 204°—205° C. It had an anæsthetic as well as a pronounced toxic action.—F. SHDN.

Galactite and α-ethylgalactoside; Identity of ——. E. Fischer. Ber., 1914, **47**, 456—459.

GALACTITE obtained from lupins by Ritthausen (Ber., 1896, **29**, 896) yielded ethyl alcohol and galactose when hydrolysed with dilute sulphuric acid at 100° C. The results obtained by elementary analysis agreed better with the formula $C_8H_{16}O_6$ (ethylgalactoside) than $C_9H_{18}O_7$, given by Ritthausen. The substance had [*α*]D = +185·2°—+186·2° in aqueous solution, melted at 141° C., and was undoubtedly identical with *α*-ethylgalactoside. It was probably formed in Ritthausen's experiments by the interaction of sulphuric acid, ethyl alcohol, and galactose. —F. SHDN.

Mustard seed; Oil content of black ——. *Localisation of certain alkaloids. The alkaloid of Vasconcellea hastata. Hydrocyanic acid content of cherry laurel leaves.* D. H. Wester. Ber. deutsch. Pharm. Ges., 1914, **24**, 123—131.

SMALL comparison cultures of black mustard showed that manuring with a mixture of ammonium sulphate, potassium nitrate and calcium phosphate produced plants with more flowers, and larger fruits containing more seeds. Seeds from plants grown on manured soil contained 1·18 and 0·89 per cent. of mustard oil, whilst seeds from plants grown on unmanured soil yielded 0·82 and 0·80 per cent. of oil.

A number of plants were examined microscopically for alkaloids. The latter were detected by the precipitate produced with a weak solution of iodine in potassium iodide, confirmed by proof of its solubility in an alcoholic solution of tartaric acid. The alkaloids were located in the parts named of the following plants: *Buxus sempervirens*, epidermis; *Ruta Graveolens*, epidermis of leaves, principal vein and leaf-stalk; *Carica Papaya*, leaf epidermis and to a lesser extent in the underlying parenchyma, epidermis of leaf-stalk; *Vasconcellea hastata*, epidermis of the leaf, principal vein, and leaf-stalk; also in the pith of the leaf-stalk, epidermis of flowering head, the fruit and the seeds (the alkaloid present in this plant is undoubtedly carpaine); *Pilocarpus Jaborandi*, epidermis of leaves; *Erythroxylon coca*, upper and lower epidermis of leaves, epidermis of leaf-stalk.

The hydrocyanic acid content of young cherry laurel leaves falls from 0·172 to 0·213 per cent. down to 0·110 to 0·159 per cent. as the season advances from the summer to the autumn. Third year leaves contain less hydrocyanic acid than first year leaves. Manuring with ammonium sulphate, potassium nitrate and sodium phosphate raises the hydrocyanic acid content.—F. SHDN.

Japanese mint oil. J. C. Umney. Perfum. and Essent. Oil Rec., 1914, **5**, 41.

"DEMENTHOLISED mint oil" is the trade name for Japanese peppermint oil from which the menthol has been partially removed by freezing; it contains from 45 up to sometimes even 55 per cent. of menthol (see this J., 1913, 306; 1914, 159). Recently much larger proportions of menthol have been extracted from the oil in Germany by a more efficient process, and since the residue from this treatment, very poor in menthol, is being sold as dementholised Japanese mint oil, the author draws attention to the need of purchasers insisting on a guaranteed percentage of menthol (not less than 45 per cent., free and combined).—A. S.

Ylang-ylang oil; Valuation of ——. J. C. Umney. Perfum. and Essent. Oil Rec., 1914, **5**, 37.

THE results of the examination of a large number of samples of ylang-ylang oil of different origin are shown in the following table:—

	Manila.	Bourbon.	Madagascar.	Mayotte.
Sp. gr. at 15° C.	0·927—0·969	0·964—0·967	0·961—0·981	0·947
Optical rotation	—38° to —51°	—39° to —41°	—30° to —42°	—48°
Refractive index at 20° C.	1·494—1·505	1·5130	1·5122	1·5070
Ester value	99·6—153·2	142·6—160·1	123·2—171·2	114·7
Non-volatile (after drying for 2 hours on water-bath	4·3—16·4%	25·1—40·3%	16·9—29·3%	14—19%

The characters of pure samples of the inferior cananga oil fell within the following limits: sp. gr. at 15° C., 0·910—0·940; optical rotation, —17° to —55°; refractive index at 20° C., 1·495—1·505; ester value, 45—100. (See also Bacon, this J., 1908, 875; 1909, 906)—A. S.

Essential oils from W. Africa. Roure-Bertrand fils. Bul. scient. et ind. de la maison Roure-Bertrand fils, 1913, [3], **8**, 16—22. Chem. Zentr., 1914, **1**, 541—542

THE leaves of *Popowia Capea*, a native of the Ivory Coast, yielded 0·59 per cent. of oil by steam distillation. About two-thirds of the oil was heavier and one-third lighter than water. The characters of the two portions and of the total oil are shown in the following table:—

	Total oil.	Heavy oil.	Light oil.
Sp. gr. at 20° C.	1·0042	1·0081	0·9960
Optical rotation	+76° 56′	+90° 54′	+51° 26′
,, ,, after acetylation	+13° 48′	+18° 4′	+ 5° 12′
Acid value	2·8	1·5	3·7
Saponif. value	166·1	192·3	123·2
,, ,, after acetylation	239·9	248·3	218·4

The total oil and the light oil dissolved in ½ vol. and the heavy oil in 1 vol. of 95 per cent., and all three were soluble in an equal volume of 80 per cent. alcohol; the solutions became turbid on standing. The oil contained esters and alcohols (one with an odour resembling that of cinnamyl alcohol) and about 6 per cent. of substances which combined with bisulphite.

Oil of the leaves of *Ocimum Canum*, Sims. At the ordinary temperature the oil (yield 0·65 per cent.) consisted of a white crystalline mass permeated by a slightly yellowish oil, and containing about 87 per cent. of methyl cinnamate. The characters were: sp. gr. 1·0330 at 32° C., optical rotation —2° 30′ at 30° C., acid value 0, saponif. value 301·4, soluble in 2½ vols. of 75 per cent. and gave a slightly turbid solution with 5½ vols. of 70 per cent. alcohol. The liquid portion of the oil appeared to consist of strongly lævo-rotatory hydrocarbons insoluble in 95 per cent. alcohol.

Oil of Ocimum gratissimum was a clear golden-yellow liquid containing 44 per cent. of thymol; sp. gr. 0·9105 at 15° C., optical rotation —0° 58′; it dissolved in 1·2 vols. of 80 per cent. alcohol but the solution became turbid on standing.—A. S.

Terpenes and essential oils. Part 116. *Reduction of carvoxime and eucarvoxime by means of palladium and hydrogen.* O. Wallach. Annalen, 1914, **403**, 73—96.

By reduction with hydrogen in presence of colloidal palladium, carvoxime was converted into a crystalline substance, m. pt. 66°—67° C., which proved to be a mixture of carvoxime and carvotanacetoxime. On allowing the reduction to proceed further, ammonia, carvacrylamine and tetrahydrocarvone were produced. Carvotanacetone took up hydrogen in the presence of palladium chloride nearly twice as fast as either *d* or *l*-dihydrocarvone. Treated in the same way eucarvoxime yielded a new crystalline tetrahydrocarvoxime, m. pt. 56°—57° C. This was converted into the semicarbazone, which could be resolved into two modifications melting at 161°—163° C. and 200°—201° C. The tetrahydroeucarvone regenerated from the semicarbazone boiled at 207° C., had the sp. gr. 0·906 at 20° C., and n_D=1·4553. It gave a nitroso compound m. pt. 104°—105° C. Partial reduction of eucarvoxime under similar conditions led to the formation of a new β-dihydroeucarvoxime, m. pt. 122°—123° C. β-Dihydroeucarvone prepared through the semicarbazone was a yellowish liquid boiling at 213°—214° C., sp. gr. 0·9325 at 21° C., n_D=1·4790. This ketone differed in its properties from the α-dihydroeucarvone obtained by a series of reactions from α-dihydroeucarveol which had been produced by reducing eucarvone with sodium.

—F. Shdn.

Phenylacetaldehyde: A new method of preparing —— and its derivatives. P. Jehl. Sealed Note No. 1374, dated Jan. 17, 1903. Report thereon by E. Noelting. Bull. Soc. Ind. Mulhouse, 1913, **83**, 805—806.

Sixteen grms. of methyl cinnamate are dissolved in 20 grms. of methyl alcohol and 10 grms. of bromine slowly added. The liquid solidifies on cooling. 12 grms. of caustic soda in 24 grms. of water are then added with agitation, the temperature not being allowed to rise above 40° C. After two hours sufficient sulphuric acid is added to neutralise all the alkali employed, whereupon the flocculent precipitate dissolves and an oil separates. After diluting to 250 c.c., 5·5 grms. of sodium carbonate are added, the phenylacetaldehyde distilled with steam and extracted from the distillate with ether. The yield is 75 per cent. of the theoretical. Nitrocinnamic acid treated in the same way gives an aldehyde smelling of cinnamon. The report explains the process by the formation first of the dibromide of the cinnamic ester, then its hydrolysis to phenylglyceric ester, which gives the lactone, and then, by loss of carbon dioxide, the phenylacetaldehyde. This method avoids the necessity of isolating any intermediate products, in which it differs from that of Erdmann described in Ger. Pats. 107,228 and 107,229 of Nov. 20, 1898 (see Eng. Pat. 5248 of 1899; this J., 1900, 273.)—J. B.

Isoprene; Transformation of dimethylallene into ——. Isomeric transformations of hydrocarbons with two double linkages. L. Kutscherow. J. Russ. Phys.-Chem. Ges., 1913, **45**, 1634—1654. Chem. Zentr., 1914, **1**, 753—754.

Dimethylallene $(CH_3)_2C:C:CH_2$, was obtained from trimethylbromoethylene, $(CH_3)_2C:CBr.CH_3$, with a yield of 45 per cent., by heating with alcoholic potassium hydroxide for 2½—3 hours at 135°—140° C. and 11—13 atmospheres pressure: to prevent oxidation it was distilled over in a current of nitrogen or carbon dioxide from the reaction product. When dimethylallene was heated with a 15—20 per cent. solution of quinoline hydrobromide in quinoline in a sealed tube for 10—12 hours at 130°—135° C., it was largely converted into isoprene (yield 50—55 per cent.), isopropylacetylene, $(CH_3)_2CH.C⋮CH$, being also formed. The crude isoprene was converted into a mixture of bromides, $C_5H_{11}Br$ and $C_5H_{10}Br_2$, by Ipatiew's method, the dimethyltrimethylene bromide separated by fractional distillation, and converted into isoprene (yield 75—80 per cent.) by heating to 150°—160° C. with powdered potassium hydroxide.—A. S.

Formic acid; Catalytic synthesis of —— under pressure. G. Bredig and S. R. Carter. Ber., 1914, **47**, 541—545.

By the action of hydrogen under high pressure on bicarbonates, or of a mixture of hydrogen and carbon dioxide under pressure on carbonates or other salts of weak acids, in the presence of a catalyst such as finely divided palladium, considerable quantities of formic acid can be produced. The following table gives a summary of the results obtained:—

Weight of palladium in grms.	200 c.c. solution used containing	Temperature	Pressures of gases in atmosphere.	Duration of experiment (hours).	Yield of formate, per cent.
		°C.			
0	10 grms. $KHCO_3$	70	H_2 60	24	0·6
1·5	10 grms. $KHCO_3$	70	H_2 60	23	74·7
1·5	10 grms. $KHCO_3$	95	H_2 50	26	66·3
1·5	0·4 grm. $CaCO_3$	70	H_2 20 + CO_2 20	4·5	100
1·5	9·5 grms. $Na_2B_4O_7.10H_2O$	70	H_2 30 + CO_2 30	16	21·7
1·5	10·6 grms. Na_2CO_3	70	H_2 60	7	0·4

—W. H. P.

Formic acid and benzene; Mutual solubility of ——, and the system: benzene-formic acid-water. A. J. Ewins. Chem. Soc. Trans., 1914, **105**, 350—364.

Pure formic acid was prepared by repeated fractionation in a distillation apparatus specially constructed to avoid contact of the vapour or liquid with cork, and recrystallisation by allowing the cooled acid to melt slowly under such conditions that the liquid portions could drain away, atmospheric moisture being always carefully excluded owing to the hygroscopic nature of the acid. The recrystallisation was continued till the melting point remained constant at 8·39° C. The critical solution temperature of the acid obtained in this way in pure benzene was 73·2° C., whilst that of the purest acid obtained by fractionation (b. pt. 100·5°—100·55° C., at 760 mm.) was 77° C. The sp. gr. of the pure acid was 1·2258—1·2260 at 18°/4° C. The benzene used was purified by recrystallisation and distillation over sodium in apparatus constructed entirely of glass. Varying weights of the two liquids were sealed in glass bulbs which were slowly heated, and the temperatures at which the liquids mixed were observed. The curve obtained by plotting solution temperatures against percentages of formic acid in the mixture showed a maximum critical solution temperature of 73·2° C., at a concentration of 48 per cent. of formic acid, the curve in the neighbourhood of the critical temperature being very flat. Determinations of the critical solution temperature of a given sample of formic acid in pure benzene gave a more trustworthy indication of the presence of water than determinations of the melting point. For instance 0·099 per cent. of water depressed the freezing point by 0·16° C., but raised the critical solution temperature from 73·2° to 75·8° C.—F. SHDN.

Formaldehyde and formaldehyde compounds; Detection of small quantities of —— by means of fuchsin-sulphurous acid-hydrochloric acid. H. Fincke. Z. Unters. Nahr. Genussm., 1914, **27**, 247—253.

THE reagent is prepared by dissolving 1 grm. of rosaniline hydrochloride in 500 c.c. of water, adding 25 grms. of crystallised sodium sulphite and 15 c.c. of hydrochloric acid (sp. gr. 1·124), and diluting the mixture to 1 litre. Ten c.c. of the liquid to be tested for formaldehyde are acidified with 2 c.c. of hydrochloric acid and 1 c.c. of the reagent is added; if formaldehyde is present, a red-violet colouration appears within a period varying from a few minutes to 12 hours. The presence of the hydrochloric acid prevents other aldehydes from giving a colouration with the reagent. It is advisable to apply the test directly to the solution or liquid without submitting the latter to a previous distillation; coloured liquids, such as wines, etc., may be treated with hydrochloric acid and animal charcoal before being tested. In the case of vegetable substances, there is a tendency for any formaldehyde present to enter into combination and escape detection; this combined formaldehyde is not liberated when the substance is treated with a mineral acid. Urea also combines with formaldehyde. Milk combines with formaldehyde to a small extent, but the greater part of the aldehyde is obtained when the milk is distilled with the addition of phosphoric acid. The test will detect the presence of 1 part of formaldehyde in about 400,000 parts of liquid. The reagent is also useful for the detection of hexamethylenetetramine when this has been decomposed by hydrochloric acid, but formaldehyde, or hexamethylenetetramine, when combined previously with sulphurous acid yields but little, if any, colouration with the reagent, even after treatment with hydrochloric acid.—W. P. S.

Chemical action of light. XXVIII. Autoxidations. VII. G. Ciamician and P. Silber. Atti R. Accad. dei Lincei, Roma, 1914, **23**, I., 113—119.

DIFFERENT organic acids in aqueous solution or in presence of water, in large flasks filled with oxygen were subjected to prolonged exposure to sunlight. Among the reaction products were detected: formic acid from acetic acid; formaldehyde and carbon dioxide from glycollic acid; carbon dioxide from oxalic acid (a 2 per cent. solution was completely oxidised in 7 months); carbon dioxide, formaldehyde and acetic acid from malonic acid; carbon dioxide, acetaldehyde, acetic and propionic acids and glyoxal from succinic acid; carbon dioxide, formaldehyde, and glyoxal from glyceric acid; carbon dioxide and formic acid from saccharic acid; salicylaldehyde, the dihydrocoumarin of Dyson, and salicylic acid from coumarin; formic acid, nonylic acid and other lower fatty acids, azelaic acid, and dihydroxystearic acid (m. pt. 133° C.) from oleic acid.—A. S.

Arsenic compounds; A new class of aliphatic ——. E. Fischer. Annalen, 1914, **403**, 106—117. (See also this J., 1913, 549.)

PURE behenolic acid was heated with 1¼ times its weight of arsenic trichloride to 140° C. for 6 hours. The excess of arsenic trichloride was removed by distillation under reduced pressure, or the mixture obtained was dissolved in ether and shaken with water. The product was converted into chloroarsinosobehenolic acid by dissolving the ethereal residue in strongly cooled $N/1$ potassium hydroxide solution. The alkaline salt was decomposed by hydrochloric acid and the oily arsenic compound taken up with ether. Prepared in this way the substance was mixed with some behenolic acid which could be removed to a great extent by cooling to —50° C. Chloroarsinosobehenolic acid undoubtedly contains the grouping —C(AsO) : CCl—. The neutral solution of the potassium salt can be kept for a few hours, but in the presence of excess of alkali, decomposition readily takes place with the production of potassium arsenite and behenolic acid. The free acid was methylated, treated with bromine and then with water, when the methyl ester of chlorobehenolarsinic acid was produced. The corresponding acid prepared through the strontium salt had the composition, $C_{23}H_{44}O_5AsCl$, and was fairly stable when heated with aqueous alkaline solutions.—F. SHDN.

PATENTS.

Tobacco leaves; Process of bleaching ——. T. Oelenheinz, Karlsruhe, Germany. U.S. Pat. 1,086,306, Feb. 3, 1914.

THE leaves are treated with water at a temperature of from 75° to 100° C., and then subjected to the action of an aqueous solution containing hydrogen peroxide and ammonia.—W. P. S.

Unsaturated aliphatic hydrocarbons; Treatment of mixtures containing ——. E. C. R. Marks, London. From E. I. du Pont de Nemours Powder Co., Wilmington, Del., U.S.A. Eng. Pat. 29,961, Dec. 30, 1912.

XXII.—EXPLOSIVES; MATCHES.

Acids from nitrocellulose manufacture; Source of error in the analysis of waste ——. T. Chandelon. Bull. Soc. Chim. Belg., 1914, **28**, 58—62.

BY either the method of Lunge or of Griesheimer (Chem. techn. Untersuchungsmethoden, Aufl. 6, I., 407) the nitric and nitrous acids are determined together; the nitrous acid is then found by titration with permanganate, and the nitric acid by difference. Oxalic acid which may be present in small quantities as an oxidation product of cellulose, would cause high values for nitrous acid and low values for nitric acid to be obtained. It would accumulate in repeatedly used baths, and render a correction necessary. It may be determined by neutralising the acid with ammonia, boiling until nitrous acid is destroyed, and titrating in the cold with permanganate.
—O. E. M.

Explosives in coal mines. Chem. Trade J., March 14, 1914 [T.R.]

AN amending Explosives in Coal Mines Order (No. 17 adding to the new list of permitted explosives certai explosives which have passed the Rotherham Test, has been issued by the Home Secretary. The names and composition of the new explosives are as follows :—

Ingredients	Parts by weight.	
	Not more than	Not less than
Bellite No. 4 (Lancashire Explosives Company, Ltd.)		
Nitrate of ammonium	68	64
Di-nitro-benzol	15	13
Chloride of sodium	21	19
Moisture	1	—
Faversham Powder No. 2 (Cotton Powder Company, Ltd.)		
Nitrate of ammonium	48·5	45·5
Nitrate of potassium	25	23
Tri-nitro-toluol	11	9
Chloride of ammonium	19·5	17·5
Moisture	1	—
Kent Powder (Cotton Powder Company, Ltd.)		
Nitro-glycerine	25	23
Nitrate of potassium	33·5	30·5
Wood-meal (dried at 100° C.)	31	28
Oxalate of ammonium	11	9
Moisture	6	3
Monarkite (Kyaoch-Arklow, Ltd.).		
Nitro-glycerine	13	11
Nitro-cotton	0·5	—
Nitrate of ammonium	51	48
Nitrate of sodium	8·5	6·5
Chloride of sodium	26	23
Starch	5	3
Mineral jelly	2·5	1·5
Moisture	2	0
Monobel No. 1 (Nobel's Explosive Company, Ltd).		
Nitro-glycerine	9·5	7·5
Nitrate of ammonium	70	66
Wood-meal (dried at 100° C.)	9	7
Chloride of sodium	16	14
Moisture	2	—
Swale Powder (Cotton Powder Company, Ltd.)		
Nitro-glycerine	20	18
Nitro-cotton	1·5	0·5
Tri-nitro-toluol	5	3
Perchlorate of potassium	38·5	36·5
Wood-meal (dried at 100° C.)	10	8
Oxalate of ammonium	29	27
Moisture	2	—

The usual stipulations are made in each case as to quality, markings, packing, etc. (See also this J., 1914. 103.)

Use of the "Mammoth-pump" in chemical industry. Meerbach. *See* I.

Patents.

Nitration of cellulose or its derivatives by means of nitric acid vapours. Deutsche Celluloidfabrik. Ger. Pat. 269,246, Feb. 10, 1912.

The cellulose is exposed to nitric acid vapour in a high vacuum at a temperature not exceeding 50° C. Uniform products of any desired nitrogen content can, it is stated, be obtained with quantitative yields.—A. S.

Explosive priming compositions. C. Claessen, Berlin. Eng. Pat. 6057, March 11, 1913.

See Fr. Pat. 455,369 of 1913 ; this J., 1913, 960.—T. F. B.

XXIII.—ANALYTICAL PROCESSES.

Mechanical precipitation in the determination of sulphuric acid, sulphates, calcium and potassium. L. Ledoux. Bull. Soc. Chim. Belg., 1914, **28**, 51—52.

Potassium is first precipitated as the chloroplatinate. This is dissolved in 150 c.c. of water, 5 c.c. of concentrated hydrochloric acid, is added in the shaker and 0·5 grm. of chemically pure magnesium. The agitation is continued, with 20 c.c. of concentrated hydrochloric acid, for 30 minutes. The reduced platinum is filtered off, washed, and ignited.—O. E. M.

Nitrites ; Detection and determination of —— by means of diphenylbenzidine. Marqueyrol and H. Muraour. Bull. Soc. Chim., 1914, **15**, 186—197.

The authors confirm Wieland (Ber., 1913, **46**, 3296) that in the diphenylamine reaction for the detection of nitrites and other oxidising agents the first step in the production of the blue colour is the formation of diphenylbenzidine, which is then converted by the oxidising agent into a quinonoid derivative, the principal constituent of the blue solution. Diphenylbenzidine is hence a much more delicate reagent for nitrites than diphenylamine. It may be prepared by adding a solution of 8 grms. of diphenylamine in 20 c.c. of acetic acid to 50 c.c. of sulphuric acid (sp. gr. 1·842) previously diluted with 150 c.c. of water and cooled. To this mixture a solution of 4·7 grms. of sodium bichromate in 200 c.c. of water and 29 c.c. of sulphuric acid (1 : 4) is added, constant stirring being maintained for about five minutes. The liquid is added to 100 c.c. of sodium bisulphite solution (sp. gr. 1·231) and 400 c.c. of water and the mixture heated on a water-bath until the dark green precipitate first formed changes to a light brown. After cooling, the precipitate is filtered off, washed with water and alcohol, dried, and the diphenylbenzidine extracted with boiling toluene. A yield of about 60 per cent. of the theoretical is obtained. —J. A.

Copper, cobalt, and nickel ; A new reaction for ——. G. Malatesta and E. Di Nola. Boll. Chim. Farm., 1913, **52**, 819—823, 855—860. Chem. Zentr., 1914, **1**, 820—821.

The reaction of copper with 1.2-diaminoanthraquinone-3-sulphonic acid, described by Uhlenhuth (this J., 1910, 1085), is intensified by addition of ammonia, and the reagent can also be used for the detection of cobalt and nickel. All three metals give a blue colouration or precipitate with the reagent : on addition of excess of ammonia the blue colour is intensified in the case of copper and cobalt, but changed to red in the case of nickel. The colourations due to cobalt and copper may be distinguished by adding ammonium chloride : there is no change in the case of cobalt, but with copper, the colour changes to red. In presence of ammonia 0·0000002 grm. Co or 0·000005 grm. Ni in 1 c.c. can be detected.—A.S.

Nickel ; Colourimetric determination of ——. V. Lindt. Z. anal. Chem., 1914, **53**, 165—172.

The red colouration produced when an ammoniacal nickel solution is treated with potassium thiocarbonate solution is compared with that produced under similar conditions by a solution containing a known amount of nickel. The solution to be tested and the comparison solution are both diluted with dilute ammonia to a volume of 20 c.c. and treated with 0·5 c.c. of a 4 per cent. potassium thiocarbonate solution. The nickel-concentration should be between 0·017 and 0·012 mgrm. per c.c., and the thiocarbonate solution employed must be not more than 7 days old. Metals of the hydrogen sulphide group, and manganese, cobalt, and zinc should not be present. —W. P. S.

Selenium ; Gravimetric determination of ——. J. Meyer. Z. anal. Chem., 1914, **53**, 145—154.

Solutions containing selenium lose appreciable quantities of selenium dioxide by volatilisation when evaporated on the water-bath ; the loss is very considerable when free hydrochloric acid is present and may, by repeated evaporation of the solution with hydrochloric acid, amount to upwards of 80 per cent. of the weight of the selenium. The addition of potassium or sodium chloride does not prevent this loss. To determine selenium in a nitric acid solution by reduction to the metal, the solution should be neutralised with ammonia, then rendered slightly acid with hydrochloric acid, and the boiling solution treated with hydrazine hydroxide solution. The flask in which the reduction is carried out should be provided with safety-bulbs containing water in order to retain fine particles of selenium which escape from the flask with the evolved gases.—W. P. S.

Mineral waters; Determination of gaseous hydrocarbons dissolved in [natural] ——. E. Hauser. Comptes rend., 1914, **158**, 634—637.

A KNOWN volume (V) of the water is rendered alkaline, in order to fix the acid gases, and then shaken for 15 mins. with about the same volume (v) of air. A test for methane, etc., may then be made by applying the combustion method to the resulting gas; further, from Henry's law, the volume (x) of gaseous hydrocarbon originally dissolved in the volume (V) of water is given by

$$\frac{w^2}{w-w_1}$$

where w and w_1 represent the volumes of combustible gas obtained from the same specimen of water by two successive extractions with air in the manner already described. For waters containing very small amounts of dissolved hydrocarbons only one extraction is necessary. The maximum and minimum values of x are then given, respectively, by

$$\frac{wv}{v-\sqrt{wv}} \quad \text{and} \quad \frac{uv}{v-w}$$

The method has been applied to the determination of the solubility of methane in water, with results intermediate between those obtained by Bunsen and by Winkler.—J. R.

PATENTS.

Density of gases: Apparatus for measuring the ——. K. Bomhard and G. König. Ger. Pat. 269,862, Feb. 23, 1913.

THE density is measured by determining the power required to set a device in rotation or other motion, in the gas; or two similar devices may be set in motion, one in the gas and the other in air, and the density of the gas calculated from the ratio of the power required in the two cases. In the apparatus described two tubular members are mounted loosely on a hollow shaft and are caused to revolve at the same time, one in the gas under examination and the other in air, by a cross-piece connected with the shaft and mounted so that it can rotate. According to the relative resistance offered by the gas under examination and by the air, one member revolves faster than the other, thus causing the cross-piece to rotate. The latter is connected with a pointer which moves over a scale.—A. S.

Trade Report.

Patent Law. Resolution of Association of Chambers of Commerce.

THE Association of Chambers of Commerce of the United Kingdom, at its annual meeting on March 11th, passed the following resolution, submitted by the Manchester Chamber:—

"That in view of the fact that Mr. Justice Parker's comments in Hatschek's case in the year 1909 as to the extent of the onus devolving upon any applicant who seeks revocation of a patent for non-working under Section 27 of the Patents and Designs Act, 1907, have deprived the section of its effectiveness, this association urges upon the Government to amend the rules in such terms as will place the burden of proof on the patentee, while adequately safeguarding him from vexatious and frivolous applications—an effect which was the object of those who drafted the Act of 1907; and that a deputation be appointed to interview the President of the Board of Trade on the subject."

Book Received.

CHEMISTRY AND ITS BORDERLAND. By ALFRED W. STEWART, D.Sc., Lecturer on Organic Chemistry in the Queen's University of Belfast, etc. Longmans, Green and Co., 39, Paternoster Row, London, New York, Bombay, and Calcutta. 1914. Price 5s. net.

THIS volume (8 by 5½ ins.) contains frontispiece, 306 pages of subject-matter, with 11 illustrations and 2 plates and an alphabetical index of subjects. The arrangement of the text is on the following lines:—I. The ramification of chemistry. II. The allies of chemistry among the sciences. III. Relations between Chemistry and Industry. IV. Immuno-chemistry and some kindred problems. V. Colloids and the ultra-microscope. VI. The work of the spectroscope. VII. Chemistry in space. VIII. The inert gases and their place among the elements. IX. Radium. X. Niton. XI. Transmutation. XII. Nature of the elements. XIII. Chemical problems of the present and future. XIV. Methods of chemical research. XV. Organisation of chemical research. Appendix A. Scheme for better utilisation of the research capacity of the country. B. Regulations for scholars, fellows, and grantees of the Carnegie Trust for the Universities of Scotland. C. Regulations for scholars and bursars of the Royal Commission for the Exhibition of 1851.

Journal of the Society of Chemical Industry.

Official Notice.

HEAT TEST COMMITTEE.

The Departmental Committee of the Home Office, having submitted its first report, is now prepared to examine any supplementary test or tests which may be submitted, and asks if any members of this Society have any test which they are disposed to put forward. Up to the present, the Committee has received no suggestions in regard to a supplementary test of explosives containing nitroglycerin. Communications should be addressed to Major H. Coningham, Secretary of the Committee, Home Office, Whitehall, S.W.

London Section.

Meeting held at Burlington House, on Monday, March 2nd, 1914.

PROF. W. R. HODGKINSON IN THE CHAIR.

BLASTING GELATINE: SOME NOTES AND THEORIES.

BY W. A. HARGREAVES, M.A., B.SC., B.C.E., F.I.C.,

Chief Inspector of Explosives, South Australia.

Blasting gelatine is the most powerful explosive in general use for mining purposes, and it forms a base for a general class of high explosives called "gelatines." It is officially defined as consisting of nitro-cotton, carefully washed and purified, combined with thoroughly purified nitroglycerin in such proportions that the whole shall be of such character and consistency as not to be liable to liquefaction or exudation, and with or without calcium or magnesium carbonate not exceeding two parts by weight in every 100 parts by weight of the finished explosive. In actual practice blasting gelatine consists only of nitroglycerin and nitro-cotton.

The ordinary process of manufacture is to add to nitro-cotton of known gelatinizing power the calculated quantity of nitroglycerin in the cold and mix roughly by hand: then after standing for some hours the temperature is raised and more complete incorporation is made, usually in a mixing machine. Since different lots of nitro-cotton may appear to have different gelatinizing powers and since the tendency to exudation of nitroglycerin from the finished blasting gelatine appears to depend in some way on the nitro-cotton, manufacturers have used varying percentages of nitro-cotton which have been as low as 7 per cent. and as high as 9 per cent. in blasting gelatines brought to South Australia.

Over 14 years' experience as an Inspector of Explosives has shown me that manufacturers, even the best, have not been able to arrive at a definite quantity of nitro-cotton to use, and also have not been certain of producing every time a blasting gelatine that will comply with the official definition given above. So far as nitroglycerin is concerned there has been no trouble for many years, owing to the fact that it is a homogeneous liquid and can be thoroughly washed free of all the impurities which are liable to make it unstable. In the case of nitro-cotton the difficulties are great, owing to its physical condition, and there is always the possibility of small impure particles remaining in the cotton surrounded and protected from the washing liquid by the colloidal matter of which the nitro-cotton is composed. The particles may be only the size of pin points, but they may serve as centres of instability, so that when the blasting gelatine is subsequently submitted to the "heat test" a low result may be obtained. It is quite a common experience in the case of blasting gelatine which has been condemned on account of low heat test to find that one portion of a cartridge will give a low test, when other parts of the same cartridge may pass the test. Apart from the difficulty of low test, which can be minimised by extra care in the preparation of the collodion cotton, there is also the more common trouble of exudation of nitroglycerin. This, indeed, may be regarded as the chief difficulty that manufacturers have to face, for no brand of blasting gelatine imported to Australia is free from liability to exude nitroglycerin when subjected to the trials of the voyage and the storage after arrival. Time after time shipments of blasting gelatine have to be condemned, wholly or in part, on account of this exudation.

It is evident, therefore, that either the true nature of blasting gelatine has not been understood or else the means of avoiding this defect have not been known. The usual and accepted remedy has been to increase the proportion of nitro-cotton, but this is open to several grave objections. In the first place, if the percentage of nitro-cotton is too high the risk of getting a low heat-test explosive is increased; secondly, the blasting gelatine is likely to be insensitive to detonation by the ordinary No. 6 detonator; thirdly, the balance of oxygen is likely to be upset, so that owing to the reduced percentage of nitroglycerin the generation of carbon monoxide is increased; and fourthly, the cost of the explosive is greatly increased. The last is by no means the least important from a manufacturer's point of view.

To find what is the real nature of blasting gelatine is, therefore, a problem of importance. Direct experiment and observation can teach much, but the difficulties of arriving at knowledge by pure deduction are very great, and one is perhaps justified in erecting on the foundation of a few observed facts an hypothesis which can be tested by subsequent observations and experiments. As my hypothesis has stood the test of four or five years' careful observation by those who are well qualified to form an opinion, I am now publishing it in the hope that it will help manufacturers to overcome some of their difficulties, and that it will be of assistance to those who, like myself, frequently have the grave responsibility of dealing with explosives which do not completely satisfy the official definition referred to above.

The theory is that blasting gelatine, instead of being a solution of a small quantity of nitro-cotton in a relatively large quantity of nitroglycerin, is in reality a colloidal solution of a certain quantity of nitroglycerin in nitro-cotton intimately mixed with some free ungelatinized nitroglycerin.

Bütschli has described a hydrogel as having a fine webbed micro-structure. This description has not been unanimously endorsed, but it conveys an idea of the mechanical condition of a jelly which explains some facts. Assuming for the present that a hydrogel has some such structure, it may take up in the meshes proportions of water which will vary with the size of the meshes, with the size of the threads or fibres constituting the structure, and possibly with the nature of these jelly "fibres," their power of adsorption, etc. It has been shown that silicic acid and other colloidal substances may be obtained with varying amounts of water of hydration. It may be assumed that a similar thing occurs in the case of blasting gelatine, where a solution of nitroglycerin in nitro-cotton or *vice versa* produces a gel having apparently the properties of a finely webbed structure, which adsorbs or otherwise entangles liquid nitroglycerin in the meshes. The proportion of nitroglycerin so held will vary chiefly with the size of the meshes and the size of the filaments or "fibres" of the gel. Hence blasting gelatines apparently similar in all outward respects may be obtained with varying ratios of nitro-cotton to nitroglycerin and they may lose varying quantities of nitroglycerin by exudation without making any apparent change in the appearance of the jelly. We have assumed that a portion of the nitroglycerin has "dissolved" in the nitro-cotton. As this is not quite the same thing as a chemical combination, the quantity of nitroglycerin so dissolved will be subject to some amount of variation without making much change in the appearance of the jelly. Assuming that a given quantity of a certain nitro-cotton can "dissolve" a certain quantity of nitroglycerin, but that owing to mode of manufacture it has dissolved or combined with a less quantity and formed a jelly of quite satisfactory appearance, then it is reasonable to suppose that the nitro-cotton will go on "dissolving" more nitroglycerin at a diminishing rate till it is saturated. The saturation point will probably depend on the temperature and on climatic conditions. There will, however, be a difference in this action from the original solution in so much as, while in the first instance nitroglycerin is in contact with nitro-cotton, now nitroglycerin is in contact with a jelly, and owing to the physical nature of this jelly in impeding contact of nitroglycerin with the nitro-cotton unacted upon or not saturated, the final stages of solution will be very slow, and only likely to occur on prolonged storage of the explosive. It seems reasonable to suppose that if a manufacturer has calculated a quantity of nitro-cotton based on its observed gelatinizing power as determined in the laboratory, but that owing to the fact of exudation having occurred with a similarly made blasting gelatine, he is tempted to increase the percentage of nitro-cotton, it may happen that on prolonged storage the whole or almost the whole of the free nitroglycerin goes into solution. The result is that there is produced a blasting gelatine which is either wholly a jelly or is such that the minute particles of free nitroglycerin in the interstices are far apart and separated by walls of jelly.

The second part of my hypothesis is that in blasting gelatine the explosive wave following detonation is transmitted by the free nitroglycerin, and only imperfectly or not at all by the jelly. If there is no free nitroglycerin or the particles of it are too far apart, the blasting gelatine becomes "insensitive." It has been shown by Dr. Comey and others that the nitroglycerin contained in 75 per cent. dynamite transmits the explosive wave at a velocity of between 6,000 and 7,000 metres per second, and nitroglycerin in an iron tube of large enough bore will give a rate of over 7,000 metres per second, but for a 10 per cent. dynamite the rate is only 2,000 metres per second, which is about the rate for gelignite unless the wave gets a greater impetus from the explosion of a dynamite primer. Even then the wave slows down as it progresses, inversely as the percentage of nitroglycerin in the gelignite. It appears therefore, that if the amount of free nitroglycerin in a gelatine is small, and the particles are far apart, or the connecting threads or surfaces have small sectional area, or if there is no free nitroglycerin at all, the rate becomes that of the jelly itself. From its physical nature it presents a buffer to the initial shock and deadens the subsequent wave. Hence the blasting gelatine in these circumstances is "insensitive" and inert and requires a stronger detonator or even a primer to get proper explosion. Such blasting gelatines are condemned by the miner and are dangerous to use on the score of misfires and incomplete detonation producing noxious gases, and are wasteful in failing to do the required work. The hypothesis therefore explains some facts which are common knowledge, namely that some gelatines on prolonged storage become insensitive, that the harder the jelly the more likely it is to be insensitive, and such gelatines require more powerful detonators than those in common use, and even then may not give satisfactory explosions.

Mr. C. Napier Hake, late Chief Inspector in Victoria, made the observation that if an insensitive gelatine is "remade" by mixing it with a large percentage of a fresh batch of gelatine, it will infect the mass and the re-made blasting gelatine will soon undergo change and become more or less insensitive. This is explained by the above hypothesis, since the free nitroglycerin of the new batch is added not to nitro-cotton but to an existing jelly having probably excess of nitro-cotton, and the initial trouble is perpetuated because the gelatinization at the time of re-making is thus interfered with, and goes on slowly during storage, and in the end the particles of free nitroglycerin are either separated too far apart or are absent altogether.

The theory assumes the fact of there being free nitroglycerin in blasting gelatine. It is difficult to get direct proof of this, but it is obvious that, since liquid nitroglycerin can be obtained from blasting gelatine merely by pressure, and also by means of blotting paper, the nitroglycerin is not chemically combined with the nitro-cotton. Neither could the nitroglycerin which is thus removed have been in solution, or in the collodial state. Hake has shown (this J., Sept. 15th, 1905) that porous wrappers will cause exudation even in the case of blasting gelatines that show no tendency to exude when in ordinary wrappers. The probability is therefore, that there is generally some nitroglycerin in the "free" or liquid state in the explosive. If the free nitroglycerin is near the limit, the tendency to exudation will be greater than when the nitroglycerin is smaller in quantity.

A sponge can take up a certain amount of water, but if the quantity is near the extreme limit, slight conditions such as gentle pressure will cause some of the water to drip out. By continued pressure all water, but that adsorbed on the fibres of the sponge, can be removed, and even then more water may be removed by contact with blotting paper. Further, the finer the meshes of a sponge and the greater the surface of the fibres, the greater the amount of water adsorbed, and the less is likely to drip out; so also with the blasting gelatine the more complete the jelly the less free nitroglycerin is likely to exude. On the hypothesis that the jelly itself is made by solution of some nitroglycerin in nitro-cotton, the more jelly formed in this way within limits, the more free nitroglycerin will be adsorbed, and the less enmeshed or entangled nitroglycerin there will be, and hence the less tendency to exudation. The particles or "fibres" of the jelly being "wetted" by nitroglycerin by surface action or capillary attraction, the free nitroglycerin can flow or move through the jelly. Suppose the surface of the cartridge is in contact with blotting paper or porous wrappers, the flow of nitroglycerin can continue in the meshes of the paper. The same sort of action occurs at the fold of the cartridge paper, where one thickness of paper overlaps the margin of the first fold, forming a small longitudinal tube attached along one side to the gelatine. The flow of free nitroglycerin is "attracted" by capillary action into this tube. Thus many gelatines show a line of free exuded nitroglycerin along the fold, and exudation does not proceed any further. Again, if this flow is checked by placing an impervious layer round the outside of the cartridge, exudation may be stopped or at any rate considerably reduced. Such a layer might be obtained by the action of a coagulant on the jelly of the cartridge. Absorbents of the nature of French chalk are apt to increase the capillary attraction, although they soak up the exuded nitroglycerin for a time, but substances like magnesium oxide appear to coagulate the jelly surface and thus check exudation. It may be possible to find a surface coagulant which will effectively stop exudation. Blasting gelatine exuding badly has been placed in fresh wrappers and in a few days' time exudation has been as bad as ever, but if the cartridges were dusted with light magnesium oxide before they were placed in fresh wrappers, in some instances there has been practically no furthe exudation for several weeks. In the meantime th explosives could be put to their legitimate use.

The theory of the constitution of blasting gelatine ha already rendered great assistance in elucidating th perplexing behaviour of gelatine explosives.

The extent of exudation that occurs at any given tim with different cartridges, possibly of the same lot of blastin gelatine, may vary considerably. To have ready means reference various scales have been proposed, but the on adopted in South Australia consists of five degrees bas on actual cartridges. According to the theory we assum that excessive exudation represents an unbalanc explosive, and that probably gelatinization has not be complete. Acting on this assumption, one favours lengt storage under observation of such an explosive, and frequently happens that when it is subsequently re-wrapp so as to remove the exuded nitroglycerin, no furth exudation takes place. It sometimes happens th re-wrapping is unnecessary, the exuded nitroglyce having been re-absorbed, possibly by capillary action, the stronger gel produced by the secondary gelatinizati On the other hand, if such material is placed in n wrappers at first there is every probability of furt exudation taking place before the secondary gelatinizat has made any progress, and the condition of the explosive may be soon as bad as it was at first. In these circumstanes re-wrapping is not recommended unless the material is to be consumed at once.

In his report on the "Composition of the Gases caused by blasting in mines" (see this J., 1911, 447, 128t), E. A. Mann has drawn attention to the fact that unaltered fragments of nitro-cotton can be seen in blasting gelatine. He further says that the general experience in Western Australia is that an explosive which, on landing from Europe, is soft and plastic, will after a lengthy storage in a magazine become stiff and more rigid to the touch, while the common experience is that such explosives explode only under excessive stimulus, and are very apt to leave unexploded portions in the bottom of the bore holes in mines. This is also the experience in South Australia. I suggested to Mr. Mann that the theory outlined above would explain these phenomena, and his study of the question led him to believe that it was a "rational and convincing explanation for some of the problems involved."

S. Soddy in "Arms and Explosives" (February, 1912), referring to the decrease of sensitiveness of gelatines on prolonged storage, gives the results of lead block tests, which showed that blasting gelatine with a No. 6 detonator which gave a volume of 570 to 600 c.c. when first tested, at the end of twelve months' storage gave only from 420 to 430 c.c. On repeating the experiments with No. 7 detonators all gave normal results. He sees in the theory I have suggested an explanation of these results. It seems to me that Soddy's results might be explained as follows. Assuming that during manufacture the usual plan was followed, by which a preliminary mixing of the nitro-cotton and nitroglycerin would be made, an imperfect gel would be produced. On standing overnight the excess of nitroglycerin would slowly act on the already formed gel and some enclosed nitro-cotton, and at the final mixing more action would take place, but in would not be so complete as it would have been, had the nitroglycerin been thoroughly incorporated with the nitro-cotton in the first instance. The reaction would continue slowly when the explosive was put in store for twelve months. If enough nitro-cotton had been used to prevent exudation at the time the explosive was sent out from the factory, it would in reality have too much nitro-cotton and consequently all the free nitroglycerin would be turned to the gel form, or at any rate the remaining particles of free nitroglycerin in the "meshes" of the gel would be too small in number or too far apart to transmit the explosive wave set up by the No. 6 detonator at sufficient velocity to get complete detonation. A No. 7 detonator, on the other hand, might give sufficient stimulus to reach from one particle of nitroglycerin to another and so normal results would be obtained.

In this connection it is interesting to revert to Comey's experiments on rate of detonation. In determining the rate with nitroglycerin, when ¼ inch bore glass tubes were used for holding the nitroglycerin, the explosive wave was not transmitted. The column could only be detonated for a few inches from the detonator. The velocity of detonation when ¾ inch glass tubes were used was only 654 metres per second, while with 1 inch light sheet iron tubes two kinds of explosive wave were obtained, one with a velocity of only 1451 metres, while the other was about 7690 metres, which is comparable with the rate given by nitroglycerin in No. 1 dynamite. With wrought iron tubes of 1¼ inch diameter a 24 grain cap gave a velocity of 8527 metres while a 12 grain cap gave only 2019 metres. Where paper tubes were used the rate was lower probably on account of the smaller confinement of the nitroglycerin charge. Applying the theory, we see that if the particles of free nitroglycerin are in continuous "threads" or surfaces sufficiently large in diameter or area and thickness, the explosive wave should be transmitted in blasting gelatine at a rate which would be directly comparable with that of nitroglycerin. If, however, the surfaces are thinner or the threads finer, the rate would be less, and may be interfered with and brought as it were to a lower octave of vibration by the buffer action of the gel. Two or more separate rates of detonation may be obtained.

When testing explosives imported into Western Australia, Mann found that some blasting gelatines gave rates of from 3759 to 4225, averaging 4063 metres per second, whereas others gave from 2400 to 2553, averaging 2457. The last figures suggest that very little free nitroglycerin remained in these blasting gelatines, or that such particles as remained were not in contact, but were effectively screened by the intervening gel.

The late W. R. Quinan was of opinion that a maximum rate of detonation implied a perfect detonation, whereas an abnormally low rate denoted insensitiveness and probably incomplete metamorphosis. In America generally, according to Soddy, a sharp detonation is preferred, which means a high rate of detonation. If one desires a lower rate one uses some other explosive than blasting gelatine. It is, therefore, now suggested that the blasting gelatine which has the most free nitroglycerin, has the greatest rate of detonation, and that it is not the extra gelatinization which takes place on storage that makes a blasting gelatine inert, but the lack of free nitroglycerin. Consequently that blasting gelatine is the best which—

(1) Has the most free nitroglycerin, provided that the free nitroglycerin is so held by the gel (by adsorption or otherwise) that the finished explosive is free from all liability to liquefaction or exudation; and

(2) Has all its nitro-cotton completely gelatinized, so that there will not be any reduction of the amount of free nitro-glycerin on storage by secondary gelatinization.

The question now arises as to what use the manufacturer can make of the hypothesis. In my opinion it should at least serve as the basis of carefully conducted experiments. In 1909 and 1910 I suggested to the representatives of several manufacturers that experiments should be carried out by *thoroughly* mixing in the cold, nitro-cotton with quantities of nitroglycerin much short of the total required to form ordinary blasting gelatine, and then after gelatinization, the further quantities of nitroglycerin to make up the total should be mixed with the existing jelly. I also suggested that the *thoroughness* of the preliminary mixing should be varied. My own experiments with wheat flour and water indicated that it is one thing to add water to flour, and a different thing to add water to a dough. Hence in determining the water absorption of flour it is necessary by preliminary trials to ascertain approximately the amount of water required to make a standard dough, and then to make the actual determination by adding the whole of the water to the flour in one operation. This is not the usual method, which is to add some water and make a dough; if this dough is not the right consistency more water is added little by little until it is right. This gives a fallacious result because the small lots of water being added in this way are added to a dough, and remain as free water in the interstices of the dough for a considerable time. Where the water is added all at once every particle of flour gets its quotum of water before the gel is formed. From analogy with the action of flour and water, assuming the presence of free (ungelatinized) nitroglycerin in blasting gelatine, the remedy for exudation is therefore not to add more nitro-cotton, but to get a larger amount of gelatinization during the initial mixing of the nitro-cotton and nitroglycerin. To obtain this result more thoroughness is necessary in the preliminary mixing, and also immediate and thorough working in a machine is required. I suggest that the remedy for insensitiveness is to reduce the quantity of nitro-cotton and make up for this by more complete mixing, especially in the preliminary stage. One of the manufacturers took the matter up with enthusiasm. There had been trouble on account of exudation. My suggestions respecting thoroughness of the initial mixing were acted upon and the result was a surprising success. It was not known here that any change in the method of manufacture had been made, but the improved quality of the blasting gelatine excited questions and the reply was that "most of the success of the last shipment is due to modified methods of mixing during manufacture, the benefits of which were first brought to our notice by you."

Another manufacturing company discussed the question with me in 1910, and subsequently made a trial of the new direct method of obtaining gelatinization. This year the company reports that "at one time it was not thought possible to manufacture a satisfactory gelatine without overnight standing and final hot gelatinization, but we have been able for some little time to obtain exceedingly good results by direct gelatinization after mixing nitroglycerin with the nitro-cotton."

It is still too early to say that this modification in manufacture will cure the exudation trouble, but the results so far obtained are very encouraging.

Discussion.

Mr. G. W. **Macdonald** said that most manufacturers had probably tried experiments on the lines suggested by Mr. Hargreaves, but in the speaker's opinion it was very difficult to arrive at any definite conclusion as to the influence of the temperature of gelatinisation and the time of incorporation on the liability of exudation. Pressure on the cartridges, increase of temperature, rapid alterations of temperature, humidity and previous freezing of the cartridge were all factors likely to produce exudation. As to the theory of free nitroglycerin, his own experience was that cartridges which were freely exuding had not a higher velocity of detonation than cartridges from the same batch which were not exuding, so he could not agree with the author's view that the increase in the collodion cotton content was associated with a fall in the heat test.

Dr. E. **Weiskopf** held that the sensitiveness of blasting gelatin was largely controlled by the physical state of the explosive. A blasting gelatin which contained a small amount of nitro-cotton was less elastic than blasting gelatin which contained a large amount of collodion cotton, and the propagation of the explosive wave in a material like blasting gelatin was very greatly counteracted by the elasticity of the substance itself. He had proved that point by adding to blasting gelatin which contained say 7 per cent. of collodion cotton (perhaps the lowest practical limit to which it could be made), a comparatively small amount of camphor, which had no other effect than making the substance more elastic, more horny, and less suitable to transmit the initial explosion, the result was that the blasting cartridge made of such a mixture was rendered so inert that it would only partly explode when it was detonated. He thought the question of the "liquid nitroglycerin" could be left out of account, because it was well recognised that nitroglycerin itself was insensitive to transmit explosion, so he thought it was quite contrary to accepted ideas that it was necessary to have "liquid nitro-glycerin" present in blasting gelatin in order to have a sensitive explosive. He thought one point had been overlooked in the question of the correct proportion of collodion cotton in blasting gelatin, that was in connection with the fact that nitroglycerin in exploding yielded a certain amount of free oxygen, whilst collodion cotton in exploding left a certain amount of carbon monoxide. The endeavour of every explosive manufacturer should be to produce an explosive which on detonation yielded no carbon monoxide or other noxious gases. Blasting gelatin, which was almost perfect from a physical point of view, consisting of about 8 per cent. of collodion cotton and 92 per cent. of nitroglycerin—yielded explosion gases which contained no free carbon monoxide, but a small excess of free oxygen.

The **Chairman** agreed with the last speaker in regard to the relation between the amount of the nitro-cotton and nitroglycerin.

Obituary.

ROBERT KENNEDY DUNCAN.

Robert Kennedy Duncan was born in Canada in 1868, and educated in the University of Toronto. He was appointed in 1905 to the chair of Chemistry in the Washington and Jefferson College, and in 1906 he became professor of industrial chemistry in the University of Kansas, where he initiated a promising scheme of industrial fellowships and bursaries. Both at Kansas and Pittsburgh the success of the scheme has been remarkable. Professor Duncan gave a full account of it in 1909 in the course of a "Discussion on Industrial Fellowships" before the London Section of this Society (see this Journal, 1909, 685—690). In 1910 he was appointed professor of industrial chemistry in the University of Pittsburgh and subsequently to the directorship of the Mellon Institute of Industrial Research.

Professor Duncan edited the "New Science Series," and was the author of "The Chemistry of Commerce," "The New Knowledge," and other works. He concludes his chapter in "The Chemistry of Commerce" on Industrial Fellowships with the following words :—"Everywhere, wherever man deals with material, there are unsolved, important manufacturing problems, best solved by combining the practical knowledge and large facilities of the factory with the new and special knowledge of the Universities, and with the aid of young men who will find therein the opportunity for success. An Industrial Fellowship affords to a young man every incentive to lay his hands on Science and make it serve the practical needs of the human race."

Professor Duncan died at Pittsburgh, Pa., Feb. 18, 1914.

Journal and Patent Literature.

Patent Specifications may be obtained by post by remitting as follows :—

English.—8*d*. each, to the Comptroller of the Patent Office, W. Temple Franks, Esq., Southampton Buildings, Chancery Lane, London, W.C.

United States.—1*s*. each, to the Secretary of the Society.

French.—1 fr. 05 c. each, as follows: Patents dated 1902 to 1907 inclusive, Belin et Cie., 56, Rue des Francs Bourgeois, Paris 3e.); Patents from 1908 to date, L'Imprimerie Nationale, 87, Rue Vieille du Temple, Paris.

German.—1 mark each (with full particulars) to Kaiserlich Patentamt, Berlin, Germany.

I.—GENERAL PLANT; MACHINERY.

Aluminium apparatus ; Destruction of —— by the galvano-catalytic action of copper. P. Pikos. Z. angew. Chem., 1914, **27**, 152.

Many liquids, especially conductors of the second class, such as glycerin, formaldehyde, methyl, ethyl and allyl alcohols, acetone, acetic acid, tannin solutions, etc., whilst having no action on pure aluminium, even at high temperatures, rapidly attack that metal if small quantities of copper salts be present : copper, or a mixture of copper and copper oxide is deposited, and exerts catalytic action, resulting in the evolution of hydrogen and formation of aluminium hydroxide.—A. S.

Patents.

Measuring vapours, gases and liquids ; Apparatus for —— H. M. Liese, Hamburg. Eng. Pat. 2597, Jan. 31, 1913.

In the apparatus described in Eng. Pat. 27,467 of 191 (this J., 1912, 761) a slide-valve is provided which put the conduit successively in connection with a series measuring openings, and the expansion chamber is loade so that by adjustment of the loading the apparatus will still measure in whichever direction the fluid passes through it.—W. H. C.

Filtering or dehydrating machines. C. Robinson, Mount Vernon, N.Y. Eng. Pat. 2806, Feb. 3, 1913.

In rotatable drum filters in which arc-shaped filter elements are attached to the surface of the drum, two revoluble hollow rings, having suitable valves, are provided to put the filter elements alternately in connection with the apparatus producing suction and pressure. The pulp or liquid is fed on to the surface of the drum at the highest point, the filter elements in that position being under suction. As the drum rotates the cake formed is washed by immersion in water, and is then stripped from the drum by a roller scraper, the vacuum being at the same time shut off and pressure applied. The surface of the filter is then washed with water before it returns to the highest position to receive a fresh charge.—W. H. C.

Pressure-filter. E. J. Sweetland, Montclair, N.J. U.S. Pat. 1,083,305, Jan. 6, 1914.

A number of flat circular filter elements, covered with filter-cloth, are arranged within a horizontal cylindrical casing, the interiors of the elements being connected with a common discharge pipe at the upper side of the cylinder. The casing is formed of two longitudinal halves with flanges, bolt holes, slots, and swing bolts by which they are fastened together. The pulp is forced into the closed casing under pressure and the filtrate passes through the filter-cloth into the interior of the elements and escapes through the discharge pipe. The opening and closing of the casing is effected by a lever worked by a hydraulic cylinder and ram and the bolts are swung into and out of position and tightened up by a series of levers and cams operated by a second hydraulic cylinder. When the press is full the cakes are washed with water introduced through the inlet pipe and then the cylindrical casing is opened and the cakes are forced off the filter elements by air or water under pressure delivered into the interior of the elements.—W. H. C.

Raising water and other liquids: Apparatus for ——. P. H. J. Paindavoine, Paris. Eng. Pat. 3295, Feb. 8, 1913.

The apparatus consists of two hollow reciprocating pistons working side by side immersed in water in a casing. By means of ports in the hollow pistons, closed by discs which slide along the piston rods, the two pistons are balanced.—W. H. C.

Raising or forcing liquids; Methods of —— and apparatus therefor. B. C. Joy, London. Eng. Pat. 3653, Feb. 12, 1913.

The descent of a column of liquid in a long pipe under the action of gravity, first causes steam or other condensable vapour to enter a chamber and then operates a spray in the chamber which causes the steam or vapour to be condensed, whereby a vacuum is produced and the flow of liquid reversed. The stoppage of the motion of the column of liquid when it reaches the end of the pipe raises the pressure sufficiently to drive some of the liquid past a delivery valve.—W. H. C.

Separating solid matter from smoke; Apparatus for ——. J. D. Jackson, Kensington, Victoria, Australia. Eng. Pat. 4636, Feb. 24, 1913. Under Int. Conv., July 24, 1912.

The smoke issues from the flue into a vertical chamber where it is washed by a series of water sprays; an adjustable baffle-plate is disposed above the end of the flue. The washing liquid flows into a tank at a lower level provided with baffle-plates to separate the solid particles, which are drawn off.—W. H. C.

Firing furnaces and kilns with pulverised fuel. E. Brunner, Manchester. Eng. Pat. 7267, March 27, 1913.

The pulverised fuel is fed into the furnace without admixture with air by several screw conveyors of small diameter and is projected into a powerful current of highly heated air which is delivered vertically upwards from ports in the floor of the furnace and which keeps the pulverised fuel in suspension until it is consumed.—W. H. C.

Liquids and gases; Apparatus for effecting intimate contact of ——. Kirkham, Hulett and Chandler, Ltd., and S. Hersey, London, and E. W. Blake, Thornton Heath. Eng. Pat 7958, April 4, 1913.

In the gas washing apparatus described in Eng. Pat. 18,129 of 1908 (this J., 1909, 873) the curved pipe scoops are perforated or slotted on their outer sides and provided with wings or vanes so that a continuous body of spray is provided for the gas to pass through between the surface of the liquid and the level of the upper edge of the trays.—W. H. C.

Condensers for distilling apparatus and the like. R. Oekel, Bonn, Germany. Eng. Pat. 8110, April 7, 1913.

Two sets of coils, one of larger diameter than the other, are arranged in the same cooling tank. Condensation takes place first in the larger coils and is completed in the smaller coils. (Reference is directed to Eng. Pats. 1939 of 1886 and 18,667 of 1905; this J., 1886, 384; 1906, 188). —W. H. C.

Distilling apparatus. C. E. Molesworth, Portland, Oreg., Assignor to The Refrigerator Corporation, New York. U.S. Pat. 1,086,684, Feb. 10, 1914.

A cylindrical insulated distillate container is located in the upper part of the still and is provided with a condensing coil. The vapours from the still pass first through a mass of inorganic fibrous material the temperature of which is controlled by a cooling coil and which is contained in a chamber mounted above the distillate container.—W. H. C.

Distilling apparatus. P. Publicker, Philadelphia, Pa. U.S. Pat. 1,087,907, Feb. 17, 1914.

The apparatus comprises a kettle in which the liquid is distilled, a condenser at a higher level, connected at the upper end by a pipe with the still and at the lower end by a pipe with a tank situated at a lower level than the still, a second condenser connected with the tank by a pipe which enters the condenser at its lower end in the form of a goose-neck, a second tank connected by a pipe with the lower end of the second condenser, a third tank connected by a pipe with the upper end of this condenser, a suction pump connected with the last-mentioned pipe, a water column and a discharge pipe from the pump projecting below the surface of the water-column.—J. F. B.

Distilling crude oil and other substances; Apparatus for continuously ——. C. B. Forward, Urbana, Ohio. U.S. Pat. 1,088,693, March 3, 1914.

The distillation products are fractionated in a system of vertical condensers of different lengths, each formed of a top and a bottom section provided with inlet and outlet connections and of one or more interchangeable intermediate sections.—W. H. C.

Column apparatus for distillation, absorption, or the like. K. Kubierschky. Ger. Pat. 269,995, May 16, 1913. Addition to Ger. Pat. 194,567.

The apparatus described in the chief patent was designed for vapours which became specifically heavier after treatment with the washing liquid, but it can also be used for gases or vapours which become specifically lighter.—A. S.

Drying machines with rotary heating devices. R. Simon and Sons, Ltd., R., W. G. and F. R. Simon, Basford, Notts. Eng. Pat. 12,237, May 26, 1913.

Two sets of rotary tubular heating systems are so arranged, end on, in the trough of the drying machine that they may be driven independently.—W. H. C.

Dryer. H. Wilson, Assignor to Pacific Kelp Co., San Francisco, Cal. U.S. Pat. 1,087,478, Feb. 17, 1914.

Stationary hoppers are arranged one above the other inside a cylindrical casing, which carries an exhaust pipe at its upper end. A hollow, vertical shaft extends centrally through the casing and carries a series of flat discs, one above the other, one disc being provided near the top of each hopper. An inner shaft is mounted inside the hollow shaft and carries at its upper end a ventilating fan, which creates an upward current of air through the casing, when operated by gearing situated at the lower end of the inner shaft.—O. R.

Drying machine; Centrifugal ——. A. Cassirer, Munich, Germany. U.S. Pat. 1,087,528, Feb. 17, 1914.

A perforated receptacle is rotated within a casing and is provided at its upper open end with an annular flange projecting inwards. A current of air enters the casing through a number of air inlets in the top, is deflected into the perforated receptacle by cups mounted on the annular flange, and leaves through a central outlet at the bottom. —A. S.

Drying apparatus. C. A. Wenborne, Chicago, Ill., Assignor to The Wenborne-Karpen Dryer Co. U.S. Pat. 1,087,563, Feb. 17, 1914.

A drying chamber is provided with an air conduit down one side and along the floor. Immediately above the lower air duct there are disposed in the order given, a screen, a heating device, and a support for the material to be dried, all extending across the chamber. The screen and the heating device have distributed throughout their area a number of air passages, those in the screen following a tortuous course. Air rises from the lower duct through the screen and heating device and over the material to be dried and passes from the drying chamber through an opening near the top into the air duct at the side, where it passes through a condenser to remove moisture, descends to the lower air duct and again rises through the drying chamber.—A. S.

Mixer, retort and digester. O. T. Zinkeisen, New York, and R. N. Riddle, Rahway, N.J. U.S. Pat. 1,086,432, Feb. 10, 1914.

A drum is rotatably mounted on hollow axial trunnions through which the material is fed into and discharged from the apparatus. The axial pipes terminate immediately after their entry into the chamber, and a diverging spreader is supported from the end wall of the drum in front of but distinct from the inlet pipe. In front of the outlet pipe a screen is similarly supported, which allows the escape of fluids but not solids from the drum, the interior of which is left clear.—W. H. C.

Separating liquids and solids and washing or otherwise treating the separated solids; Process of ——. J. J. Berrigan, Orange, N.J., Assignor to F. J. Arend, New York, and J. Bernstrom, Stockholm, Sweden. U.S. Pat. 1,087,094, Feb. 10, 1914.

The solids are separated from the liquid by a centrifugal machine and are then passed successively through one or more centrifugal machines which contain the washing liquid or liquids.—W. H. C.

Gas furnaces; Regenerative ——. F. K. Siemens. Fr. Pat. 461,938, Aug. 27, 1913.

Improvements in the gas furnace described in the second addition to Fr. Pat. 409,650 (see Eng. Pat. 10,824 of 1912; this J., 1912, 972; also Eng. Pat. 23,534 of 1909; this J., 1910, 701), the conduit for conducting gas to the furnace passing centrally through an air chamber the lower part of which is divided by a vertical partition into two chambers communicating respectively with two regenerative chambers. Small holes on opposite sides of the gas conduit allow a small amount of air from one regenerative chamber to pass into the gas conduit, thus forcing a corresponding amount of gas out of the opposite hole into the passage leading into the other regenerative chamber, where it burns in contact with air passing round the top of the air chamber. The regenerative chambers are thus heated by gas which has not passed through the furnace. No additional valves are needed for reversal of the direction of flow of the gas through the regenerative chambers. The main body of air passes from the air chamber into the furnace through a passage arranged above the gas conduit.—H. H.

Furnaces for melting glass, metals, and minerals; Process for heating —— *by liquid fuel.* R. G. and K. H. Siegwart. Fr. Pat. 462,684, Sept. 9, 1913. Under Int. Conv., Feb. 17, 1913.

Liquid fuel for heating smelting furnaces, etc., is caused to drop from supply pipes into one or other of two open trays of refractory material situated centrally in air supply passages admitting air from recuperative chambers at opposite sides of the furnace. These passages are arranged above sills at opposite sides of the furnace and act alternately for the admission of air and vaporised fuel and for the outlet of burnt gases passing to the recuperative chambers. The liquid fuel becomes heated in passing through the supply pipe, which contains a small tank in proximity to the roof of the furnace, and is vaporised in the trays by heat radiated from the walls and interior of the furnace.—H. H.

Colloidal substances; Dehydration of ——. Richter und Richter. Ger. Pat. 270,061, Nov. 29, 1912.

Colloidal materials such as brewers' grains, vinasses, yeast, etc., are intimately mixed with lime and simultaneously treated with atomised air, oxygen, or ozone, before the water is removed by pressing.—A. S.

Reactions in gases by means of contact substances Apparatus for effecting ——. A. Wilhelmi. Ger. Pat. 270,062, Nov. 17, 1912.

The contact chamber is heated externally and is so mounted that it can be easily removed for filling, emptying, repairing, etc. It is annular in form and is disposed above the annular furnace chamber and enclosed by a removable cover formed in two parts. The furnace gases rise through the annular space between the cover and the contact chamber and then descend through the central conduit on their way to the stack. The contact chamber is made with welded joints and the cover has upturned edges which are welded to the inner wall of the chamber.—A. S.

Crystals; Apparatus for obtaining large well-formed —— *from hot-saturated solutions.* V. Schütze. Ger. Pat. 270,396, Aug. 27, 1912.

The solution flows through a jacketed vessel, a liquid acting as a heat-insulator being passed through the jacket. Vertical partitions are disposed in the jacket at distances appropriate to the solubility of the salt being crystallised, so that the velocity of the heat-insulating liquid decreases with the solubility of the salt as the solution cools.—A. S.

Evaporation of liquid and apparatus therefor. Soc. d'Exploitation de Procédés Évaporatoires, Système Prache et Bouillon, Paris. Eng. Pat. 4515, Feb. 21, 1913. Under Int. Conv., Feb. 21, 1912.

See Fr. Pat. 453,995 of 1913; this J., 1913, 858.—T. F. B.

Filtering material and process for producing same. F. Pott, Friedenau, Germany. Eng. Pat. 18,119, Aug. 8, 1913.

See Fr. Pat. 461,386 of 1913; this J., 1914, 187.—T. F. B.

Filtering material; Process of manufacturing ——. F. Pott, Friedenau, Germany. U.S. Pat. 1,089,346. March 3, 1914.

See Fr. Pat. 461,386 of 1913; this J., 1914, 187.—T. F. B.

Filtering machine. J. Drage, Boulder, Western Australia. U.S. Pat. 1,087,647. Feb. 17, 1914.

See Fr. Pat. 424,857 of 1911; this J., 1911, 879.—T. F. B.

Liquid films; Apparatus for treating ——. C. V. Boys, London. U.S. Pat. 1,088,202. Feb. 24, 1914.

See Eng. Pat. 22,886 of 1912; this J., 1913, 809.—T. F. B.

Drying articles formed from plastic masses; Apparatus for ——. O. Eberhard, Heidenau, Germany. U.S. Pat. 1,088,555, Feb. 24, 1914.

See Fr. Pat. 455,959 of 1913; this J., 1913, 933.—T. F. B.

Drying paste goods; Apparatus for ——. O. Müller, Plüderhausen, Germany. U.S. Pat. 1,089,944, March 10, 1914.

See Fr. Pat. 434,758 of 1911; this J., 1912, 321.—T. F. B.

Distilling, cooling, heating, and similar purposes; Column apparatus for ——. H. A. Gasser, Wiesbaden, Germany. U.S. Pat. 1,089,831, March 10, 1914.

See Fr. Pat. 434,323 of 1911; this J., 1912, 321.—T. F. B.

Gases; Disintegrator apparatus for washing, purifying, and cooling ——. H. E. Theisen. Fr. Pat. 462,437, Sept. 10, 1913. Under Int. Conv., Dec. 20, 1912, April 10 and May 19, 1913.

See Eng. Pat. 21,427 of 1913; this J., 1914, 241.—T. F. B.

IIa.—FUEL; GAS; MINERAL OILS AND WAXES.

Combustible and explosive mixtures of gases and air; Lower limits of ——. E. E. Somermeier. J. Ind. Eng. Chem., 1914, **6**, 191—198.

Published data relating to the combustion and explosion of gaseous mixtures are often incomplete and misleading owing to lack of precision in the definition of the terms employed. The ignition temperature of a gaseous mixture is defined as the temperature to which it must be raised to bring about an appreciably rapid chemical reaction. The ignition temperature of combustion, or of explosion, is the temperature to which a portion of the mixture must be raised so that a combustion or an explosion may be propagated throughout the entire mixture. If the heat of the reaction, ignition temperature, and thermal capacities of the reacting gases and products of combustion be known, the lower limits of combustible and explosive mixtures of gas can be calculated. The values obtained are lower than those found experimentally, as the amounts of heat required to compensate losses by radiation and conduction are not taken into account, but they are of considerable practical value, since mixtures containing such proportions of gas must be regarded as potentially explosive and hence dangerous, for in mines, etc., the conditions (presence of combustible dust, etc.) may change them into actually explosive mixtures. Taking the ignition temperatures of combustion of mixtures of hydrogen and air and methane and air as 600° and 700° C. and the ignition temperatures of explosion as 700° and 850° C. respectively, and assuming combustion as occurring at constant pressure and explosion at constant volume, the lower limits of combustible mixtures were calculated to be: H_2 6·8, and CH_4 2·8 per cent., and of explosive mixtures: H_2 5·9, CH_4 2·4 per cent. Natural gas and gas in coal mines frequently contain 10—15 per cent. of ethane, and a 2 per cent. mixture of such gas would be at least as explosive as a 2·4 per cent. mixture of methane. —A. S.

Petrol-store in the Osthafen, Berlin; Safety ——. T. Rosenthal. Chem. Ind. 1914, **37**, 150—151.

The plant, constructed on the Martini-Hüneke system, has a total capacity of 1,000,000 litres in 36 cylindrical tanks of various sizes lying 1 metre underground upon a concrete bed surrounded by concrete walls. The safety arrangements include: displacement of the petrol by a mixture of carbon dioxide and nitrogen under a pressure of half an atmosphere; devices to prevent access of air by diffusion when pipes or fittings leak; pipes, valves, and fittings which prevent escape of petrol at damaged places; prevention of rusting, access of flame, etc., by burying the containers. The tanks are filled from railway tank-wagons by siphons, the gas being simultaneously exchanged, or from barges by an electrically-driven centrifugal pump; they are emptied through pipes brought to lock-up iron cupboards provided with cocks, meters, gauges, etc. Any petrol spilt flows to special drains, and thence to an underground container; admixed water is separated and diverted to the sewers.—O. E. M.

Hydrocarbons; Separation of —— *by means of liquid sulphur dioxide.* L. Edeleanu. Petroleum, 1914, **9**, 862—864.

On shaking a petroleum distillate with liquid sulphur dioxide at a low temperature the aromatic and cyclic unsaturated hydrocarbons are dissolved, whilst the paraffin and naphthene hydrocarbons remain practically unaffected. A quantity of sulphur dioxide equal to twice the weight of the distillate is used; sufficient of this to form a separate layer after shaking, is first added, and the remainder in three portions, shaking and drawing off the liquid sulphur dioxide after each addition. In the case of distillates of high b. pt., such as gas oil or lubricating oil, the sulphur dioxide may be removed by evaporation, and the residual hydrocarbons weighed or their sp. gr. determined, but with products of low b. pt. such as benzine and lamp oils, the sulphur dioxide is neutralised with alkali, water added, and the volume and sp. gr. of the hydrocarbons ascertained.—C. A. M.

Petroleum prospects in the Union of South Africa: Report on the ——. E. H. C. Craig. Board of Trade J., March 19, 1914. [T.R.]

Petroleum.—There is little likelihood of any extensive oil-fields being found anywhere in the Union of South Africa. Favourable geological structure exists only in Cape Colony, and there only in a narrow strip at the southern edge of the Karroo. No petroleum prospecting has apparently been carried out in this district, but the conditions are not favourable for large productions. It is suggested that the area south of Aberdeen, near Jansenville, Saxony, and Klipplaat Station, should be examined. Though it is by no means certain that petroleum will be found, such a well, if successful, would open up a wide area, and, if unsuccessful, would set at rest all hopes of striking oil in the Union. Certain areas in north-eastern Natal, which were not inspected, may perhaps furnish favourable geological structures.

Natural Gas.—There are areas in the coal measures in the Transvaal and Natal where natural gas can be struck in fair quantity. Supplies of gas under sufficient pressure to supply distant towns are improbable, but the gas may possibly be used locally at a profit.

Oil Shale.—None of the shales examined, with the exception of that at Kikvorschfontein, are comparable with the best Scotch shales, but the laboratory tests prove that very fair quantities of shale oil can be produced. The seams are thin as a rule, but might prove quite profitable in South Africa, on account of the great demand and high price of oil. The Kiksvorschfontein, Moorfontein, Waaihoek, and Hlatimbe-Umkomaas areas are all worth consideration, especially the last area, which lies within 100 miles of Durban, and because it seems probable that shale deposits may be found near the projected railway to Himeville. Prospecting of the folded belt of the Karroo system for crude petroleum and natural gas is of less importance than the development of the shale industry. All the evidence leads to the belief that an oil-shale industry has good prospects of proving successful.

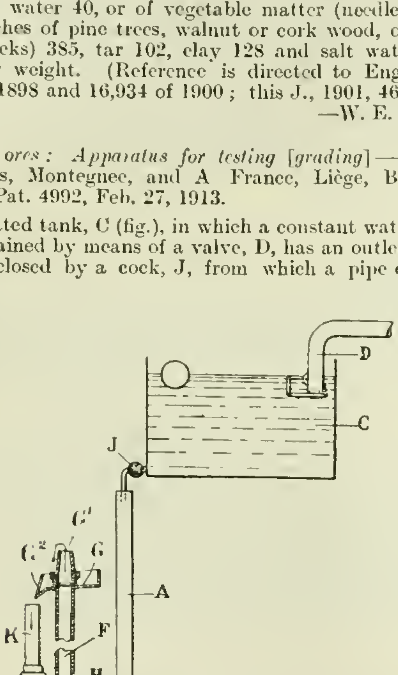
PATENTS.

Fuel; Manufacture of artificial ——. R. Blumberg, Lisbon. Eng. Pat. 4909, Feb. 26, 1913. Under Int. Conv., Feb. 29, 1912.

BRIQUETTES composed of pine needles 540, tar 380, clay 40, and salt water 40, or of vegetable matter (needles, bark or branches of pine trees, walnut or cork wood, or dried vine stocks) 385, tar 102, clay 128 and salt water 385, parts by weight. (Reference is directed to Eng. Pats. 8723 of 1898 and 16,934 of 1900; this J., 1901, 462.)
—W. E. F. P.

Coal or ores: Apparatus for testing [grading] ——. P. Habets, Montegnee, and A France, Liège, Belgium. Eng. Pat. 4992, Feb. 27, 1913.

AN elevated tank, C (fig.), in which a constant water level is maintained by means of a valve, D, has an outlet at the bottom closed by a cock, J, from which a pipe extends into the longer arm of a metal U-tube, A, the other arm of the latter having a glass tube, F, secured to it at E. The glass tube is "closed" at the bottom by copper wire gauze of very fine mesh, and prolonged at the top by a tapering nozzle-piece, G^1, provided with an annular tray, G, having an outlet, G^2. I is a cock for emptying the tube, F; and H a graduated reservoir (end view) carrying a number of collecting-tubes, K, having wire gauze bottoms. A weighed quantity of the coal, etc., is placed in the tube, F, and the cock, J, opened so as to produce in F, water currents of successively increasing velocities, the overflow at each rate being collected in a separate tube, the product dried and weighed and the quantity of water measured. The cock, J, is provided with an indicator disc marked to show the degree of opening necessary to produce any required velocity in F.
—W. E. F. P.



Fuel; Process of burning solid ——. A. G. Glasgow, London. Eng. Pats. 16,910 and 16,911, July 23, 1913.

THE formation of clinker (in gas-producers, etc.) is prevented by dividing the air and steam blasts and distributing the same within the combustion chamber so that, in the fuel bed, superposed horizontal zones are maintained, one (at a relatively high temperature) in which agglomeration of the fused ash is prevented by an excess of carbon, and the other (at a relatively low temperature) in which this carbon is finally consumed without fusion of the ash.—W. E. F. P.

Coke ovens; Process of and apparatus for charging ——. W. Puschmann. Eng. Pat. 22,763, Oct. 8, 1913. Under Int. Conv., Nov. 22, 1912.

THE use of a single large motor truck, of the same capacity as the oven, for charging the latter, cannot be adopted in many existing installations owing to the extensive alteration of plant required. According to the present patent, several motor trucks are used, which run on the existing tracks, and are automatically brought to rest above the oven to be charged or below the filling tower, for example by stops or levers, fitted on the track and adapted to stop the motor and, if desired, also set a brake in operation.—A. S.

Retorts for use in the manufacture of gas or for like purposes. Drakes Ltd. and W. A. Drake, Halifax. Eng. Pat. 4104, Feb. 18, 1913.

VERTICAL retorts for use in the manufacture of gas, distillation of shale, etc., are provided, at the lower end, in the known manner, with extensions open to the atmosphere. Each extension is encircled by a wall, an annular space being left, open at the bottom, for the entry of cold air, which is preheated by the hot coke or the like leaving the retort, and then passes through suitable passages to cavities in the structure surrounding the retort, where it is used for burning the gases used for heating.—A. S.

Gas; Purification of ——. L. Bergfeld. Ger. Pat. 270,204, Dec. 19, 1911.

THE gas passes first through a solution of a feebly or partially saturated compound of an alkali, such as a metaborate or the like, to remove acid impurities, including hydrogen sulphide, and then through a solution of a partially saturated compound of an acid, *e.g.* primary potassium phosphate, bifluoride, polyborate, or citrate, or esters of weak acids, to remove ammonia. By heating to about 100° C., the absorbed impurities are expelled and the absorbents regenerated.—A. S.

Fuel; Liquid —— specially applicable for internal combustion engines. T. Terry, New Ferry, Cheshire. Eng. Pats. 7807 and 7808, April 3, 1913.

CRUDE petroleum (1 gal.), or a mixture of crude or refined petroleum and benzol in equal proportions, is agitated, hot or cold, with a mixture (4 to 6 oz.) of crystallised sodium carbonate and "Montreal ash" (a wood ash used in the alkali and other industries) in equal quantities, and then separated for use. The sodium carbonate may be replaced by caustic soda, and the Montreal ash by potash or sodium nitrate.—W. E. F. P.

Asphaltum from crude mineral oil or residuum thereof; Process for the manufacture of ——. C. B. Forward, Urbana, Ohio. U.S. Pat. 1,088,692, March 3, 1914.

THE volatile light and heavy constituents are distilled off by forcing the crude mineral oil or residuum, under pressure, and in an atomised condition, through a still heated to a temperature below that at which coking takes place. The distillation residue is mixed with a larger or smaller proportion of the heavy distillate according to the quality of asphaltum required and the mixture heated in an open vessel until the desired adhesive and cohesive condition has been attained.
—W. H. C.

Petroleum oils; Treating —— with ultra-violet light. C. Ellis, Montclair, N.J., Assignor to Ellis-Foster Co. U.S. Pat. 1,089,359, March 3, 1914.

THE oils are exposed in thin layers and at a temperature below that at which decomposition takes place to ultraviolet light of high voltage to destroy fluorescence and polymerise gum-forming constituents.—W. H. C.

Autoclave apparatus for the transformation of petrol and similar hydrocarbons. G. Renard. Fr. Pat. 462,286, Sept. 8, 1913.

The hydrocarbon is forced under a pressure of 40 or 50 atmospheres through a tube having two serpentine coils arranged in series, the first being at a temperature of from 400°—450° C. and the second being immersed in a cooling liquid. The hydrocarbon remains in a liquid state throughout, but is broken down into fractions of lower boiling point in the process.—H. H.

Heavy hydrocarbons; Treatment of ——. H. M. Hyndman. Fr. Pat. 462,481, Sept. 11, 1913.

The hydrocarbon is forced by means of a high-pressure steam jet through a long coil of pipe maintained at a cherry-red heat, and the lighter hydrocarbons produced are condensed in a series of condensers. The furnace surrounding the tube is automatically maintained at different temperatures at different parts so as to compensate for varying heat absorption by the hydrocarbon at different parts of the tube and thus maintain the temperature of the tube uniform throughout. The presence of magnetic iron oxide in the tube facilitates the action. The proportion of steam mixed with the hydrocarbon is adjusted by observation of the colour of a test flame of the hydrocarbon produced, the proportion of steam being increased slightly above that at which the flame is yellowish.—H. H.

Oils; Processes and apparatus for refining —— by distillation. R. A. Dornès, New York. Eng. Pats. 27,615, Nov. 30, 1912, and 1269 of 1914, date of appl., Nov. 30, 1912. Under Int. Conv., Dec. 1, 1911.

See Fr. Pat. 448,658 of 1911; this J., 1913, 415.—T.F.B.

Sulpho-acids from crude petroleum hydrocarbons and acid residues; Process for extracting and separating ——. G. Petroff, St. Petersburg. U.S. Pat. 1,087,888, Feb. 17, 1914.

See Fr. Pat. 448,207 of 1912; this J., 1913, 415.—T. F. B.

Apparatus for continuously distilling crude oil and other substances. U.S. Pat. 1,088,693. *See* I.

Manufacture of volatile hydrocarbons. Fr. Pat. 462,935. *See* III.

Manufacturing sulphuric acid from the sulphur compounds of ammonia-freed coal-gas. Eng. Pat. 4770. *See* VII.

Detectors of combustible gases. Eng. Pat. 5467. *See* XXIII.

IIb.—DESTRUCTIVE DISTILLATION; HEATING; LIGHTING.

Hardwood distillation in the United States. R. C. Palmer. Oil, Paint, and Drug Rep., March 9, 1914. [T.R.]

The number of plants in the United States engaged in the distillation of hardwoods for the production of products besides charcoal were as follows:—1880, 17; 1890, 53; 1900, 93; 1907, 100; 1909, 116; 1910, 117; 1911, 105.

The production and values of various primary and secondary products are given below:—

Production of charcoal.

Year.	Production. Bushels.	Value.
1880*	54,000,000	$3,678,000
1890*	67,000,000	4,523,000
1900	17,154,000	726,000
1906	45,657,000	2,966,000
1907	50,772,000	3,838,000
1908	37,286,000	2,644,000
1909	53,000,000	3,299,000
1910	56,000,000	3,762,000

* Includes charcoal from softwood and from charcoal kilns producing no other products.

The figures subsequent to 1890 do not include those for the production of charcoal for pig-iron alone, which are as follows:—

Year	No. of plants	Value of product.
1900	183	$1,134,000
1904	74	1,292,000
1910	76	872,000

Production of crude wood alcohol.

Year.	Gallons.	Value
1880	130,000*	$86,000
1890	1,116,075	688,000
1900	4,945,000	1,977,000
1906	7,871,494	2,676,191
1907	7,741,645	1,153,307
1908	6,285,678	1,084,223
1909	8,468,083	2,082,253
1910	8,691,525	2,226,768
1912	9,500,000*	2,660,000*

* Estimated.

Production of acetate of lime

Year.	Pounds.	Value.
1880	6,593,000	$156,000
1890	26,000,000	315,000
1900	86,826,000	981,000
1906	96,376,000	2,017,000
1907	133,375,000	2,566,000
1908	106,099,000	1,636,000
1909	148,769,000	2,203,000
1910	152,772,000	2,467,000

Production of acetic acid.

Year.	Production. Pounds.	Value.	Proportion of acetate for acetic acid.
			per cent.
1900	26,660,000	$427,000	25
1904	27,001,000	537,000	25
1909	51,963,000	1,136,000	27

Production of acetone.

Year.	Production. Pounds.	Value.	Proportion of acetate for acetone.
			per cent.
1900	1,638,715	$178,000	10
1904	1,300,000	161,000	8
1909	6,928,000	719,000	23

French manufacture of transparent quartz and its applications. Mercury vapour lamps. Gallois. *See* VIII.

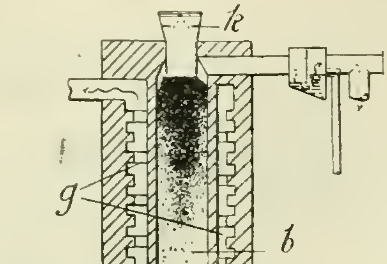
Patents.

Oils from coal, cannels and shales; Production of —— A. Rollason, Long Eaton, Derbyshire. Eng. Pat. 19,697, Sept. 1, 1913.

Coals, cannels and shales containing a high proportion of oxygen are ground, mixed with 3—5 per cent. of ground limestone or other suitable carbonate, and the mixture slowly heated in retorts to about 500° C. The carbon dioxide given off from the limestone tends to prevent the combination of oxygen and hydrogen and favours the production of oils.—W. H. C.

Distilling and gasifying solid carbonaceous matter. G. P. Lewis, Tal-y-Cafn, Denbighshire. Eng. Pat. 4572, Feb. 22, 1913.

The coal or other carbonaceous material is charged through the hopper, *k*, into the upper retort, *b*, the axis of which is out of line with that of the lower chamber or generator, *a*. The fuel passes downwards by gravity, part of the coke is withdrawn through the branch, *d*, and the remainder is gasified in the producer, *a*. Part of the producer gas is withdrawn through the port, *e*, and is burned with air which is admitted through the port, *p*, in the flues, *g*, to heat the upper retort. The remainder of the producer gas is passed through the retort, *b*, and serves to assist in the removal of the distillation gases —W. H. C



Peat; Utilisation of ——. T. Rigby, Dumfries, N. Testrup and Wetea bonizing Ltd., London. Eng. Pat. 25,146, Nov. 2, 1912.

The peat is first subjected to heat treatment (wet carbonisation) as described in Eng. Pats. 17,427, and or 17,428 of 1912 (this J., 1913, 1099, 861) and the water is separated by a filter-press or other suitable filter. The hot filtrate serves to preheat the incoming peat pulp and the press cakes of partially dehydrated peat are in part gasified (with "recovery of nitrogen") to provide the fuel and power for the process and in part converted into solid or gaseous fuel as desired.—W. H. C.

Peat; Process for obtaining volatile liquids from ——. P. P. Pease. Fr. Pat. 463,104, Sept. 30, 1913.

Partly dried peat mixed with about 1 per cent. of sulphur is introduced into a distillation chamber having a perforated plate at the bottom through which hot air is forced after ignition of the mass, the temperature being raised to a white heat. The distillation gases pass through a condenser which removes tar, etc., and then through a purifier to a gasometer which is weighted to maintain a pressure of about 70 kilos. per sq. cm. throughout the apparatus. The gas which consists of methane and higher hydrocarbons, methyl alcohol, and other volatile substances is drawn from the gasometer by a pump and forced at a pressure of about 225 kilos. per sq cm. into a reservoir, where it may be cooled and pumped at a still higher pressure into a vessel where it is stored in the liquid state.—H. H.

Distillation of liquids or of substances dissolved or suspended in liquids [*e.g., waste lyes from cellulose manufacture*]*; Destructive* ——. E. L. Rinman. Ger. Pat. 269,994, Jan. 28, 1913.

Distillation is effected in an annular furnace in which an annular hearth is mounted. The material is distributed over the hearth and heating gases are passed through an annular space below the hearth, the latter being rotated in the opposite direction to the flow of the heating gases. The heating chamber is closed against the space above the hearth by liquid- or sand-seals, and the conduit through which the distillation residue is discharged is connected with a vertical pipe of such height that the column of residue therein is sufficient to provide a gas-tight seal.—A. S.

Gas from sewage sludge; Process for obtaining ——. F. Berghauer. Ger. Pat. 270,338, Feb. 18, 1913.

The sludge is dried in a chamber in the upper part of the oven and is then carbonised in retorts in the lower part. Pipes open at both ends extend through the heating chamber, alongside the retorts, and open into the drying chamber, and air is drawn through these pipes by natural draught from the carbonising house, thus ventilating the latter, and delivered into the drying chamber.—A. S.

Heating solid, liquid, or gaseous bodies by the heat generated in the formation of sulphur compounds, principally metallic sulphides. A. Lang. First Addition, dated Sept. 10, 1913, to Fr. Pat. 395,536, Oct. 21, 1908 (this J., 1909, 591).

A mixture of sulphur and metal according to the principal patent is mixed with sulphites and an adhesive, and employed for coating wood strips which can be lit like matches and the gases evolved used for destroying parasites.—H. H.

Arc-light carbons. H. Ayrton, London. Eng. Pat. 1775, Jan. 22, 1913.

A negative carbon is formed with a hard core, a softer or more readily combustible shell and an outer casing of sheet copper or other suitable metal. The metal sheath melts and drops away at such a distance from the burning tip that it does not contaminate the arc.—W. H. C.

Charcoal; Method of making ——. L. Félizat, Assignor to La Soc. Savonnerie et Huilerie de Lurian, Bouches-du-Rhône, France. U.S. Pat. 1,087,486, Feb. 17, 1914.

See Fr. Pat. 409,916 of 1909; this J., 1910, 806.—T. F. B.

Coal, oil shale, and similar substances; Process and apparatus for treating —— *in vertical retorts.* A. Waddell. Fr. Pat. 463,440, Sept. 13, 1913. Under Int. Conv., Sept. 27, 1912.

See Eng. Pat. 21,991 of 1912; this J., 1913, 690.—T. F. B.

Metallic bodies [*tungsten*] *for use in making incandescence lamps; Preparation of refractory* ——. Comp. Française pour l'Exploitation des Procédés Thomson-Houston. First Addition, dated Oct. 6, 1913 to Fr. Pat. 433,131, Aug. 10, 1911.

See Eng. Pat. 1915 of 1913; this J., 1914 319.—T. F. B.

III.—TAR AND TAR PRODUCTS.

Phenol; Determination of —— *in the presence of hexamethylenetetramine and formaldehyde.* L. V. Redman, A. J. Weith, and F. P. Brock. J. Ind. Eng. Chem., 1914, 6, 205—206.

The bromination method for the determination of phenol described previously (this J., 1913, 591) gives good results in presence of hexamethylenetetramine but not in presence of formaldehyde. In the latter case ammonia should be added up to a concentration of 2*N* (to convert the formaldehyde into hexamethylenetetramine) and the solution allowed to stand for 5 mins. before proceeding with the determination.—A. S.

Hydrogenation of diaryl-ketones and aryl-alcohols; Direct catalytic ——. Preparation of poly-aryl-hydrocarbons. P. Sabatier and M. Murat. Comptes rend., 1914, **158**, 760—764

THE vapour of the compound to be reduced was carried, by means of a current of hydrogen, over the nickel heated to the desired temperature. At 300 C., using nickel obtained by reduction of the oxide at 400 C., benzophenone yielded diphenylmethane, whereas at 160—170 C., with very active nickel obtained by reduction at 350 C., it yielded dicyclohexylmethane, $C_6H_{11}.CH_2.C_6H_{11}$ (b. pt. 250°—251 C.). Desoxybenzoin (phenylbenzylketone) and phenylbenzylcarbinol at 350—360 C., yielded *symm.* diphenylethane (dibenzyl); dibenzylketone at 400 C. and phenylbenzoylethane at 360° C., yielded *symm*-diphenylpropane (b. pt. 300 C., corr.); benzyl alcohol at 370 C. yielded toluene (yield 90 per cent.): phenylethyl alcohol at 380° C. and phenylmethylcarbinol at 350° C. gave ethylbenzene. Diphenylcarbinol at 380° C. was quantitatively converted into diphenylmethane, and this affords an economical method of preparing the latter compound. Phenyl-*p*-cresylcarbinol at 350°—380° C. gave phenyl-*p*-cresylmethane, and triphenylcarbinol at 400° C. gave triphenylmethane.—A. S.

PATENTS.

Hydrocarbons; Manufacture of volatile ——. R. Hense. Fr. Pat. 462,935, Sept. 4, 1913.

MIXTURES of heavy hydrocarbons, mineral oils, tar distillates, benzene, alcohols, resinous products, etc., are distilled in presence of an oxygenating body for the purpose of obtaining light oils suitable for use as engine fuels. The mixture is first purified by successive treatment with alkali and acid and the residue of the washing water removed by means of a hygroscopic salt such as sodium sulphate or by freezing. The oxidising substance may be a nitro-compound such as picric acid, a peroxide such as magnesium peroxde, or an organic compound such as hydroxybenzoic or pyrogallic acid. It is advantageous in certain cases to add a small proportion of turpentine or an ester such as ethyl acetate. The distillate may be saturated with ozone more particularly for the purpose of giving high illuminating value when the liquid is used for lighting or enriching gas.—H. H.

Phenols Process for the manufacture of polyvalent —— from the corresponding chlor-substitution products of aromatic hydrocarbons. C. Torley, Brussels, and O. Matter, Troisdorf Germany. Eng. Pat. 9450, April 22, 1913.

SEE Fr. Pat. 458,136 of 1913; this J., 1913, 1060.—T.F.B.

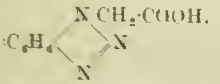
Petroleum and tar; Manufacture of nitro-products from ——. A. S. Flexer, Vienna. Eng. Pat. 16,031, July 11, 1913. Under Int. Conv., July 13, 1912.

SEE Fr. Pat. 460,280 of 1913; this J., 1914, 17.—T. F. B.

IV.—COLOURING MATTERS AND DYES.

Indigo. Preparation of substituted ——. A. Reissert. Ber., 1914, **47**, 672—681.

THE author's aim was to prepare indigo derivatives in which the nitrogen atoms would be involved in a second ring external to the indigo structure. 1-Benztriazylacetic acid,



was prepared but it gave on fusion with sodamide only a small quantity of ordinary indigo, two nitrogen atoms evidently having been split off. The author, however, succeeded in preparing an indigo from benzidinoacetic acid $NH_2.C_6H_4.C_6H_4.NH.CH_2.COOH$, prepared by condensing benzidine with free chloroacetic acid in aqueous solution. The new indigo derivative has the constitution:

$$NH_2.C_6H_4.C_6H_3{<}^{CO}_{NH}{>}C{:}C{<}^{CO}_{NH}{>}C_6H_3.C_6H_4.NH_2.$$

It dyes wool in shades similar to those of ordinary indigo, which become redder on treatment with acid.—J. B.

Saffron: The detection of adulterants in —— by means of phosphomolybdic acid. A. Verda. Chem.-Zeit., 1914, **38**, 325—327.

SAFFRON is distinguished from its usual vegetable adulterants by its green colour-reaction with phosphomolybdic acid. The reagent is prepared by dissolving 25 grms. of sodium phosphomolybdate in 90 c.c. of water and 20 c.c. of pure nitric acid, allowing to stand 8 days and then filtering. The test is carried out like the older one with sulphuric acid, over which it has the advantage of giving a more permanent colouration. On this account it is especially suitable for microscopic analysis. The sulphuric acid test is improved by the addition of phosphomolybdic acid, *e.g.*, by mixing 40 c.c. of a 10 per cent. solution of sodium phosphomolybdate with 60 c.c. of concentrated sulphuric acid. The blue colour which this solution gives with saffron remains for over a day. The new colour reaction is ascribed to the crocin in the saffron, this substance having the character of a glucoside.—J. B.

PATENTS.

[Azo] dyestuffs; Manufacture of ——. R. B. Ransford, London. From L. Cassella und Co., Frankfort-on-Maine, Germany. Eng. Pat. 4058, Feb. 17, 1913.

THE tetrazo-compound of a diaminotriarylmethanesulphonic acid (*e.g.*, that from benzaldehyde-*m*-sulphonic acid and aniline) is combined with two mols. of the same or of different arylmethylpyrazolone derivatives. Greenish-yellow wool dyestuffs are obtained.—J. B.

V.—FIBRES; TEXTILES; CELLULOSE; PAPER.

Straw-board pulp. B. Haas. Papierfab., 1914, 12, 305—310.

In the manufacture of straw-board pulp, oat-straw is digested with 10 per cent., wheat-straw with 13—15 per cent. of lime; the capacity of the digesters ranges from 900 to 2000 kilos. but considerable differences occur among different mills in the quality of lime, the manner of slaking, the composition and quantity of water and the dryness and pressure of the steam. The industry is devoid of any general scientific control and the quality of the product varies considerably. In many cases, too much lime is employed, with the result that the pulp becomes "greasy" and drains very slowly, clogging up wires and felts. The lime should be slaked slowly and completely and used in the freshly slaked condition. By adjusting the chaff-cutting machine, running in the liquor at the time of charging, and steaming gently at the same time, the capacity of a digester may be increased 10 per cent. The charged digester should be rotated for a short time without steam, to distribute the liquor uniformly; then stopped and the steam admitted with release-cock open to expel the air. After this, the full pressure of steam (4 atmos.) should be admitted, with the digester rotating. Digestion may be continued for 2½—3 hours, but towards the end of the period the digester should be stopped and steam shut off temporarily to allow the material to settle down, the digestion being then carried to completion as before. By observing these rules and increasing the quantity of water where necessary, satisfactory results may be obtained with 2—3 per cent less lime than formerly, the pulp will be brighter in colour and run far more easily on the machine. Wheat straw was satisfactorily digested by the author's method with only 6 per cent. of lime.—J. F. B.

Patents.

Wood refuse; Treatment of —— *for the recovery of valuable products therefrom.* A. Zimmermann, Bromley, Kent. Eng. Pats. 3963, Feb. 15, 8359, April 9, and 13,746, June 13, 1913.

The waste product obtained by the treatment of wood sawdust with acids for the production of sugar or alcohol may be digested with an alkali for the preparation of cellulose. The alkaline extract, whether separated from the cellulose or not, when concentrated, yields a product suitable for use as a fertiliser. On treatment with acid the alkaline extract drained off from the cellulose gives a precipitate of "lignon body." The lignon body is soluble in caustic soda or potash and the evaporated solution yields a perfectly soluble, flaky product, which may be used as a colouring matter or fertiliser. The alkali salts of the lignon "body" are precipitated from solution in the form of double salts on treatment with a salt of a heavy metal; these double compounds of the lignon may be employed as anti-fouling pigments, preservatives or fertilisers.—J. F. B.

Sulphite cellulose; Process of producing ——. E. Oman, Stockholm. Eng. Pat. 1145, Jan. 15, 1914. Under Int. Conv., Feb. 6, 1913.

Waste liquor from the digestion of sulphite cellulose is used instead of water for the preparation of fresh liquor by dissolving therein lime, magnesia or alkali and sulphur dioxide. Preferably also a suitable quantity of the dilute

liquors obtained in the washing of the pulp is incorporated with the waste digester lye for the preparation of fresh liquor. When the waste liquor has attained, by repeated use, the desired concentration in respect to useful by-products, it is treated for the recovery of the latter.
—J. F. B.

Waste sulphite cellulose lyes or similar liquids; Method of removing organic constituents from residues obtained in producing alcohol from ——. P. G. Ekström, Skutskär, Assignor to Stora Kopparbergs Bergslags Aktiebolag, Falun, Sweden. U.S. Pat. 1,087,356, Feb. 17, 1914.

Alcohol is first produced from the lye in the usual manner and the residual lye treated with a basic reagent, *e.g.*, caustic lime, and then oxidised by aeration. Humus-like calcium compounds are precipitated; alternatively, aeration may be performed in the presence of an oxidising catalyser.—J. F. B.

Sulphite pulp digester liquor; Process and product of treating ——. O. Grothe, Jersey City, N.J. U.S. Pat. 1,087,911, Feb. 17, 1914.

The neutral liquor, after the removal of the free sulphurous acid, is concentrated and the sulphur-bearing groups of the organic compounds are removed by subjecting the liquor to the action of a cyanide- or cyanamide-compound under heat and pressure. The product of the reaction is diluted with water and an organic cyanogen- or cyanamide-compound precipitated by a mineral acid; the precipitate is filtered off and dried at the ordinary temperature.—J. F. B.

Cellose; Method of producing ——. Converting of cellose into fermentable sugar. P. G. Ekström, Skutskär, Sweden. U.S. Pats. 1,087,743 and 1,087,744, Feb. 17, 1914.

Cellose is produced by the action of concentrated acid upon cellulosic material for a suitable time and at a temperature adapted to the nature of the reacting substances, maintaining during the treatment a vacuum sufficient to allow the organic acids produced to distil off. In converting concentrated solutions of cellose into fermentable sugar, the solutions are diluted with waste sulphite cellulose lyes and the mixture is boiled under atmospheric pressure.—J. F. B.

Blotting and absorbing materials. M. A. Halle, London. Eng. Pat. 4610, Feb. 24, 1913.

Raw cotton, cotton or linen fabric, etc., is purified by repeated boiling in water before being treated with an alkali and a bleaching agent. The material may be further treated by a solution of ammonia and soap, dyed, and finished by boiling in several changes of water containing acetic acid. If desired, the material may be boiled in water containing acetic acid after the treatment with boiling alkali and before the treatment with a bleaching agent; after bleaching it may be subjected to the action of hydrochloric acid or hydrogen peroxide, or both.
—J. F. B.

Paper; Coated —— and process of making the same. H. Wrede, Berlin, and Corn Products Co., Ltd., London. Eng. Pat. 4706, Feb. 24, 1913.

About 17½ lb. of starch, preferably of the modified variety known as "thin-boiling," are boiled with 4 galls. of water, and the clear mobile solution is treated with 2 quarts of a 10 per cent. solution of alum, and then mixed with about 40 lb. of fine china clay uniformly suspended in a mixture of about 2 quarts of syrupy sodium silicate ("water glass") and 3 galls. of water. The colloidal precipitate of starch and mineral matters thus obtained is employed as a coating for paper by the usual brushing-on method. The sodium silicate in the mixed preparation should be slightly in excess and not completely neutralised by the precipitating agent. Precipitation may also be effected by borax, calcium, barium, strontium or magnesium chloride or even by acids, but alum is preferred.—J. F. B.

Cellulose; Process for the manufacture of organic acid esters of ——. Knoll und Co., Ludwigshafen on Rhine, Germany. Eng. Pat. 4353, Feb. 20, 1913. Under Int. Conv., Feb. 21, 1912. Addition to Eng. Pat. 2491 of 1913, dated Feb. 1, 1912.

See Fr. Pat. 453,835 of 1913; this J., 1913, 785.—T. F. B.

Films or bands from materials [celluloid] dissolved in volatile solutions; Apparatus for the production of ——. B. Borzykowski, Berlin. Eng. Pat. 4601, Feb. 22, 1913.

See Fr. Pat. 454,692 of 1913; this J., 1913, 865.—T. F. B.

Artificial silk; Manufacture of ——. H. Timpe, Assignor to Naamlooze Vennootschap Hollandsche Zijde Maatschappij, Amsterdam. U.S. Pat. 1,087,700, Feb. 17, 1914.

See Ger. Pat. 236,908 of 1910; this J., 1911, 1050.—T. F. B.

Cellulose; Compounds or derivatives of —— and process of obtaining the same. E. Knoevenagel, Heidelberg, Germany. U.S. Pat. 1,090,074, March 10, 1914.

See Fr. Pat. 369,123 of 1906; this J., 1907, 91.—T. F. B.

Wood or other elastic material; Method of compressing —— [in boilers] F. Ziebarth, Frankfort, Germany U.S. Pat. 1,089,687, March 10, 1914.

See Eng. Pat. 10,548 of 1912; this J., 1913, 19.—T. F. B.

Destructive distillation of liquids or of substances dissolved or suspended in liquids [e.g., waste lyes from cellulose manufacture]. Ger. Pat. 269,994. *See* IIb.

VI.—BLEACHING; DYEING; PRINTING; FINISHING.

Dyeing; The theory of —— II. W. D. Bancroft. J. Phys. Chem., 1914, **18**, 118—151. (Compare this J., 1914, 197.)

The author continues the discussion of his conception of the adsorption theory of dyeing, in connection with basic dyestuffs, relying mainly on the published literature, especially Pelet-Jolivet's "*Die Theorie des Färbeprozesses,*" for confirmation of his generalisations. He concludes in regard to a basic dyestuff that the dye is most readily taken up in alkaline solution, the presence of a readily adsorbed anion increasing the amount taken up, a readily adsorbed cation decreasing it. The views of Hantzsch, Baeyer and others on the ammonium base → carbinol → quinonimine base tautomerism of certain basic dyestuffs are extensively quoted in connection with the form in which these dyestuffs are fixed by charcoal, and the assumption of Freundlich that a condensation product of the imine base is formed is considered unnecessary. Green's observation that Aniline Black in the presence of the fibre is no longer soluble in 80 per cent. acetic acid is considered to indicate a phenomenon analogous to that of the insolubility in water of the basic dyestuffs after adsorption by charcoal.—J. B.

Patents.

[Bleaching] Treating vegetable fibres, yarns, and fabrics; Process of ——. J. Hirschberger, Jersey City, N.J., Assignor to H. A. Metz, New York. U.S. Pat. 1,087,584, Feb. 17, 1914.

Before bowking the goods are treated with a substance containing a fatty sulpho-acid radical and a volatile solvent and then with a weak solution of a mineral acid, afterwards washing, whereby the resistant impurities of the fibre are rendered easily removable.—J. B.

Dyeing machine. J. M. Payne, Sommerville, Ala., Assignor to Perfection Dyeing Machine Co., Columbus, Ga. U.S. Pat. 1,088,617, Feb 24, 1914.

The periphery of a warp beam consists of a number of fixed slats, with intermediate slats provided with mechanism for moving them reciprocally, either outwards to form a skeleton beam of greater diameter than that of the fixed slats, or inwardly within the periphery of the cylinder formed by the fixed slats, the motion being provided through wedges on the movable slats acting against cam faces on spiders which are caused to slide longitudinally on the axis of the beam by reciprocating mechanism.—J. B.

Dyeing machine. T. Allsop and W. W. Sibson, Assignors to The Philadelphia Drying Machinery Co., Philadelphia, Pa. U.S. Pat. 1,089,102, March 3, 1914.

THE machine consists of an outer drum constructed in two sections, the upper section of which is provided with a hinged door, and an inner rotatable drum, together with a circulating pump, dye-liquor reservoir, etc.—J. B.

Printing textile fabrics. H. Levinstein and Levinstein Ltd., Manchester. Eng. Pat. 4316, Feb. 20, 1913.

FAST prints are obtained after the manner described in Eng. Pat. 3427 of 1913 (this J., 1914, 309) by using any non-substantive dyestuff capable of forming an insoluble compound with formaldehyde, with the exception of the dyestuffs already claimed (*loc. cit.*). Suitable dyestuffs are, for example, mono-azo compounds containing as end-components derivatives of resorcinol, *e.g.*, chlororesorcinol, phloroglucinol, *m*-aminophenol, aminonaphthols, dihydroxynaphthalenes, etc.—J. B.

Wool cleansing apparatus. A. Thibeau et Cie., Tourcoing, France. Eng. Pat. 8689, April 12, 1913. Under Int. Conv., April 20, 1912.

SEE Fr. Pat. 442,930 of 1912; this J., 1912, 1028.—T. F. B.

Bleaching fibrous material. A. G. Bloxam, London. From Luftbleiche Ges. m. b. H., Eilenburg, Prussia. Eng. Pat. 13,902, June 16, 1913.

SEE Ger. Pat. 262,047 of 1912; this J., 1913, 824.—T. F. B.

Yarn-mercerising machine. P. Hahn, Niederlahnstein-on-Rhine, Germany. U.S. Pat. 1,087,442, Feb. 17, 1914.

SEE Eng. Pat. 21,539 of 1912; this J., 1913, 422.—T. F. B.

Cellulose esters; Coating materials with ——. Act.-Ges. f. Anilinfabr., Treptow, Germany. Eng. Pat. 21,015, Sept. 17, 1913. Under Int. Conv., Nov. 15, 1912.

SEE Fr. Pat. 461,058 of 1913; this J., 1914, 20.—T. F. B.

Viscose: Printing —— on textile fabrics. E. A. Fourneaux, Assignor to Calico Printers' Association, Ltd., Manchester. U.S. Pat. 1,087,938, Feb. 24, 1914.

SEE Eng. Pat. 15,080 of 1912; this J., 1913, 284.—T. F. B.

VII.—ACIDS; ALKALIS; SALTS; NON-METALLIC ELEMENTS.

Hydrofluoric acid and fluosulphonic acid. O. Ruff and H. J. Braun. Ber., 1914, **47**. 646—656.

IN preparing aqueous hydrofluoric acid from calcium fluoride and sulphuric acid the best yields (up to 81 per cent.) with the theoretical quantity of sulphuric acid are obtained when it contains about 10 per cent. of water. With 97—100 per cent. sulphuric acid, a 60 per cent. yield of 95—96 per cent. hydrofluoric acid can be obtained, but not the anhydrous compound. In any case the residue will contain some calcium fluosulphonate. With fuming sulphuric acid and fluorspar fluosulphonic acid is obtained, the yield increasing with the anhydride content of the sulphuric acid, and becoming practically theoretical with acid containing 60 per cent. of anhydride (*i.e.*, a little more than the theoretical amount). Fluosulphonic acid boils at 163° C., is not easily decomposed on heating, and is converted by reducing agents into sulphur dioxide and hydrofluoric acid.—W. H. P.

Fluosulphonic acid. O. Ruff. Ber., 1914, **47**. 656—660. (See also Traube, this J., 1913, 1008, and preceding abstract.)

SODIUM fluosulphonate was prepared by heating sodium chloride and fluosulphonic acid in a platinum retort and crystallising the residue from alcohol. Fluosulphonic acid could be heated to 900° C. without decomposing, to form sulphuryl fluoride in the manner suggested by Thorpe and Kirmann (Z. anorg. Chem., 1893, 3, 63). By the reaction of fluosulphonic acid on potassium bichromate and chromium trioxide a gaseous compound containing chromium and fluorine was evolved along with hydrofluoric acid. Attempts to condense the former gave a complex product and the author was not able to decide if this contained chromyl fluoride. With potassium permanganate a violet gas of an explosive character was evolved, probably either manganyl fluoride or permanganic anhydride.—W. H. P.

Sodium carbonate deposits in South Africa; Working of ——. Board of Trade J., March 19, 1914. [T.R.]

A COMPANY has recently been formed for the purpose of working a valuable deposit of crude carbonate of soda, situated about 25 miles from Pretoria. Some 3,000 tons of the soda have already been mined and sold in Johannesburg. The company also has a complete plant at Ophirton, Johannesburg, for the manufacture of washing soda, with a capacity of about 10 tons per day.

Ammonia; Electrolytic oxidation of ——. G. Oesterheld. Z. anorg. Chem., 1914, **86**, 105—142. (See also this J., 1905, 279, 280 and 550; 1906, 185; 1909, 704 and 1910, 21.)

IN the electrolysis of ammonia the gases at the anode always contain appreciable quantities of nitrous oxide (which can be isolated in the liquid state), as well as nitrogen and oxygen. When a solution of ammonium carbonate containing ammonia is electrolysed, practically the whole of the current can be accounted for from the oxygen, nitrogen and nitrous oxide evolved and the nitrate left in solution. The distribution of the current effect among these products varies with the anode material, the temperature, the current density and the ammonia concentration. Hydroxylamine, hyponitrite and nitrite are probably formed as intermediate products between the ammonia and the nitrate. These may escape further reduction by decomposition or interaction, *e.g.*, ammonium nitrite gives nitrogen, hyponitrite gives nitrous oxide, hydroxylamine and nitrite give hyponitrite. The course of the oxidation of the intermediate products, in the presence of varying quantities of ammonia may be observed by noting the anode potential at various current densities. Of all the successive changes the highest anode potential is required by the first reduction of the ammonia to hydroxylamine; hence the intermediate products will not tend to accumulate, and the predominating end product will be ammonium nitrate, the proportion of which can be appreciably reduced only by careful choice of concentration, current density, and temperature. To obtain a comparatively large current yield of oxidised products in the absence of a catalyst, an anode with a high oxygen over-voltage (*e.g.*, platinum or palladium) must be used, with iron, the tendency for oxygen to be evolved is very much greater. As the concentration of ammonia is raised the oxygen disappears: the nitrate increases and also the nitrogen and nitrous oxide. After a certain point the nitrate yield diminishes and the nitrogen and nitrous oxide (particularly the former) continue to increase. This is due to the fact that the anode potentials of nitrite and ammonia do not differ very greatly in equivalent solutions. If the ammonia concentration is increased the rate of oxidation of the nitrite diminishes, so that it is mainly decomposed. If a catalytically active anode is used the ammonia oxidation may be so much favoured that good yields of nitrite can be obtained as final product. Rise of temperature has an effect somewhat similar to that of increasing ammonia concentration, *i.e.*, the oxygen disappears, nitrate increases and then diminishes, and nitrogen and nitrous oxide steadily increase. Increasing current density increases the extent of oxidation.—W. H. P.

Ammonium sulphate; The colouration of ——. K. Leo. Stahl u. Eisen, 1914, **34**, 439—445.

The causes of the colouration of commercial ammonium sulphate were investigated by determining the impurities present in coloured samples, and by preparing tho salt on a small scale using sulphuric acid containing known amounts of impurities. A gray colour resulted from the presence of traces of tar, or of sulphides of lead or copper; blue and red from the presence of cyanides; yellow from the presence of the sulphides of arsenic and cadmium. Markedly coloured products were obtained with acid containing from 0·01 to 0·07 per cent. of the metallic impurities.—T. St.

Sulphur and calcium hydroxide; Reaction between —— *in aqueous solution.* H. V. Tartar. J. Amer. Chem. Soc., 1914, **36**, 495—498.

When an aqueous solution of calcium hydroxide was heated with sulphur in presence of air, decomposition of the thiosulphate produced into sulphite and sulphur always occurred even at temperatures much below 100° C. Experiments under varying conditions in an atmosphere of hydrogen showed that the primary reaction was:

$$3Ca(OH)_2+10S \rightarrow 2CaS_4+CaS_2O_3+3H_2O.$$

When excess of sulphur was used, it combined with the calcium tetrasulphide to form pentasulphide. (See also this J., 1910, 837; 1914, 74.)—A. S.

Fluorspar; Valuation of ——. E. Bidtel. J. Ind. Eng. Chem., 1914, **6**, 265.

The method described previously (this J., 1912, 332) is modified as follows:—After treating with acetic acid, instead of filtering, the mixture is evaporated to dryness, treated with 50 c.c. of water, heated to boiling to precipitate any iron dissolved as basic acetate and then filtered. (Calcium fluoride is less soluble in water than in acetic acid, and a correction of 0·001 grm. instead of 0·0015 grm. is sufficient.) After volatilising the silica as described earlier, and weighing the residue, 2 c.c. of hydrofluoric acid and 10 drops of nitric acid are added, the covered crucible warmed for 30 mins., the contents evaporated to dryness, and the residue evaporated with 2 c.c. of hydrofluoric acid. A correction of 0·002 grm. is made for loss of weight in the treatment with mercuric oxide and hydrofluoric acid and one of 0·001 grm. for loss in the treatment with ammonium acetate (*loc. cit.*).—A. S.

Chlorides of lead and sodium; Equilibrium between ——, *in aqueous solution.* N. Demassieux. Comptes rend., 1914, **158**, 702—703.

Isotherms at 13°, 15° and 100° C. are represented graphically. The solubility of lead chloride diminishes slightly till the solution contains about 3 grms. of sodium chloride per 100 grms.: after which the solubility increases, owing to the formation of a labile double salt, until the attainment of the transition point, at which the corresponding amount of sodium chloride is about 27 grms. at each temperature, while that of lead chloride varies from about 2 grms. at 13° to 12 grms. at 100° C. (See also this J. 1914, 254.)—J. R.

Ferrous and chromous metaphosphates. A. Colani. Comptes rend., 1914, **158**, 794—796.

Ferrous metaphosphate, $Fe_3(PO_3)_2$, was prepared by the action of fused metaphosphoric acid on metallic iron or ferrous chloride, oxalate or phosphate in an atmosphere of carbon dioxide under similar conditions to those prescribed for molybdenum metaphosphate (this J., 1914, 253). It was obtained as a white powder, slightly greenish in mass, insoluble in hydrochloric and nitric acids, and oxidised by hot concentrated sulphuric acid, with liberation of sulphur dioxide. Attempts to prepare chromous metaphosphate failed, the chromic salt, $Cr(PO_3)_3$, being always produced owing to oxidation by water evolved from the metaphosphoric acid.—A. S.

"Infusible white precipitate"; Constitution of ——. H. Saha and K. N. Choudhury. Z. anorg. Chem., 1914, **86**, 225—229.

Cold hydrochloric acid acts on the compound, H_2NHgCl, to give ammonium and mercuric chlorides in molecular quantities. Hydrobromic and hydriodic acids act similarly, giving a mixture of bromides and iodides respectively. Hydrofluoric acid gives mercuric chloride, mercuric fluoride and ammonium fluoride, indicating that in the original compound the chlorine is attached to the mercury and not to the nitrogen. The formula $H_2N.Hg.Cl$ is further supported by the composition of the yellow crystalline precipitate $NH_2HgCl.PtCl_4$, obtained from an ammoniacal solution of the "white precipitate" on addition of chloroplatinic acid, and by the formation of the "white precipitate" by the action of sodamide on mercuric chloride.—W. H. P.

Nickelous oxide; Reduction of ——, *and existence of a suboxide.* P. Sabatier and L. Espil. Comptes rend., 1914, **158**, 668—675. (Compare Meigen and Bartels, this J., 1914, 323.)

Carefully purified hydrogen was passed over a known weight of heated nickelous oxide, the extent of the progressive reduction being ascertained by weighing the water produced during observed intervals of time. The velocity of reduction depends upon the nature of the oxide, the rapidity of the hydrogen current, and the temperature. Oxide prepared at a high temperature is reduced far more slowly than that prepared at a low temperature, especially when the reduction is effected at a low temperature. Results are quoted for reduction temperatures between 155° and 250° C. with hydrogen currents varying from 6 to 24 c.c. per min. and times from 1 to 163 hours. The velocity of reduction is an exponential function of the temperature; and the results show further that fairly rapid reduction first occurs to a suboxide, which is then reduced to the metal at a much slower rate. The probable formula of the suboxide is Ni_4O, corresponding to the compound $Ni_4(NO_2)_2$. The reduction is retarded by traces of moisture.—J. R.

Phosphides of manganese: The higher ——. S. Hilpert and T. Dieckmann. Ber., 1914, **47**, 780—784.

A mixture of 2 grms. of manganese and 2·4 grms. of red phosphorus was heated in an exhausted sealed tube first for 48 hours at 400° C. and then for 48 hours at 600 C. The product was triturated with benzene, separated by filtration, washed with alcohol and ether, and dried over sulphuric acid. It had a composition corresponding to MnP_2. When heated in hydrogen for 13 hours at 290° C. (the boiling point of phosphorus) it remained unaltered, but at 400° C. it gradually lost phosphorus, and after about 50 hours was completely converted into MnP (sp. gr. 5·39 at 20°/4° C.). Both phosphides were dark grey powders, not readily attacked by acids, and possessed ferromagnetic properties, the transformation point (Curie point) being about 38 C. for MnP_2 and 28° C. for MnP. When heated in air they burned like phosphorus, leaving black, strongly magnetic residues. For the purposes of analysis the phosphides were mixed with about 20 times their weight of sodium peroxide, heated very slowly to incipient fusion, the melt treated with water, the solution evaporated to dryness twice with hydrochloric acid, and the residue dissolved in hydrochloric acid. The manganese was then determined by titration with permanganate (this J., 1913, 510) and the phosphorus by precipitation as ammonium phosphomolybdate and reprecipitation as magnesium-ammonium phosphate.—A. S.

Nitrogen hexoxide and isonitrogen tetroxide: The —— of F. Raschig. E. Müller. Z. anorg. Chem., 1914, **86**, 230—238.

THE green substance obtained by Raschig (this J., 1911, 1208) and by the author (this J., 1912, 685) is considered to be not nitrogen hexoxide, but a mixture of the oxides NO_2, N_2O_4, N_2O_3 and NO. The green colour can be exactly reproduced by dipping a test-tube containing liquid air into liquid N_2O_3 and then into liquid N_2O_4, or even by depositing these oxides separately on tubes which will fit one inside the other. On washing with liquid nitrogen the green substance does not lose oxygen or pass into NO_2 or isonitrogen tetroxide.—W. H. P.

Hydrogen sulphide; Colourimetric determination of small quantities of ——. W. Mecklenburg and F. Rosenkränzer. Z. anorg. Chem., 1914, **86**, 143—153.
